In withdrawing the probe unit, the needle is retracted into the needle guide by pulling on the rubber grip, two marks on the aluminium tube indicating full extension and full retraction of the needle. The probe sheath is then drawn slowly back to the exterior. By repeating the procedure described, the counter may be used to search the walls of the uterus, cervix and vagina and the external organs of reproduction. If a sharp-pointed needle guide is attached to the probe sheath in place of the blunt-ended one, then such a point can be used to pierce the wall of the vagina, and search for activity in the Fallopian tubes or ovaries or in the abdominal cavity.

Acknowledgment is due to Dr. J. C. Boursnell for his helpful interest and advice. J. P. BENNETT

A Possible Explanation for the Failure of Non-Surgical Ovum Transfers in the Cow

SURGICAL transfer of fertilized ova by puncture of the uterine wall has been successful in several mammalian species including the cow[1], but the non-surgical approach through the cervix has so far been successful only in the mouse[2]. In the rabbit, transfer of the ovum through the cervix has also been successful, but it involved a surgical incision in the vagina[3]. In the cow many attempts have been made to obtain pregnancies by the non-surgical transfer of ova through the cervix, but all have been unsuccessful[4]. Work on cows, however, has shown that stimulation of the cervix causes the release of oxytocin, thus increasing uterine contractions, and that an injection of oxytocin induces uterine contractions at all stages of the œstrous cycle[5].

The experiments reported here were designed to throw some light on the problems involved in the non-surgical transfer of ova to the cow. It was felt that such a transfer, which is carried out in the early luteal phase of the cycle owing to the necessity of synchronizing the development of the ovum with that of the uterine endometrium, might stimulate the cervix, release oxytocin, and produce uterine contractions, as a result of which the ova would be either expelled into the vagina or driven towards the utero-tubal junction. The technique employed depended on the use of 'artificial ova', consisting of resin spheres impregnated with radioactive gold[6]. Between 10 and 30 such spheres were transferred, in 0·75–1·0 c.c. of sterile homologous blood serum, non-surgically through the cervix of recipient heifers about three days after œstrus, using a stainless steel catheter of external diameter 1·5 mm. and length 40 cm. connected to a 5-c.c. syringe by a 15-cm. length of polythene tubing (external diameter 2·25 mm.). It was hoped that by using such a fine catheter for the transfer, stimulation of the cervix would be reduced to a minimum. At varying times after the insertion of the spheres the uterus, cervix and vagina were checked for radioactivity with a needle-probe Geiger counter, which is described in the previous communication.

It was found (Table 1) that, 1¼–1½ hr. after transfer, the spheres started to move through the cervix, and that after 1½ hr. a large proportion of the spheres had been expelled from the uterus altogether. In exp. 7 (Table 1) 11 out of 25 spheres were recovered from the vagina 4¼ hr. after insertion. In two animals examined (exp. 8 and 9), 20½ hr. after insertion, some spheres had already been voided from the vagina and consequently little or no radioactivity could be demonstrated in the vagina, whereas some other spheres were still retained by the uterus. In another animal (exp. 10) the spheres were transferred surgically, and these, too, were found in the vagina 4¾ hr. later, probably as a result of the traction applied to the uterus during the laparotomy, which may have been quite sufficient to cause the release of oxytocin.

In another group of four experiments (Table 2), cow ova were transferred non-surgically to recipient heifers, and at varying intervals after the transfer the animals were slaughtered, and the reproductive tracts searched for the ova. Of the 37 ova transferred,

	Total	37	Total	6	8	5 = 19 (51·4 per cent)	

only 19 (51·4 per cent) were recovered. Some of the ova were expelled into the vagina just as rapidly as the radioactive spheres, but it is possible that at the peak of the luteal phase (exp. 14) expulsion is slower than during its early stage (exp. 1–13); during œstrus, expulsion occurs even more rapidly. Altogether, our results show that the radioactive 'artificial ova' do in fact behave in a similar manner to normal ova.

Preliminary attempts to block the ejection mechanism by the injection of adrenaline have been so far unsuccessful. This does not necessarily mean that the factor causing the ejection is not oxytocin, since the action of adrenaline is known to be a transient one, only blocking uterine activity for 4–8 min.[5d]. Spinal anæsthetics sufficient to paralyse the whole hind quarters of the cows were also tried, but again the spheres were ejected as in the untreated cows.

From the observations reported in this communication it is concluded that one of the reasons for the failure of non-surgical ovum transfers in the cow is the ejection of the ova about 1½ hr. after insertion. This may be due to stimulation of the cervix at the time of the transfer, which causes the release of oxytocin from the pituitary gland, and consequently uterine contractions.

We are grateful to Dr. T. R. R. Mann for discussing this manuscript. We acknowledge generous financial assistance from the Milk Marketing Board, and one of us (M. J. K. H.) acknowledges the receipt of an Agricultural Research Council Postgraduate Studentship.

COPRECIPITATION OF MITOCHONDRIA AND CHLOROPLASTS

By RACHEL M. LEECH

To obtain critical evidence for the presence of an enzyme or multi-enzyme system in a particular cell organelle, it is necessary to prepare this organelle free from all other types of sub-cellular particle. In the case of isolated chloroplasts, differential centrifugation is the method generally employed in attempts to free chloroplasts from smaller particles. Since 1956, many workers have followed the procedure of Arnon *et al.*[1] in which the chloroplasts are sedimented from the leaf homogenates at 1,000*g* after removal of debris and whole cells. Resuspension of the chloroplast pellet, followed by centrifuging at 1,000*g*, has been commonly employed with the view of removing residual amounts of smaller particles[1–3].

However, the absence of biochemically active mitochondria from these preparations has usually been assumed rather than demonstrated. With the advent of a technique for separating chloroplasts from contaminating mitochondria by centrifugation in a density gradient[4], it has been shown that *Vicia faba* chloroplasts, prepared by the usual method[1] and twice washed, are still accompanied by numerous mitochondria. The aim of the present work was to determine how far the presence of mitochondria in chloroplast preparations can account for one of the features attributed to the plastids, namely, the presence of glutamic–oxaloacetic transaminase.

Aspartate is one of the compounds labelled when isolated spinach chloroplasts fix $^{14}CO_2$ in the light[5,6], while the addition of phosphoenolpyruvate and $^{14}CO_2$ to a water extract of spinach chloroplasts leads to the formation of labelled oxaloacetate and labelled aspartate[7]. Although mitochondria from leaves have not been extensively studied in this respect, glutamic–oxaloacetic transaminase has been shown to be present in mitochondria from a number of higher plant sources[8–11]. In view of these findings, the assumption that the formation of aspartate is an aspect of chloroplast metabolism[7] has been further investigated.

Chloroplasts and mitochondria were isolated from leaves just fully expanded of *Vicia faba* plants 2–3

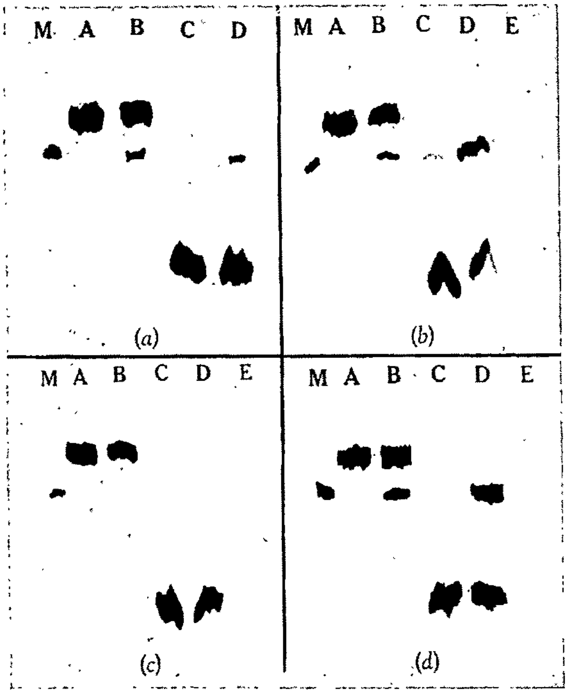

Fig. 1. Assay of transaminases by paper chromatography. Pellets of unpurified chloroplasts (*a*), mitochondria (*b*), purified chloroplasts (*c*), and a mixture of mitochondria and purified chloroplasts spun at 1,000*g* for 12 min. (*d*), were washed once in sucrose–phosphate medium and taken up in 6 ml. distilled water. Samples (2 ml.) were incubated with α-ketoglutarate (75 μmoles) and either DL-aspartate (150 μmoles) or L-alanine (50 μmoles) in a total volume of 3 ml. phosphate buffer (0·067 *M*, *p*H 7·3) for 4 hr. at 30°. The ethanol-soluble material was chromatogrammed in phenol. *M*, marker glutamate; *A*, aspartate + α-ketoglutarate, zero time; *B*, aspartate + α-ketoglutarate, 4 hr.; *C*, alanine + α-ketoglutarate, zero time; *D*, alanine + α-ketoglutarate, 4 hr.; *E*, α-ketoglutarate, 4 hr.

weeks old. The procedure of James and Das was employed[4], except that the leaves were ground by hand in sucrose (0·3 *M*) containing phosphate buffer (0·067 *M*, *p*H 7·3). Mitochondrial and crude chloroplast preparations were obtained from the same homogenate. The crude chloroplast preparations were then purified by centrifugation in a sucrose–glycerol density gradient. Purified chloroplasts were disintegrated at 2° C. by ultrasonic vibration and the green fragments ('grana') separated from the straw-coloured supernatant solution ('stroma') by centrifuging at 105,000*g* for 30 min. Water extracts were prepared by adding small volumes (5–6 ml.) of ice-cold distilled water or dilute phosphate buffer to the mitochondrial and chloroplast pellets; after 30 min. the particulate material was centrifuged down and the clear solution decanted. Glutamic–oxaloacetic transaminase and glutamic–pyruvic transaminase were detected qualitatively by the chromatographic separation of amino-acids present in reaction mixtures; glutamic–oxaloacetic transaminase was assayed quantitatively in water extracts by the spectrophotometric measurement of oxaloacetate at 280 mμ[12].

Crude chloroplast preparations were found by chromatography to contain the two transaminases (Fig. 1*a*); the glutamic–oxaloacetic transaminase was also detected in water extracts of crude chloroplast preparations, confirming previous results[7]. However, mitochondrial preparations obtained from the same homogenates as were used for the isolation of chloroplasts also contained both transaminases (Fig. 1*b*). The purified chloroplasts were next examined; on four occasions, no transaminase activity could be demonstrated by the chromatographic method in either intact chloroplasts (Fig. 1c) or the 'grana' or 'stroma' fractions prepared from these chloroplasts. In addition, glutamic–oxaloacetic transaminase could not be detected by the spectrophotometric method either in the 'stroma' or in water extracts of whole chloroplasts. Chloroplast suspensions containing as much as 2·5 mgm. chlorophyll or the 'stroma' obtained from chloroplasts equivalent to 4 mgm. chlorophyll were used in the reaction mixtures (final vol., 3 ml.). The addition of pyridoxal 5-phosphate ($0{\cdot}75 \times 10^{-4}$ *M*) had no effect.

From these results it seemed possible that the transaminase activity of the crude chloroplast preparations could be attributed to the presence of mitochondria. An experiment was therefore designed to test the possibility that mitochondria are co-precipitated with chloroplasts. Mitochondria and purified chloroplasts were prepared from bean leaves (fresh weight 325 gm.) and suspended in sucrose–phosphate medium. Increasing volumes of the mitochondrial suspension were added to a constant volume of the chloroplast suspension, and the mixtures centrifuged at 1,000*g* for 12 min. The pellets were washed once in 10 ml. of medium and resuspended in 5 ml. phosphate buffer (0·005 *M*, *p*H 7·3). After 30 min. at 2° C., the suspensions were centrifuged at 17,000*g* for 45 min., and the clear supernatant solutions assayed for glutamic–oxaloacetic transaminase by the spectrophotometric method. The results (Table 1) show that a linear relationship exists between the amount of transaminase and the volume of mitochondrial suspension added to the purified chloroplasts. The contamination of the chloroplast pellets by mitochondria as shown by the presence of the transaminases was confirmed by the chromatographic method (Fig. 1*d*). Mitochondria were observed microscopically in washed pellets from tubes *B*–*G*, but were absent from tube *A* (Table 1).

In view of the assumption that washing removes the mitochondria, the effect of washing a mixture of purified chloroplasts and mitochondria was studied. Fig. 2 shows that the first wash removes a considerable fraction of the transaminase activity, but that additional washing has little further effect.

These experiments clearly demonstrate that mitochondria sediment with chloroplasts when suspensions containing both types of particle are spun at 'chloroplast' speed (1,000*g*), and that these mitochondria are not completely removed by two washings. The possibility must therefore be considered that mitochondrial contamination is responsible for some of the properties of chloroplasts isolated by procedures involving only differential centrifugation. It is

M., mitochondrial suspension; Ch., purified chloroplast suspension; both in sucrose–phosphate medium

suggested that the amount of glutamic–oxaloacetic transaminase could be used as an index of the degree of contamination of chloroplast preparations by mitochondria. As we have found that the purified chloroplasts, as well as the mitochondria, contain highly active malic dehydrogenase[13], the sensitivity of the transaminase assay could be increased considerably by linking the production of oxaloacetate with the oxidation of reduced diphosphopyridine nucleotide[14].

The possibility cannot be ruled out that purification by the glycerol technique completely removes transaminases from the chloroplasts. Zelitch and Barber have found that high concentrations of glycerol reduce, but do not eliminate, the oxidative activity of spinach mitochondria[15]. The glutamic–oxaloacetic transaminase activity of water extracts of bean leaf mitochondria is also reduced (by about 50 per cent) by pretreatment of the mitochondria with 60 per cent glycerol[13]. In neither case does the glycerol treatment result in a complete disappearance of enzymic activity. The chloroplasts purified by the glycerol technique are not devoid of enzymes; they are able to carry out the complete process of photophosphorylation, and contain triphosphopyridine nucleotide-triose phosphate dehydrogenase and malic dehydrogenase[16]. In addition, chloroplasts freed from mitochondria by an alternative technique (centrifuging in a sucrose–diodone density gradient[4]) do not contain any glutamic–oxaloacetic transaminase but still exhibit triphosphopyridine nucleotide-triose phosphate dehydrogenase and malic dehydrogenase activity. The available evidence, therefore, suggests that the absence of transaminases from the purified chloroplasts is not a result of the purification procedure. In any event, the great advantage of working with chloroplasts free from mitochondria must be weighed against any possible disadvantage associated with the purification procedure.

INDUCTION OF HERITABLE RESPIRATORY DEFICIENCY IN *SACCHAROMYCES* BY PANTOTHENATE STARVATION

By Prof. ALVIN SARACHEK and GREGORY L. FOWLER
Department of Biology, University of Wichita, Kansas

CYTOPLASMICALLY inherited respiratory deficiency in *Saccharomyces* is characterized by the permanent loss or depression of the activities of a number of enzymes structurally associated with the mitochondrion[1]. Though a variety of chemical and physical treatments have been described which induce this condition[2–5], the particular metabolic disturbances which comprise the inducing event are not yet defined. Bearing on this question, we have reported that anaerobically grown yeast cells are more responsive to inducers of respiratory deficiency than cells grown aerobically[6]. Since the terminal electron transport system is inoperative in anaerobically grown cells, it is possible that at least one of the metabolic processes which sustain inducing damage is partially debilitated simply by a limitation of intracellular hydrogen acceptors. The severe reduction of overall lipid synthesis which occurs characteristically when yeasts are grown anaerobically[7] suggested to us that the oxidation of pyruvate to acetate might represent such a process. If this were so, then limiting the ability of cells to generate acetate during aerobic growth on glucose should increase their susceptibilities to induction of respiratory deficiency. To test this possibility we have attempted to prepare acetate-deficient yeasts by both aerobic and anaerobic propagations on a pantothenate-free medium. Growth under these conditions is known to depress cellular coenzyme *A*-levels and result in a consequent depression of both acetate formation and utilization[8]. The present article describes our observations that cells are transformed directly into respiration-deficient mutants when grown aerobically in the absence of pantothenate and that such transformation can be prevented by the provision of exogenous acetate or certain higher fatty acids.

The test organism was a tetraploid strain of *Saccharomyces* possessing absolute and partial growth requirements for adenine and pantothenate respectively. Respiration-deficient mutants of spontaneous origin occur within this strain in a frequency of about 0·3 per cent. The basal pantothenate-free growth medium used was of the following composition : glucose, 40 gm. ; ammonium tartrate, 2 gm. ; potassium dihydrogen phosphate, 1·5 gm.; dipotassium hydrogen phosphate, 0·3 gm. ; crystalline magnesium sulphate, 0·5 gm. ; calcium chloride, 0·33 gm. ; crystalline ferrous sulphate, 3 mgm. ; crystalline zinc sulphate, 3 mgm. ; crystalline copper sulphate, 0·5 mgm. ; crystalline manganous sulphate, 0·4 mgm.; $(NH_4)_6Mo_7O_{24}.4H_2O$, 0·15 mgm.; $Na_2B_4O_7.10H_2O$, 0·9 mgm.; inositol, 10 mgm.; thiamine hydrochloride, 1 mgm.; *para*aminobenzoic acid, 0·6 mgm.; pyridoxine, 0·6 mgm.; nicotinic acid, 0·6 mgm.; biotin, 0·02 mgm.; adenine sulphate, 150 mgm.; water, 1,000 ml. To prepare pantothenate-supplemented medium, 1 mgm. of calcium pantothenate was added per litre. This as well as other additions to the medium as indicated in the text were made prior to autoclaving at 10 lb. pressure for 10 min. For aerobic growth, the medium was dispensed in 50-ml. quantities into 250-ml. Erlenmeyer flasks; following inoculation the flasks were incubated at 28° C. on a reciprocal shaker operating at 100 2-in. strokes per minute. For anaerobic growth, screw-cap test-tubes 20 cm. × 2 cm. were filled to a depth of about 17 cm. with 50 ml. of medium, inoculated and incubated statically at 28° C. Though these static growth conditions are properly described as micro-aerobic, they are effectively anaerobic since cells so cultivated fail to achieve the enzymatic adaptation to oxygen utilization which occurs under aerobiosis[9]. Cells for experimental inocula were harvested from the log phase of pantothenate-supplemented aerobic cultures, washed four times in *M*/15 potassium dihydrogen phosphate and introduced to a density of about $3{\cdot}0 \times 10^4$ cells per ml. into the experimental flasks or tubes. At intervals during subsequent incubation 1-ml. samples of the cultures were plated to determine increases in cell numbers and the frequencies of respiratory mutants appearing in the populations. The composition of the plating medium and the technique for scoring respiration-deficient mutants have been described previously[10].

Curves presented in Fig. 1 illustrate the increases in number of cells and the frequencies of respiratory variants scored in cultures prepared as indicated above. It is seen that cells express a partial growth requirement for pantothenate under both aerobic and anaerobic conditions. It may also be noted that in pantothenate-free medium both aerobically and anaerobically cultivated cells show initially rapid, though declining, rates of increase which are stabilized into logarithmic rates of growth approximately 12 hr. after inoculation. Undoubtedly, this anomalous growth behaviour is due to a carry-over of stored pantothenate in the cells of the inoculum. Through the early and middle portions of the logarithmic periods of growth, the frequencies of respiratory variants are maintained at the spontaneous levels in all cultures. However, during the period of transition from the logarithmic into the stationary phase of growth, cells cultivated aerobically in the absence of pantothenate are converted *en masse* into respiration-deficient mutants; no such transformation occurs in either the pantothenate-supplemented culture or in anaerobic cultures with or without pantothenate.

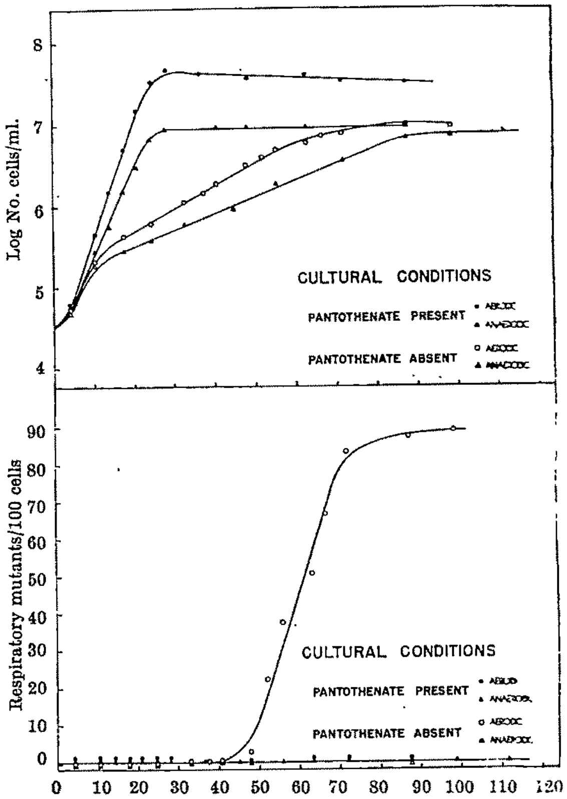

Fig. 1. Growth and mutation curves of cells cultivated aerobically or anaerobically in the presence or absence of pantothenate

To determine what bearing lipid metabolism might have on this mutation, acetate as well as representative sterols and higher saturated and unsaturated fatty acids were tested individually for possible influences on the compositions of early stationary-phase populations attained in pantothenate-free aerobic cultures. The results summarized in Table 1 show that, with the exception of cholesterol, each of the lipids examined increases the total cell yield over that obtained in the absence of lipid. This is consistent with a previous report that pantothenate starvation causes multiple lipid deficiencies in *Saccharomyces*[11]. On the other hand, only acetate and the mono-unsaturated oleic acid appear highly effective in preventing the occurrence of respiratory

Table 1. EFFECTS OF ACETATE, HIGHER FATTY ACID AND STEROL SUPPLEMENTS ON THE TOTAL NUMBER OF CELLS AND THE FREQUENCIES OF RESPIRATION-DEFICIENT MUTANTS PRODUCED IN PANTOTHENATE-FREE CULTURES AFTER 72 HR. INCUBATION. CULTURES WERE INOCULATED TO AN INITIAL DENSITY OF $2{\cdot}9 \times 10^4$ CELLS/ML.

	Cell No./ml.	Mutants/100 cells
Supplement*		
None	$7{\cdot}6 \times 10^6$	86·6
Potassium acetate	$2{\cdot}4 \times 10^7$	1·7
Unsaturated fatty acids		
Linoleic acid	$1{\cdot}1 \times 10^7$	81·3
Oleic acid	$2{\cdot}1 \times 10^7$	1·2
Saturated fatty acids		
Palmitic acid	$1{\cdot}7 \times 10^7$	37·8
Stearic acid	$1{\cdot}9 \times 10^7$	12·9
Sterols		
Cholesterol	$6{\cdot}9 \times 10^6$	88·1
Ergosterol	$2{\cdot}5 \times 10^7$	93·0

* Potassium acetate was added directly to the medium to a concentration of 4·5 mgm./ml.; other fatty acids and the sterols were added to the medium from ethanolic solutions to concentrations of 50 μgm./ml. The ethanol content of each experimental flask, including the lipid-free control, was adjusted to a concentration of 0·2 per cent (v/v) prior to autoclaving.

mutation; the fully saturated stearic and palmitic acids are considerably less effective in this regard while the di-unsaturated linoleic acid and the sterols, ergosterol and cholesterol, are without effect.

Evidently yeast cells require a supply of certain fatty acids in order to ensure the genetic stability of their aerobic respiratory apparatus. Their need for oleate is particularly critical. Under conditions of pantothenate deficiency, cells are incapable of providing these materials for themselves when approaching the stationary phase of growth in aerobic culture. The fact that exogenous acetate is as effective as oleic acid in satisfying this requirement establishes that the pantothenate-starved cells possess sufficient quantities of coenzyme *A* to permit an adequate rate of fatty acid production from acetate and indicates that their lipid need results from their limited ability to generate acetate during growth on glucose. It is known that yeast cells grown aerobically incorporate acetate into lipids at equivalent rates during the logarithmic and stationary phases of growth; their ability to oxidize acetate, however, does not develop appreciably until the termination of the logarithmic phase[12]. Since the oxidation of acetate by yeast is an aerobic process, it can be concluded that pantothenate-starved cells conduct no significant acetate oxidation either during logarithmic aerobic growth or at any state of anaerobic growth. The fact that they also do not mutate under these conditions indicates that their production of acetate is at least sufficient for the biosynthesis of the fatty acids which stabilize respiration. Accordingly, the extensive mutation which pantothenate-starved cells undergo at the inception of the stationary phase of aerobic growth can be attributed to their oxidative depletion of that limited supply of endogenous acetate which is essential for biosynthetic purposes. Thus acetate metabolism does appear to be of basic importance in the genetic maintenance of cellular respiratory competence.

The respiratory activity of the normal mitochondrion depends uniquely on the structural orientation of its constituent enzymes[13]. Lipids and ribonucleic acid along with the enzymic proteins themselves contribute to the preservation of this organization. While it may be assumed that the biosyntheses of mitochondrial enzymes, like those of other enzymes, are genically directed, the fact that mitochondria do not arise *de novo* shows that their fabrication is contingent on the structural organization of pre-existent mitochondria. Thus treatments which upset normal mitochondrial organization might be expected to give rise to lines of mutant mitochondria exhibiting depressed respiratory activities. The heritable loss of respiratory competence induced in cells by pantothenate starvation can most simply be ascribed, at present, to such a disorganization resulting from a cellular deficiency for particular fatty acids.

This work was aided by a contract between the Office of Naval Research, Department of the Navy, and the University of Wichita, *NR* 103-459, and a grant from the Kansas Division of the American Cancer Society.

RADIOSENSITIZATION OF *E. COLI* BY PURINE AND PYRIMIDINE ANALOGUES INCORPORATED IN DEOXYRIBONUCLEIC ACID

By PROF. HENRY S. KAPLAN, DR. KENDRIC C. SMITH and PATRICIA TOMLIN

Department of Radiology, Stanford University School of Medicine, Palo Alto, California

THE radiosensitivity of a given species and strain of bacteria is characteristic of that species and strain, but is subject to modification by a variety of physiological and environmental factors[1]. Among the factors which modify radiation sensitivity are oxygen[2], nitric oxide[3], and the sulphydryl-amines, such as cysteine[4], cysteamine[5] and AET[6].

A number of considerations have led investigators to postulate that the lethal effects of radiation might be mediated by damage induced in the molecular structure of the nucleic acids, in particular deoxyribonucleic acid (DNA). The discovery in recent years that certain purine and pyrimidine analogues are incorporated into bacterial DNA[7-12] makes it of interest to study the effect of the resulting alteration of molecular structure of DNA on radiosensitivity.

The work described here was initiated about a year ago[13], and is focused primarily on the X-ray sensitivity of various strains of *E. coli*, though some experiments with ultra-violet have also been performed.

Greer[14] has recently reported a striking increase of ultra-violet sensitivity in *E. coli*, strain $15T^-$, a thymine-deficient mutant, after incorporation of the thymine analogue, 5-bromouracil (BU). Djordjevic and Szybalski[15] have reported a similar response to ultra-violet in mammalian cells cultivated *in vitro* in the presence of 5-bromouracil deoxyriboside (BUDR), as well as the corresponding iodinated compound (IUDR). These authors also reported limited experiments with X-rays, indicating increased lethality in mammalian cells the DNA of which was labelled with these halogenated deoxyribosides.

We have used the wild-type *E. coli* strains *B* (*W*3292, radiosensitive) and *B*/*r* (radioresistant[16]); a thymine-deficient mutant of strain *B* (*W*4516); and a purine- and thiamin-deficient mutant of strain *K*12 (*W*3687), all obtained through the kindness of Dr.

Esther Lederberg of the Department of Genetics, Stanford University.

All incubations were carried out under aerated conditions at 37° C. The mutant strains were grown from slants in a fortified medium[17] to which thymine (strain *W*4516) or purines (strain *W*3687) were added. Primary cultures of strains *B* and *B*/*r* were grown on mineral medium[18]. Secondary cultures employed mineral medium to which 2 per cent sulphanilamide was added to block *de novo* purine and pyrimidine synthesis. The sulphanilamide medium required supplementation with several other bases, vitamins and minerals. The purine and pyrimidine analogues under investigation were usually added at a level of 100 μgm./ml. Analogues studied to date include BU, IU, 5-fluorouracil (FU), thioguanine (TG), 2-aminopurine (AP), and 2,6-diaminopurine (DAP).

X-irradiation was carried out at 250 kV., 15 m.amp., 30 cm. distance, 0·25 mm. copper + 1·0 mm. aluminium filter, 1·10 mm. copper half-value layer, dose-rate 360–390 r./min. Cultures were collected by centrifugation, washed, suspended and diluted in phosphate buffer to concentrations of about 1×10^7 organisms/ml., and irradiated in 'Teflon' cups fitted in a 'Lucite' block, as described by Gunter and Kohn[19]. Ultra-violet irradiations were performed with an unfiltered low-pressure mercury lamp with a measured output of 16·6 ergs/sq. mm./sec. at 43 cm. distance. Samples were withdrawn at successive time-intervals from an open Petri dish buffer suspension. After irradiation, samples were appropriately diluted and plated on nutrient agar (fortified with thymine or adenine for the mutant strains) and incubated at 37° C. Colony counts at each radiation dose-level are expressed as a fraction of the viable counts of non-irradiated samples. Radiosensitivity is expressed in terms of the experimental/control slope ratios of dose – log survival curves.

DNA was isolated from aliquots of control and experimental cultures by differential chemical extraction; mixed nucleic acids by lysis with 2 per cent sodium lauryl sulphate. When necessary, RNA was removed by alkaline hydrolysis. BU incorporation into DNA was established by three different methods: cæsium chloride density gradient determination[20]; incorporation of radioactive ^{82}Br–BU (synthesized by Dr. Joseph P. Kriss[21]); and base hydrolysis and chromatography. TG incorporation was determined with the analogue labelled with sulphur-35. Detection of DAP incorporation into DNA required the use of carbon-14-labelled analogue.

The incorporation of ^{82}Br–BU into DNA was linear with time until the end of the phase of exponential growth, by which time there was 35–50 per cent replacement of thymine by BU. Stationary phase cultures showed further incorporation with a plateau at about 70 per cent replacement of thymine by BU. Base hydrolysis and chromatographic analysis of DNA from stationary phase cultures indicated 68 per cent replacement. The flotation density of the isolated DNA was 1·763 (control 1·712), corresponding to 70 per cent replacement of thymine by BU. There was little or no decrease of viability of organisms that incorporated BU through the log phase; but a rapid decrease in viability with further BU incorporation during stationary phase was noted. For this reason most of the radiation experiments were carried out on organisms collected during the log phase.

Strains *W*4516 and *B*/*r* labelled with BU exhibited a striking enhancement of sensitivity to ultra-violet, the curves being essentially identical to those reported by Greer[14]. The thymineless mutant, strain *W*4516, showed a multi-hit type of X-ray dose-survival curve, with an extrapolation number which fluctuated somewhat but was usually in the range 1·5–2·0. When this organism was grown on BU, the shoulder of the X-ray survival curve narrowed appreciably, and in some instances vanished, while the slope of the linear portion of the curve exceeded that of the control curve by a factor of 1·8–2·2 in various experiments (Fig. 1). For the wild-type strains, the control curves of which were of the single-hit type, radiosensitization by BU yielded slope ratios of approximately 1·6–1·8 for strain *B*/*r* and 1·4–1·5 for strain *B* under log-phase conditions. Organisms grown on reciprocal 9 : 1 mixtures of thymine and BU exhibited responses intermediate between the extremes of 100 per cent thymine- or 100 per cent BU-grown cultures. Radiosensitization was a function of incubation time in the presence of BU, being undetectable after 2 hr. (8 per cent thymine replacement), barely detectable at 4 hr. (about 20 per cent replacement), and maximal by 8 hr. (approximately 40 per cent replacement). The possibility that some threshold-level of BU incorporation is required merits further study in the time-interval between 2 and 4 hr. When the thymineless mutant strain *W*4516 was grown through log phase in BU, then diluted ten-fold and re-incubated in thymine long enough to permit one replication of DNA, the resulting organisms, containing DNA which was presumably labelled in only one strand with BU, exhibited a radiosensitivity intermediate between that of controls and fully BU-labelled cells. A somewhat greater loss of radiosensitivity has been reported in BUDR-labelled mammalian cells after one replication in the presence of thymidine[15].

In one experiment, IU-grown strain *W*4516 cells exhibited conversion to a single-hit type of curve, but the slope was essentially identical to that of the controls. In the same experiment, cells grown on BUDR showed slightly greater radiosensitization than BU-grown cells, with slope ratios of 1·80 versus 1·35 relative to thymine-grown controls, respectively. The mere presence of the analogues in the culture medium, under conditions in which incorporation into DNA could not proceed (for example, in the absence of sulphanilamide) yielded radiation dose-survival curves identical with those of controls. In

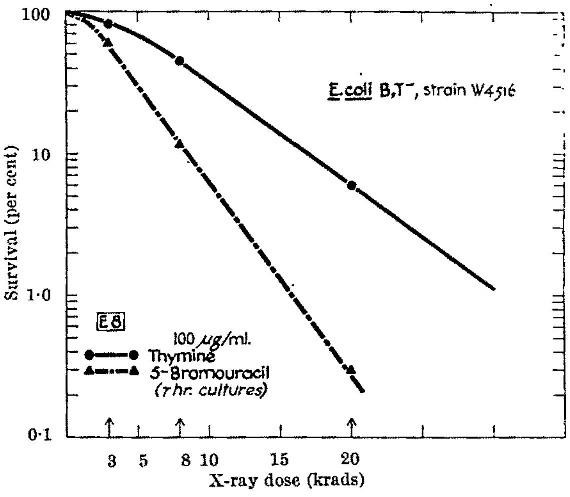

Fig. 1

limited trials to date, pre-incubation of strain *B/r* with 5-FU has revealed no radiosensitization. This analogue, unlike IU and BU, is incorporated into RNA, but not into DNA (ref. 22).

Thioguanine is incorporated into log-phase strain *B/r* to the extent of about 0·6 per cent, calculated on the basis of replacement of DNA guanine. Although the extent of incorporation is considerably less than that of BU at corresponding time-intervals, the degree of radiosensitization to both ultra-violet and X-rays was approximately the same (Fig. 2). Consistent with this observation is the finding (to be reported in detail in a separate paper) that aqueous solutions of TG were appreciably more sensitive than any of the natural bases to spectral degradation by ultra-violet, whereas BU was only slightly more sensitive than thymine. The spectral degradation of TG by X-rays was markedly more sensitive than that of guanine and essentially identical with the responses of BU and thymine. Since purines and pyrimidines are presumably incorporated into DNA more or less independently, the effect of combined BU and TG was studied in sulphanilamide-grown strain *B/r*. In the presence of TG, BU incorporation was markedly reduced, reaching a level of only 12 per cent thymine replacement, as compared with 70 per cent in the absence of TG. None the less, organisms which had incorporated both analogues into their DNA exhibited a further increase in X-ray sensitivity (slope ratio 2·95 versus 2·2 for TG or BU alone, Fig. 3).

Although most of the radioactivity of DAP labelled with carbon-14 incorporated into DNA of purine-deficient strain *W*3687 cells was in guanine and adenine, the incorporation of unchanged DAP to the extent of about 1 per cent was demonstrable by careful chromatographic separation from guanine in the presence of carrier DAP. Replicate experiments with this strain indicated a slight increase in radiosensitivity, with slope ratios in the range 1·15–1·25. There was a departure from linearity at higher dose-levels, indicating the presence of a small proportion of cells which had failed to incorporate the analogue. In one experiment with AP in strain *W*3687, neither radiosensitization nor incorporation into DNA was demonstrable.

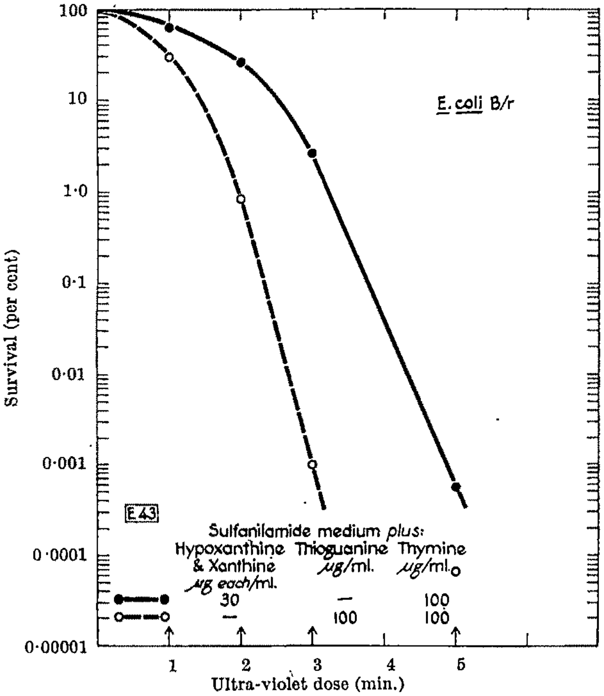

Fig. 2

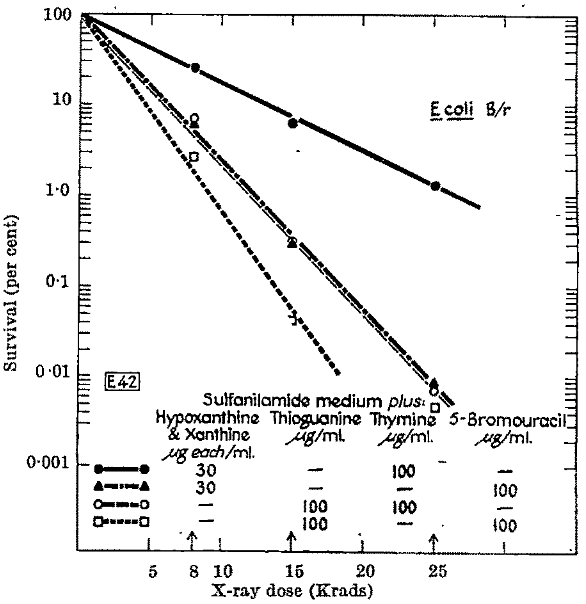

Fig. 3

In summary, it appears that both ultra-violet and X-ray sensitivity of *E. coli* are enhanced when appreciable proportions of the natural bases of DNA are substituted by any of several purine and pyrimidine analogues. Analogues which fail to enter bacterial DNA (FU, AP) have to date failed to elicit this response. Based on relative extent of incorporation, TG is the most active radiosensitizing agent thus far reported, with BUDR, BU, IU, and DAP following in order of decreasing activity.

These investigations were aided by grants *C*-3352 and *C*-2896 from the National Cancer Institute, National Institutes of Health, U.S. Public Health Service. Analogues were obtained from the California Corporation for Biochemical Research, Los Angeles, California; ^{35}S-TG from Isotopes Specialties Company, Burbank, California.

ASTROPHYSICS

Solar Flare Effects in the *F* Region of the Ionosphere

ELEVEN years ago, Dieminger reported that the large solar flare of November 19, 1949, had a marked effect on the *F* region over Lindau, Germany[1]. A similar *F*-region effect was observed at Okinawa and probably at Singapore at the time of the outstanding flare of February 23, 1956[2,3]. In addition to being very large, these flares were notable in that they were two of the five flares that had occurred up to that time during which increases in sea-level cosmic ray had been observed. Yet, because the *F*-region effect had been detected at so few of the sunlit ionospheric sounding stations, some doubt remained as to the correct interpretation of these observations.

The purpose of this communication is to report two additional cases of *F*-region effects which were recently observed accompanying the two large solar flares that occurred at 1323 U.T. on November 12, 1960, and at 0207 U.T. on November 15, 1960. Because these flares were also followed by cosmic ray increases recorded at sea-level (flares number eight and nine in the series now numbering ten, the tenth having been observed on November 20, 1960), the connexion between the relatively few flares that are associated with the emission of these very high energy particles ($\gtrsim 2$ BeV.) and apparent *F*-region effects is considerably strengthened. It is likely that the *F*-region effects are not caused by the cosmic-ray particles themselves but rather that flares associated with the emission of these very high energy particles are also unusual in their photon radiation. However, it should be noted that, in the course of this work, several apparently similar, but considerably smaller, *F*-region effects have been found in association with solar flares that were not observed to be followed by sea-level cosmic ray increases or polar cap absorption events.

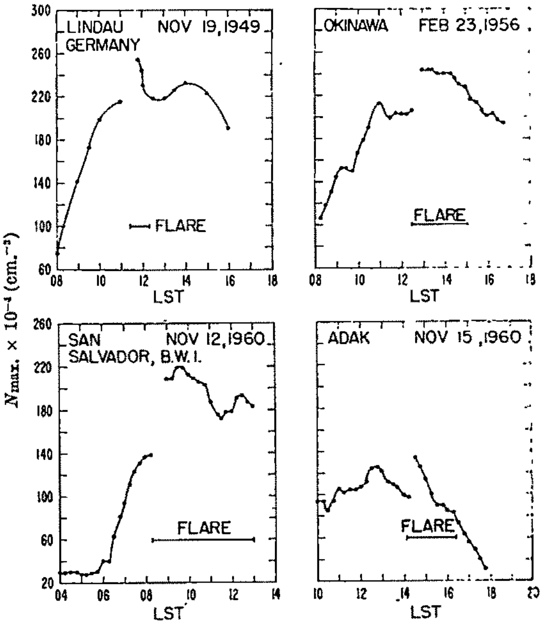

Fig. 1. Variations in *F*-layer maximum electron density during four cosmic ray-associated solar flares

Fig. 1 shows the variation of *F*-region maximum electron density, as determined from observations of the vertical-incidence penetration frequency, around the time of the two November 1960 flares and the two earlier flares discussed above. It can be seen that increases of about 20–50 per cent in maximum electron density occurred during the course of each flare. Examination of the soundings data taken on November 12, 1960, at other sounding stations along the east coast of the United States and in the Caribbean suggests that the *F*-region effect may have extended over the entire area, but at no other station was the effect as definite as at San Salvador, British West Indies, possibly due to the fact that the rapid diurnal increase in electron density was occurring at most of the stations at the time of the flare. Fortunately, however, an independent observation of the *F*-region effect associated with the flare of November 12, employing a different technique, is also available. Since January 1960, an experiment has been going on at the National Bureau of Standards that involves the study of oblique incidence propagation characteristics by means of recordings of frequency changes on high-frequency transmissions[4]. At the time of the November 12 event, recordings were being made in Boulder, Colorado, of the precise frequency of the *WWV*-20 Mc./s. transmission from Washington, 2,370 km. away. The effect shown (Fig. 2), which begins within about a minute of the time of commencement of the flare, can be interpreted as a 22 ± 5 km. lowering of the reflexion height at the midpoint of the path. (Note that no other effect, comparable in magnitude, has been observed in the 14 months since recording began.) While it was not possible to obtain meaningful electron density profiles from the November 12 San Salvador ionograms, due to large *D*-region absorption effects, it was possible to deduce profiles from the soundings taken at Adak during the November 15 event. Examination of the Adak profile data, shown in Fig. 3, reveals that the height of the plasma frequency-level of 6 Mc./s., which approximates to the

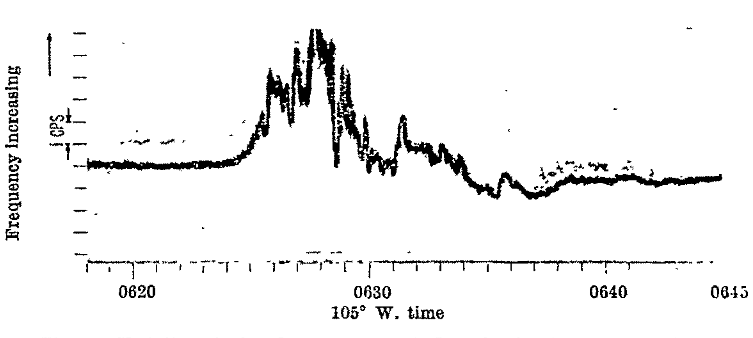

Fig. 2. Variations in the frequency of *WWV*-20 Mc./s. signal as recorded at Boulder, Colorado, November 12, 1960. The flare began at 0623 and the increase in sea-level cosmic ray at about 0640 (Deep River, Ont.)

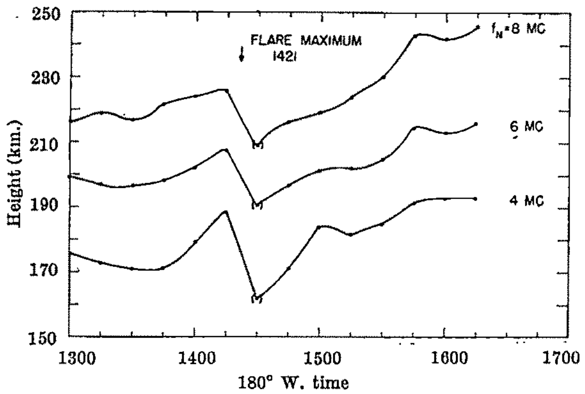

Fig. 3. Height variation of several fixed plasma frequencies during the solar flare of November 15, 1960; Adak, Alaska

equivalent vertical incidence frequency for 20 Mc./s. propagation over a 2,370-km. oblique path, decreased about 18 km. during this flare event, an effect of the same magnitude as that observed on the records of change in frequency during the November 12 event.

As mentioned above, less well-marked *F*-region effects that may be flare-associated were observed at several other locations during the November 1960 events. However, many sunlit hemisphere stations, with good *F*-region observations throughout most of the duration of the flares, show no change in *F*-region maximum electron density. A more complete examination of vertical soundings data obtained at sunlit locations during flares having sea-level cosmic ray increases is now under way.

PHYSICS

Effects of High Pressure on Glass : a Possible Piezometer for the 100-Kilobar Region

THE measurement of pressures of the order of 10,000–200,000 bars and upward on uniaxial pressure transmitting devices is a formidable problem. At present, inter-laboratory comparison of results obtained at ultra-high pressures is not satisfactory. The availability of a convenient pressure calibration substance that is useful over a wide temperature-range, and the agreement on a satisfactory scale of pressure based on this calibration substance, are imperative for future work.

To date, the only convenient high-pressure calibration substances for extreme pressure devices depend on the temperature-dependent phase transitions which occur in some metals. This is unsatisfactory, since it allows only point-wise calibration over a limited range of pressures and is limited to the room-temperature 'fixed' points.

Bridgman and Simon[1] have reported that silica glass could, above a threshold pressure of about 100,000 atmospheres, be made permanently more dense, and at pressures of about 200,000 atmospheres this increase in density amounted to about 6–7 per cent. In an attempt to check pressure apparatus in this laboratory against Bridgman's data, some very surprising findings were encountered.

The apparatus used has been described by Dachille and Roy[2] and is similar to that employed by Bridgman and Simon[1]. Automatically regulated pressure was applied to two opposed anvils of the Bridgman type by means of a hydraulic press. The pressure was calculated on the basis of the total force developed by the ram of the press and the area of the anvil face after removal of pressure. The sample was heated and its temperature automatically regulated by means of a split external furnace. A basic difference in procedure used by us was the use of powdered glass instead of a continuous disk.

The effect of pressure on the density and refractive index of silica glass was found to be much greater than that reported by Bridgman and Simon[1]. Further, the change in density was found to be a continuous function of pressure above 20,000 atmospheres at room temperature. No threshold effect was observed at 600° C. The density of silica glass, which has a normal refractive index of 1·458, could be increased by a pressure of 150,000 atmospheres at room temperature to a form with a refractive index as high as α-quartz, namely, 1·54 (see Fig. 1). The changes achieved by Bridgman and Simon[1] at a reported pressure of 200,000 atmospheres could be achieved at pressures as low as 55,000 atmospheres at room temperature.

The effect of temperature is also very important. Silica glass which has been subjected to 40,000 atmospheres at 25° C. has an index of refraction, after returning to ambient conditions, of 1·48, whereas the index of the glass subjected to 40,000 atmospheres pressure at 500° C. has an index of refraction of 1·50 under ambient conditions.

For each pressure and temperature there is a pseudo-equilibrium volume for the silica glass. This volume is attained in less than 15 sec. and does not alter after several days at pressures and at temperatures (less than 600° C.) less than those initially applied.

The compressed silica glass is quite stable under ambient conditions. Samples of the compacted silica glass have been kept undesiccated for 1½ years without any noticeable change in index of refraction. Further, the glass can be kept for a week at 600° C. at atmospheric pressure without undergoing any noticeable relaxation. Glasses compacted by the uniaxial device show a spread of about ±0·005 index of refraction unit. This is probably a result, as Bridgman

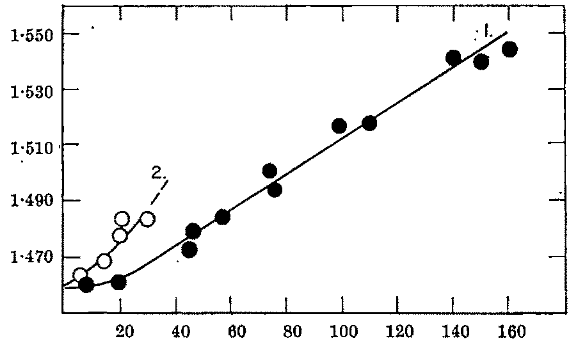

Fig. 1. Index of refraction of the quenched phase of silica glass as a function of the pressure of the run: (1) at 25° C.; (2) at 600° C.

and Simon suggest, of the uniaxial nature of the pressure-transmitting device. Glasses subjected to 10,000 atmospheres argon pressure (hydrostatic pressure) in a bomb appear homogeneous when examined by the standard immersion-oil technique (that is, within ± 0·001 unit), with indices falling on the same curve.

The continuous compaction of glass as a function of pressure is not unique to silica glass. Similar results of somewhat lesser magnitude have been observed in germanium oxide, boron oxide, as well as silver phosphate and 'window' glass. A detailed report on the effects of pressure and temperature on these glasses will be given elsewhere[3].

In view of the observed continuous increase of density of silica glass as a function of both temperature and pressure, it is proposed that the refractive index of silica glass be used as a piezometer. Silica is particularly inert and could be mixed with many samples to provide a check on the actual pressure and/or temperature of a run. It is suggested that it would be quite valuable if several laboratories interested in high-pressure measurements determined independently the effect of pressure and temperature on the refractive index of silica glass. Perhaps a satisfactory pressure-scale could then be agreed upon.

This investigation has been supported by a grant to the University for fundamental studies in defect solids by the Bausch and Lomb Optical Company. We are much indebted to our colleague, Dr. F. Dachille, for help with equipment and ideas.

Estimation of Dynamic Modulus and Dynamic Yield Stress for 'Perspex'

IT has been found that a steel ball dropped on to a thick flat plate of 'Perspex' produces an electrostatic charge over the contact area. This effect has been investigated with the view of developing a simple method for estimating the dynamic modulus and dynamic yield stress.

The technique for determining modulus was as follows: A cylindrical 'Perspex' rod 2·54 cm. diameter and 30 cm. long with polished flat ends was supported in a horizontal position. One end was placed against a fixed steel plate and a 1-cm. thick 'Perspex' end-piece was wrung on the other end with 'Vaseline'. A clean steel ball of diameter 3·2 cm. was suspended as a simple pendulum, so that on release from a given height, h cm., impact took place on the end-piece. A fine wire connected the ball to an oscilloscope amplifier which had a high resistance across the input. The voltage–time record showed that as the ball approached the polymer surface, it became charged by induction due to the surface electrostatic charge which is readily built up on 'Perspex'. In close proximity to the polymer the ball began to discharge, but on contact, the rate of induction decreased rapidly so that the potential of the ball fell below a minimum discharge potential resulting in a marked decrease in rate of discharge. However, once good contact had been established between ball and polymer, the rate of discharging increased until contact was broken when the process ceased. The duration of contact could thus be obtained from the oscilloscope record. For an impact velocity of 77 cm. sec.$^{-1}$ the measured duration of contact, t, was $37{\cdot}8 \times 10^{-5}$ sec. According to the Hertz[1] theory:

$$t = \frac{2{\cdot}94}{v^{1/5}}\left(\frac{5}{4}\,\frac{m}{n}\right)^{2/5}$$

where m is the mass of the ball, v the ball velocity on impact and n is given by:

$$n = \frac{4\pi\sqrt{R}E_1^2E_2^2}{3[(1-V_1^2)E_2 + (1-V_2^2)E_1]^2}$$

The quantities E_1, E_2, V_1 and V_2 are the Young's moduli and Poisson's ratios of steel and 'Perspex' respectively. The radius of the ball is denoted by R. Putting the above-measured value of t in the equations with values of E_1 and V_1 given by Davies[2] and V_2 given by Davies and Hunter[3], resulted in a dynamic Young's modulus (E_2) of $5{\cdot}3 \times 10^{10}$ dynes cm.$^{-2}$ for 'Perspex'. A different form of ball impact experiment by Tillet[4] using a 0·63-cm. diameter ball at a velocity of 90 cm. sec.$^{-1}$ gave with the Hertz calculation a modulus of $5{\cdot}4 \times 10^{10}$ dynes cm.$^{-2}$. These dynamic values compare favourably with the 'static' value of $1{\cdot}8 \times 10^{10}$ dynes cm.$^{-2}$ computed from Kolsky's[5] 'static' stress–strain curve and the dynamic moduli of $6{\cdot}8 \times 10^{10}$ (ref. 5) and $6{\cdot}0 \times 10^{10}$ dynes cm.$^{-2}$ (ref. 3), obtained at very high rates of stressing by pressure-bar methods.

Attempts have also been made to measure the diameter of the maximum indentation. A specimen was impacted and held over a tray of lycopodium powder and gradually lowered towards it until a quite distinct circular patch of powder had been attracted to the impact area. It was then assumed that the diameter of the powder patch d_p was equal to the diameter of maximum indentation d_e given by Hertz as:

$$d_e^3 = 6PR\left(\frac{1-V_1^2}{E_1} + \frac{1-V_2^2}{E_2}\right)$$

where P is given by:

$$P = n\left(\frac{5mv^2}{4n}\right)^{3/5}$$

There was a range of values of d_p for a given height of impact, but it seemed reasonable to suppose that it was the maximum value of d_p which was required. The maximum values of d_p obtained using an impactor of diameter 3·8 cm. at impact velocities in the range 58–310 cm. sec.$^{-1}$ gave calculated moduli in the range 8×10^{10}–$6{\cdot}3 \times 10^{10}$ dynes cm.$^{-2}$. As will be seen from the previous paragraph, these values of modulus are impossibly large; they should not be greater than moduli obtained by pressure-bar methods. Thus it must be concluded that $d_p < d_e$.

The above conclusion and the fact that the stresses vary over the contact area are used to estimate the dynamic yield stress. It is assumed that during impact the ball discharges most efficiently where really good contact is made. Thus powder is primarily attracted where plastic yielding has occurred. Hence maximum values of d_p may correspond to a yield stress of the material. There may be other effects involved, but the above is assumed to predominate.

To calculate the yield stress corresponding to a maximum of the ratio d_p/d_e for a given h, where d_e was calculated using the modulus $5{\cdot}3 \times 10^{10}$ dynes cm.$^{-2}$, the Guest–Mohr hypothesis of elastic failure was taken in conjunction with Huber's[6] equations,

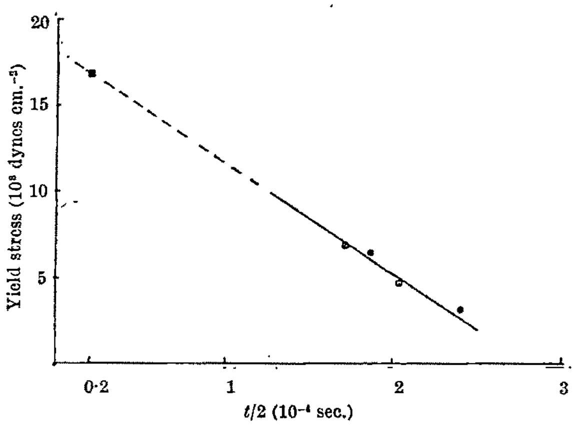

Fig. 1. Estimated yield stresses

which were then solved using a value of 0·35 for Poisson's ratio to give solutions of a graphical form described by Davies[2]. For values of h ranging from 48 cm. to 2 cm. the values of dynamic yield stress obtained were $6\cdot9 \times 10^8$–$3\cdot1 \times 10^8$ dynes cm.$^{-2}$. A straight-line plot was obtained for dynamic yield stress against half the duration of contact, $t/2$, given by the Hertz calculation with the modulus $E_3 = 5\cdot3 \times 10^{10}$ dynes cm.$^{-2}$. A typical set of results is shown in Fig. 1. Extrapolating the line to $t/2 = 0\cdot2 \times 10^{-4}$ sec., which is approximately the time to reach maximum stress in the pressure-bar experiments[3,5], gave a yield stress of $16\cdot9 \times 10^8$ dyne cm.$^{-2}$. Thus, assuming 'Perspex' behaves as a Hookean solid at pressure-bar rates of stressing, a yield stress of about $16\cdot9 \times 10^8$ dynes cm.$^{-2}$ should be observed. The dynamic stress–strain curve of Kolsky[5] does not show this, but the more recent results of Davies and Hunter[3] show a linear stress–strain curve up to a yield stress of approximately $16\cdot6 \times 10^8$ dynes cm.$^{-2}$. Thus the present simple technique may be of value in predicting high stress-rate behaviour.

A more detailed account of the above experiments for 'Perspex' and additional results for a number of other polymers will be published elsewhere.

Packing of Spheres

In connexion with Bernal's theory of liquids, Scott[1] has determined the packing density of equal spheres by experiments with steel balls. In this laboratory we were interested in the dense random packing of beads of ion-exchange resins. Although particles of ion-exchange resins may vary in diameter from 1·3 mm. to 0·03 mm. or less, if the ratio of the diameters of the larger to the smaller beads in any batch exceeds 3 or 4, segregation may occur when the beads are backwashed or allowed to settle under water. If the ratio exceeded 6·5, it would be possible for the smallest spheres to fit into spaces between close-packed spheres of the largest diameter and so increase the packing density; but, if the problem is limited to the smaller ratios which occur in practice, only holes and not spaces can be filled by the smaller beads and the packing density should be 0·64–0·74.

The beads were sieved and packed under water, and to avoid peripheral errors at least 50,000 beads were taken for each determination. Narrow fractions with few irregular particles had packing densities close to 0·64. The value obtained for the most regular narrow fraction (irregular particles <4 per cent) was 0·63(8), in good agreement with Scott's extrapolated value of 0·63(7) for equal spheres. In this fraction the mean deviation from the mean diameter was 10·5 per cent. Wider fractions had increased packing densities, and a value of 0·66(7) was obtained for a fraction with mean deviation from the mean diameter of 23 per cent. Even higher values were obtained by mixing in various proportions beads of mean diameter 0·09 mm. with beads of mean diameter 0·31 mm. The smaller and larger beads alone each had packing densities of 0·66, but the packing density of the mixture reached a maximum of 0·70(5) when the proportion of the smaller beads was about 30 per cent of the mixture. Most batches of ion-exchange resin contain irregular fragments produced by the shattering of some of the beads, and these fragments probably affect the packing more than do rounded particles that are not truly spherical. The packing density of crushed resin was found to be 0·54 for particles of similar size. When various proportions of irregular particles were mixed with spheres of the same average size, the packing density remained at 0·64 until 10 per cent by intrinsic volume of irregular particles had been added. Thereafter the packing density decreased in proportion to the percentage of irregular particles in excess of 10 per cent.

GEOLOGY

Potassium–Argon Ages of the Dartmoor and Shap Granites using the Total Volume and Isotopic Dilution Techniques of Argon Measurement

Early in 1960, J. L. Kulp and others reported potassium–argon and rubidium–strontium ages for a number of granites from Great Britain and Eire[1]. The argon measurements were made at the Lamont Geological Observatory by the isotopic dilution technique, and the rubidium–strontium determinations were made at Oxford and Harwell. Some of the rocks examined, including the Shap and Dartmoor granites, had been measured by Mayne *et al.*[2], using the total volume technique for measuring the argon. There was a serious discrepancy between the potassium–argon measurements reported in these two communications, the results obtained by Kulp *et al.* being in agreement with the rubidium–strontium data (Table 2).

In this communication the results of new potassium–argon measurements on the Shap and Dartmoor granites, using both total volume and isotopic

dilution techniques, are reported. The total volume measurements were carried out at Cambridge on newly developed apparatus, and at Oxford on the apparatus employed previously by Mayne *et al.* The isotopic dilution measurements were made at Oxford.

The total volume apparatus used at Oxford is similar to that described by Thomson and Mayne[3]. The apparatus used for the isotopic dilution measurements is a bakeable glass system which will be described elsewhere. Aliquots of argon-38 were prepared by a method similar to that of Wasserburg and Hayden[4], and calibrated by mixing with known amounts of spectroscopically pure argon. The accuracy of this system of argon measurement was checked from time to time by measuring the argon content of the reference biotite *B*.3203 supplied by Dr. P. M. Hurley of the Massachusetts Institute of Technology. The results of three measurements differed by 0·2–1·5 per cent from the mean of the American measurements. Duplicate determinations on younger materials suggest, however, that the accuracy is ± 3 per cent for the more recent measurements quoted in this communication, and rather more for the earlier ones.

The Cambridge apparatus used in the extraction and purification of argon is built mainly of stainless steel. It is small in size, and is connected directly to the mass spectrometer, which makes it easy to operate and reduces the likelihood of loss of gas by absorption, or the presence of small leaks which would add to the volume of gas finally measured. For successful total volume work both these troubles must be avoided, and also the McLeod gauge on which the volumes are measured must be accurately calibrated. This has been done in three ways:

(1) By the measurement of accurately known volumes of argon of different sizes, made up from spectroscopically pure argon using a gas pipette.

(2) By introducing samples of air from containers of known volume filled at a measured temperature and pressure.

(3) By measuring argon liberated by fusing the reference sample, *B*.3203.

Results from these experiments were consistent to about 1 per cent, which besides giving a reliable calibration of the McLeod gauge, indicated that the loss of argon by absorption was negligible, and that the method of purification of the gas was adequate.

For the work in both Oxford and Cambridge the potassium determinations were made by flame photometric methods. Each determination at Cambridge is the average of six analyses, and at Oxford the average of four. The accuracy of the Cambridge measurements is estimated to be ± 1 per cent, and of the Oxford ones ± 2 per cent.

The results of the new determinations are given in Table 1. Their mean values, weighing all determinations equally, are 265 ± 5 million yr. for the Dartmoor granite and 397 ± 8 million yr. for the Shap. In Table 2 these are compared with the corresponding results from the earlier reports. The new figures are in good agreement with both the potassium–argon and the rubidium–strontium ages of Kulp *et al.* (except that the difference between the new age for the Shap granite and the rubidium–strontium age slightly exceeds the uncertainties given). They confirm that the results of Mayne *et al.* are too high, particularly for the Shap granite. The reason for this is not known.

The differences in the levels of contamination by atmospheric argon found in the two laboratories (Table 1) arise mainly from the use at Oxford of graphite crucibles, which have a large surface area for absorption of gas, while molybdenum crucibles are used at Cambridge.

Table 2. COMPARISON WITH EARLIER RESULTS

Reference	Method	Age of Dartmoor granite (million yr.)	Age of Shap granite (million yr.)
Mayne *et al.* (ref. 2)	K/Ar, total volume	298*	465–499*
Kulp *et al.* (ref. 1)	K/Ar, isotopic dilution	271 ± 5	391 ± 7
Kulp *et al.* (ref. 1)	Rb/Sr	277 ± 5	381 ± 7
This work	K/Ar, both techniques	265 ± 5†	397 ± 8†

* Recalculated values.
† Error is twice standard deviation of mean.

In the figures obtained for the argon content of the Shap sample 20512 there is some evidence for a small systematic difference between the results by the two techniques. However, this is not large enough to be investigated easily at separate laboratories. The Cambridge apparatus is being modified to permit both techniques to be used on the same sample of gas.

It may be concluded from these results that the total volume technique can give good results on materials of Palæozoic age. The chief limit to its accuracy is the error in reading the McLeod gauge. The possibility of incomplete purification, however, must always be borne in mind, since the amount and composition of the contaminating gases which are evolved when a sample is fused are both variable. These limitations become less important for older rocks, and in our experience there seems to be little to choose in most respects between the two methods for work on Palæozoic and earlier materials. In general, however, it is considered that the isotopic dilution technique is preferable, since its accuracy can be maintained for much younger samples.

We wish to thank the Department of Scientific and Industrial Research for its financial support for these projects, and Prof. L. R. Wager and Sir Edward Bullard for their interest and encouragement.

Karroo Igneous Activity and Tectonics in South-East Southern Rhodesia

During the period 1959–60 the work of the Research Institute of African Geology on Karroo igneous activity in Southern Rhodesia was extended to include the suite of Karroo igneous rocks which lie between the Lundi and Sabi Rivers some eighty to ninety miles to the north-east of those described by Cox *et al.*[1] (Fig. 1*a*). It is hoped to publish the detailed results of the work on this area soon.

Between the Sabi and Lundi Rivers the geological sequence is identical with that to the south-west. Basement gneisses, schists and quartzites of the east-north-east trending Limpopo Orogenic Belt[4] are unconformably overlain by Karroo sediments[6], and those in their turn underlie a considerable thickness of Karroo volcanic rocks.

The Karroo lavas in this region are estimated to be about 13,000 ft. thick and have a uniform dip of 7–10° to the south-east. They may be divided into a lower group of olivine-rich basalts and an upper group of more tholeiitic basalts in which olivine is noticeably scarce or absent. The ignimbrites, which characterize the uppermost part of the volcanic succession in the Nuanetsi District[1], are absent or overlain by later formations.

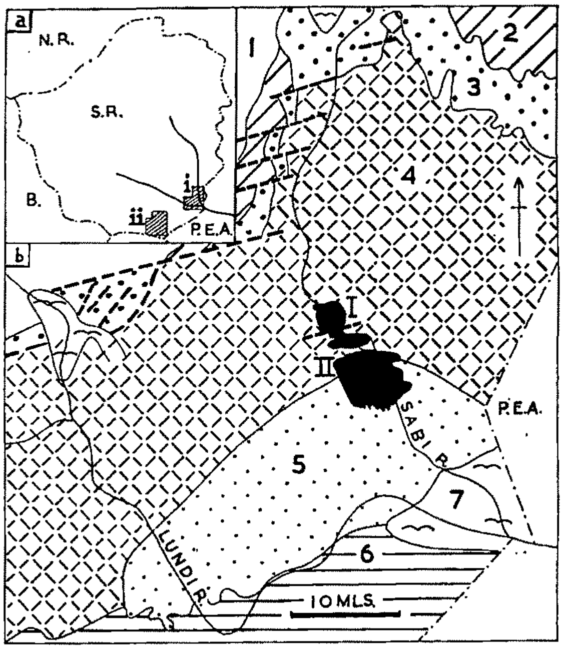

Fig. 1. (*a*) *N.R.*, Northern Rhodesia; *B*, Bechuanaland; *P.E.A.*, Portuguese East Africa; i, area shown in (*b*); ii, area described by Cox *et al.* (ref. 1). (*b*) 1, Basement Complex; 2, Umkondo System; 3, Karroo sediments; 4, Karroo basalts; 5, Main Granophyre; 6, Cretaceous; 7, Alluvium; I, Mutandawhe Complex; II, Chiwonje Complex

The extrusion of this thick sequence of lavas in the Sabi-Lundi area was followed by the intrusion of a series of rocks mainly of granitic affinities. Apart from a small horizontal tonalite body situated to the south-east of Mutandawhe, the earliest of these intrusions was a large sheet of porphyritic granophyre, the intrusion of which was localized at, or near, the upper limit of the basalts. This granophyre has an areal extent of 500 sq. miles and crops out from beyond the Lundi River in the south-west to beyond the Sabi River in the north-east (Fig. 1*b*); it can be correlated with the Main Granophyre of the Nuanetsi Area[1].

Subsequent phases of Karroo igneous activity are represented by two intrusive complexes in the Lower Sabi Valley. Mutandawhe, the more northerly of the complexes, is composed of granites and syenites and is characterized by a series of ring intrusions, but the Chiwonje complex to the south is composed entirely of granites which are intruded in part concordantly and in part discordantly. The rocks of these complexes have been responsible for copper, lead and tungsten mineralization in the surrounding basalts.

The final phase of igneous activity in the area is represented by a series of minor acid and basic intrusions.

In the southern part of the area the Main Granophyre and lavas are overlain by the conglomeratic basal member of a sedimentary series presumed to be Cretaceous in age. This latter group is in outcrop continuity with the post-Karroo sediments of the Nuanetsi area.

Structurally, the rocks as a whole overlie the east-north-east trending Limpopo Orogenic Belt[3,4], and the Chiwonje and Mutandawhe Complexes lie at the intersection of this belt with the southward projection of the Sabi Valley Fault[5]. The influence of the Limpopo Orogenic Belt during post Pre-Cambrian times has been noted by Dixey[2] and is further suggested by the many faults which affect the Karroo rocks and which strike parallel to the orogenic belt.

CHEMISTRY

Sorption of Copper by Cellulose

Belford, Preston and co-workers[1,2] have made a study of the sorption of metal ions, particularly the cupric ion, by native cellulose. They suggest that the ions are adsorbed to form a regular two-dimensional lattice on the surfaces of microfibrils by complex formation with hydroxyl groups of the cellulose molecules. Should this be so, copper sorption might give information relating to the surface area of the crystalline fraction in cellulose, and, with such a possibility in view, it was considered worth while to make a further study of the interaction of cellulose with the cupric ion.

Preliminary experiments confirmed that beech α-cellulose[3] and bleached cotton thread do in fact take up copper from copper sulphate solution, but the extent of sorption by the α-cellulose (namely, 0·9 m.mole copper per 100 gm.) was found to be lower than that reported by Belford, Myers and Preston[1] for similar material by a factor of five. In seeking an explanation for this discrepancy, the possibility was considered that acidic groups within the cellulose molecule might be responsible for the uptake of copper, variation in acid content resulting in varying sorption of copper: as a result of further investigation, it now seems reasonably certain that this is the case.

Experiments were carried out on de-waxed, scoured Egyptian cotton, two samples of periodate–chlorite oxycellulose[4], and two samples of nitrogen dioxide oxycellulose[5] prepared from cotton; also studied were 'Tenasco Super 70', 'Viscose Rayon' and 'Fortisan *H*'. Specimens (about 0·5 gm.) were immersed for at least 15 min. in filtered 0·1 *M* copper sulphate solution (100 ml.). The *p*H of the medium was determined before and after immersion of the cellulose samples; in every case immersion was followed by a fall in *p*H of 0·01–0·7 unit (increasing with uptake of copper). Bound copper was removed from the thoroughly washed material in three extractions with 0·1 *N* hydrochloric acid and determined by the standard iodimetric method, using 0·005 *N* sodium thiosulphate. The cellulose specimens were then washed until free from acid and the carboxyl content determined by the alkali back-titration method of Neale and Stringfellow[4,6] using 0·01 *N* hydrochloric acid. Duplicate determinations were made in every case.

Fig. 1 shows that uptake of copper is proportional to the carboxyl content. This would appear convincing evidence that sorption of copper in these experiments is due solely to the presence of carboxylic acid groups in the cellulose molecule: sulphonic acid groups, which might occur in α-cellulose isolated from wood, would presumably act in the same way.

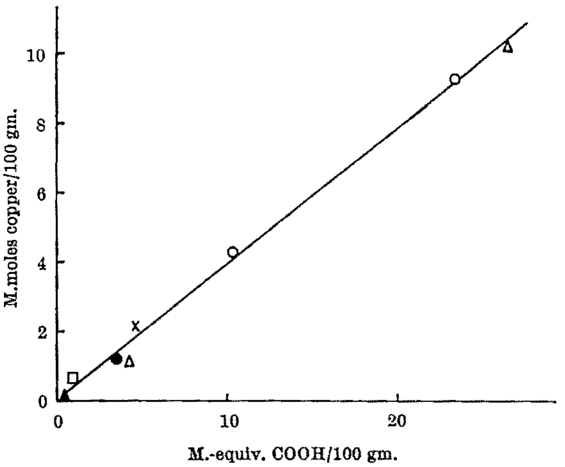

Fig. 1. ▲, Cotton; ○, periodate-chlorite oxycellulose; △, NO_2-oxycellulose; ●, 'Tenasco'; ×, 'Viscose'; □, 'Fortisan'

Further evidence that uptake of copper by cellulose is not due to the acidic action of hydroxyl groups was obtained by dissolving 5 gm. of α-methyl-D-glucopyranoside in 100 ml. of 0·1 *M* copper sulphate solution. The *p*H remained unchanged, establishing the absence of any reaction liberating hydrogen ions comparable with that occurring when cellulose takes up copper.

In attempting to interpret the results quantitatively, two apparently conflicting observations must be taken into account: (1) uptake of copper by a beech α-cellulose from 0·1 *M* copper acetate was approximately double that from 0·1 *M* copper sulphate solution[1]; (2) sorption from copper sulphate is governed by a Langmuir isotherm, maximum uptake being virtually attained with 0·1 *M* solution[1]. This would normally be taken to imply that at such concentration all the active sites are occupied.

A possible explanation for the apparent anomaly is forthcoming from a consideration of the equilibria involved, with the simplifying assumption that the system can be treated as one phase. Thus, if K_a is the acid dissociation constant of the carboxyl groups, K_s the dissociation constant of the copper salt ($=[RCOO^-][Cu^{2+}]/[RCOOCu^+]$) and C the total carboxyl content ($=[RCOOH] + [RCOO^-] + [RCOOCu^+]$), it can be shown that:

$$\frac{C}{[RCOOCu^+]} = \frac{K_s}{[Cu^{2+}]} + \frac{K_s[H^+]}{K_a[Cu^{2+}]} + 1 \qquad (1)$$

This would lead to a linear relation between reciprocal copper uptake and reciprocal copper concentration, with a limiting uptake at high copper concentration equal to half the theoretical maximum (that is, equal to half the carboxyl content) if the term $K_s[H^+]/K_a\,[Cu^{2+}]$ were constant and equal to unity. In fact, *p*H measurements on solutions of copper sulphate in the concentration-range 0·005–0·1 *M* have shown that the hydrogen ion activity is approximately proportional to the copper concentration, particularly in the region of higher concentration where more accurate sorption determinations are possible. If the constants K_s and K_a are given respectively the values of approximately 10^{-2} and 10^{-5} (as would appear not inconsistent with published results[6,7]), equation (1) predicts the observed sorption isotherm and also predicts about a two-fold increase in uptake of copper if the hydrogen ion concentration is decreased by a factor of 10 or more, as is the case in passing from 0·1 *M* copper sulphate to 0·1 *M* copper acetate (namely, sulphate *p*H 4·2, acetate *p*H 5·4). The system is obviously more complicated than depicted here, but it seems reasonable to suppose that the foregoing interpretation of the facts is essentially correct.

To sum up, therefore, the evidence now available makes it appear most probable that sorption of copper from solution by cellulose is due entirely to the action of acidic groups in, or associated with, the cellulose molecules. From this it follows that measurements of sorption of copper cannot be expected to yield any information necessarily related to the physical structure of the cellulose.

I am indebted to Dr. T. P. Nevell, of the Shirley Institute, for providing the specimens of oxycellulose used in this investigation. The work forms part of the programme of fundamental research undertaken by the Council of the British Rayon Research Association.

[7] *Stability Constants of Metal Ion Complexes*, by Bjerrum, Schwarzenbach and Sillén. Special Publication No. 6, Part 1, p. 3 (Chemical Society, London, 1957).

I am not completely certain that Dr. Michie is discussing quite the same problem as that investigated by my co-workers and me. Although we used the term 'copper-cellulose complex' in some of our papers, we were consciously using the term 'cellulose' as defined by two of us in another connexion[1] as a family of polysaccharides built into microfibrils of a substance which, by virtue of the extraction procedure by which it is obtained and of certain physical properties, is normally called cellulose; we were therefore not discussing those rare products—which we term 'eucellulose'[1]—which yield glucose only on hydrolysis.

In collaboration with Mr. Dennis, I am following up our earlier work on what should be called a 'copper-microfibril' complex. Our results and conclusions will eventually be published *in extenso* elsewhere; at the moment we can say only that the bulk of the uptake of copper is not by the 'pure' cellulose component but by pentosans so firmly bound to the microfibril that they withstand the chemical procedures normally used for the extraction of α-cellulose. It is complexes with these, moreover, which give the sharp electron diffraction diagrams. We are ourselves not certain that copper adsorbed on 'pure' cellulose yields such a diagram; certainly none has been obtained with *Valonia* cellulose in spite of a measurable uptake of copper.

On the point of adsorption in 'pure' cellulose, Dr. Michie may well be correct for the materials and conditions he uses, though his interpretation rests on the straight-line relationship between uptake of copper and the so-called $-COO^-$ content of the cellulose as determined by a method which itself depends on cation adsorption. The difference between the cotton used by him and by us was that, whereas our cotton had been treated with strong alkali in the cold, his had been scoured (that is, boiled in 1 per cent sodium hydroxide). We have reason to believe that the effect of scouring is complex, but we cannot report on this at the moment.

The Borohydride Ion in the Lithium Borohydride Lattice

In a recent communication in *Nature*, Dr. C. J. H. Schutte[1] has suggested that the anomalous band occurring at about 1,250 cm.⁻¹ in the paraffin-oil mull spectrum of lithium borohydride at room temperature[2] may be assigned to the doubly degenerate frequency, $\bar{\nu}_2(E)$, of the tetrahedral BH_4^- ion. This frequency is normally inactive in the infra-red, but it is suggested that under the space-group V_h of crystalline, orthorhombic lithium borohydride, the BH_4^- ions occupy sites of symmetry C_s; the degeneracy is thereby removed so that all the fundamentals are now allowed.

I suggest that confirmation of the above assignment is provided by a previous calculation of some of the vibration frequencies of the tetrahedral hydride ions[3]. The calculation was based on a theoretical discussion of the dynamics of binary hydrides[4], in which it was shown that, with the assumption of a spherical and rigid electron distribution in the molecule, the doubly degenerate frequency, $\bar{\nu}_2(E)$, of a tetrahedral XH_4 molecule (or ion) could be determined to within 5 per cent by the formula:

$$4\pi^2\bar{\nu}_2^{\,2} = 9(6)^{1/2}e^2/32\ mr_0^{\,3}$$

where e and m are the charge and mass of the proton and r_0 is the equilibrium XH distance. With the value of the B-H distance obtained from proton magnetic resonance measurements on the BH_4^- ion[5], namely 1·25 Å., the above formula gave a calculated frequency of 1,171 cm.⁻¹ (±59 cm.⁻¹) for $\bar{\nu}_2$. This value, therefore, gives good support to the above assignment of Schutte and is also in good agreement with the value of 1,210 cm.⁻¹ obtained[6] from measurements of the Raman spectra of solutions of the borohydride ion in liquid ammonia.

ALTHOUGH the comments of Dr. Brown on my communication are very encouraging for further theoretical investigations, it should be pointed out that the equation used by Brown to calculate the doubly degenerate $\nu_2(E)$ vibration of the BH_4^- ion was derived for a tetrahedral ion or molecule which has a spherical and rigid electron distribution. This assumption is certainly not valid in the case of the BH_4^- ion in the $LiBH_4$ lattice. In this lattice the tetrahedral ion is considerably deformed, having the site symmetry C_s. In addition, it must be pointed out that the crystalline field in which any ion is embedded has a profound influence on the frequencies of vibrational modes (see, for example, refs. 1 and 2). The frequency of ν_2, calculated according to the formula derived by Brown, is that of the free tetrahedral BH_4^- ion and can only be compared, for example, with the Raman frequencies of BH_4^- in liquid ammonia.

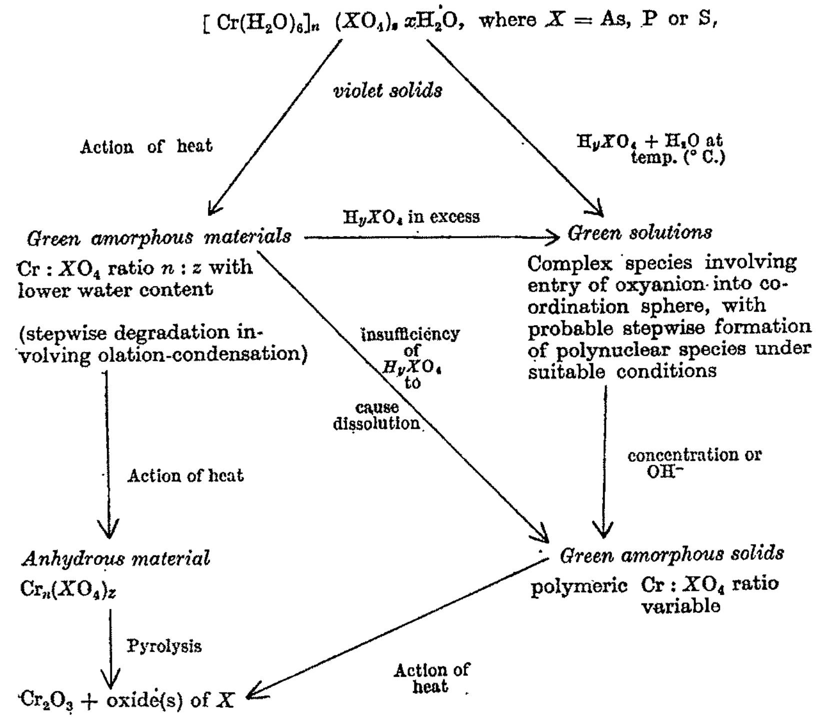
Chromium(III) – Oxyanion Systems

CERTAIN hexaquochromium(III) oxyanion compounds (in particular, the phosphate, arsenate and sulphate) have shown marked similarities in their behaviour on thermal degradation and in solutions with their corresponding oxyacids. This behaviour can best be explained on the basis of olation-condensation reactions which are believed to occur both in the solid state and in solution.

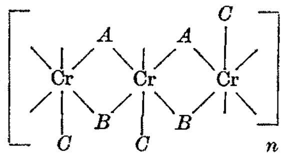
The behaviour may be represented schematically :



$[Cr(H_2O)_6]_n\ (XO_4)_z\ xH_2O$, where X = As, P or S,
violet solids
Action of heat
$H_yXO_4 + H_2O$ at temp. (° C.)
H_yXO_4 in excess
Green amorphous materials
Cr : XO_4 ratio $n : z$ with lower water content
(stepwise degradation involving olation-condensation)
Green solutions
Complex species involving entry of oxyanion into co-ordination sphere, with probable stepwise formation of polynuclear species under suitable conditions
insufficiency of H_yXO_4 to cause dissolution
Action of heat
concentration or OH^-
Anhydrous material
$Cr_n(XO_4)_z$
Green amorphous solids
polymeric Cr : XO_4 ratio variable
Pyrolysis
Action of heat
Cr_2O_3 + oxide(s) of X

Work on the solution and solid phases of the systems: Cr_2O_3–P_2O_5–H_2O at 0°, 40°[1], and 70°[2], Cr_2O_3–As_2O_5–H_2O at 25°[3] has already been reported. The system Cr_2O_3–SO_3–H_2O is being studied at 25° and 70°.

Thermogravimetric studies of hexaquochromium(III) phosphate, arsenate and sulphate indicate that the dehydration process is complex. Inflexions in curves of the loss in weight against temperature are interpreted as stages in a process of olation-condensation occurring in the solid phase, which is initiated by the entry of the oxyanion into the chromium(III) co-ordination sphere. Such a process is expected to result in the formation of cross-linked polymers incorporating groupings of the type :



Where $A = HXO_4^{a-}$, $B = OH^-$ or HXO_4^{a-} or no linkage, and $C = HXO_4^{a-}$, $H_2XO^{(a-1)-}$, or H_2O.

This type of structure accounts for the ion-exchange properties encountered in these systems[2,3]. X-ray studies have shown that the products of dehydration of these hexaquochromium(III) salts are amorphous and possess no long-range order. This might be accounted for by a random arrangement of the bridging groups. However, recrystallization occurs in these materials prior to complete dehydration to the phase $Cr_n(XO_4)_z$.

The kinetics of thermal decomposition have been studied by the method developed by Freeman and Carroll[4]. The results are presented in Tables 1–3, together with supporting evidence obtained from preliminary differential thermal analysis.

Infra-red studies of the products of progressive dehydration show that the characteristic absorption bands associated with water in the complex are initially extremely broad due to the effect of hydrogen bonding. In the course of the dehydration this band (3,750–2,100 cm.$^{-1}$) becomes modified in length and intensity, shortening occurring in the 3,750–3,100 cm.$^{-1}$ region. Finally the band disappears on complete dehydration (together with that due to the bending vibrations (~1,600 cm.$^{-1}$)). The characteristic bands of the oxyanion undergo broadening and splitting in the course of dehydration—implying a lowering of T_d symmetry, which might be expected if the formation of HXO_4-groups were involved. Magnetic studies on the arsenate have shown that the compound obeys the Curie–Weiss law down to liquid-nitrogen temperatures and has a very small value of the Weiss constant θ. Progressive dehydration of this material

does not show any departure from the linear law, although a progressive increase in θ is observed, a value of ~30° K. being obtained for $CrAsO_4\frac{1}{2}H_2O$. Such behaviour would seem to indicate the absence of —O—links in the polymeric compounds[5].

Assurance of Thermostatic Control during Electrophoretic Experiments

Precise thermostatic control is of paramount importance if absolute electrophoretic mobilities are to be measured. Moreover, recently proposed supporting media in the form of gels (starch gel and cyanogum gel) introduce an additional need for constant temperature since the diameters of the gel pores (a factor largely determining migration in those media) depends on thermal agitation of the pore-forming bridges[1].

Generally, electrophoresis in a supporting medium is conducted without positive control of temperature. At best, the medium is placed in a container maintained at constant temperature (for example, an ice chest) and the temperature gradient existing between the room and the medium is kept within reasonable limits by using small field strengths and low ionicities. Another method is that of using a cooling fluid circulating in rather close contact with the electrophoretic medium. Yet in all those methods it is the temperature of the cooling medium that is directly controlled and not that of the electrophoretic medium itself.

This could, nevertheless, easily be achieved if use were made of the following property: since the medium used for electrophoresis has nearly always electrolytic conductivity, it possesses a rather large (negative) temperature coefficient. Thus the resistance of the medium could be used as a temperature-sensing element. Resistance variations can easily be converted into voltage variations if the electric field is established from a power supply regulating for constant intensity. Indeed, if the temperature of the electrophoretic medium rises, its resistance decreases, and to maintain a constant current intensity, the voltage at the electrodes will automatically be reduced. This decrease in voltage can be made to

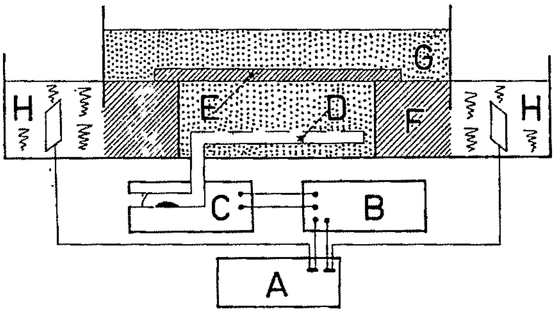

Fig. 1. Diagram of the apparatus for conducting high-voltage agar-gel electrophoresis at constant temperature. *A*, Electric power supply regulating for constant intensity; *B*, amplifier that closes a relay if the voltage at *A* decreases; *C*, air pump switched on by relay in *B*; *D*, tube provided with small holes for blowing air in *G*; *E*, electrophoresis plate; *F*, agar gel; *G*, petroleum ether; *H*, electrode vessels

close a relay, switching on some cooling device. The temperature will go down again and the voltage will rise to its initial value. At that moment active cooling will be cut out. In fact, electrophoresis is then conducted at (nearly) constant intensity and voltage.

Very effective cooling, giving the additional advantage of sealing the electrophoretic medium against evaporation, is obtained by bathing that medium in a neutral, volatile fluid : if its evaporation is activated, the heat generated in the electrolyte is absorbed. Evaporation of the volatile fluid is easily controlled by blowing finely dispersed air through it ; this makes at the same time for effective stirring.

These principles[2] have been applied to a technique of agar-gel electrophoresis described some time ago[3]. The experimental apparatus is illustrated in Fig. 1. The electrophoresis plate is bathed in petroleum ether of low boiling point (25–50° C.). A small air pump blows air through a tube provided at its distal end with small holes. If the temperature of the electrophoresis plate tends to rise, the pump starts blowing air until the temperature in the plate has reverted to its initial value. In an actual experiment effected at a field-strength of 30 V./cm. (agar 1 per cent in barbital buffer of *p*H 8·4 and ionicity 0·05) and conducted at 12° C., the temperature variations in the plate were found to be less than 1° C., with the pump acting in short cycles at a frequency of 8/min. With this method any temperature between +4° C. and 25° C. can be set by activating the evaporation of the petroleum ether prior to the experiment, until the fluid is at the desired temperature. The plate is then left for a few minutes to reach temperature equilibrium. The electric field is then applied and the temperature in the plate will automatically be maintained at a constant value.

Separations, already of outstanding quality when agar gel is used, are even better if the separation is effected at low temperature (+4° C.), since diffusion is then strongly checked while the decrease in mobility can be compensated for by increasing the electric field strength. Application of the principles here exposed to other types of electrophoresis, for example to the column type, could be fruitful.

BIOCHEMISTRY

Quinine Oxidase in Liver and Blood Plasma of Rabbits poisoned with Carbon Tetrachloride

RABBIT liver has been shown to be a rich source of quinine oxidase[1,2]. The enzyme was also demonstrated in other organs of the rabbit but in much smaller amount (spleen, lungs) ; none was found in the pancreas, heart, kidney and skeletal muscles[2]. In normal human blood, quinine oxidase is present in negligible amounts. However, in cases of parenchymatous lesions of the liver, increased amounts could be detected in the blood. Therefore, the determination of this enzyme has been recommended by Baier[3] and by Roman and Dulmanis[4] as a test for liver damage.

Since carbon tetrachloride is regarded as a strong hepatotoxic agent, I decided to investigate its effect on quinine oxidase of the liver and blood plasma.

Quinine oxidase was determined using a method previously worked out and based on the reduction of the dye triphenyltetrazolium chloride in evacuated Thunberg tubes, the substrate being N′-methylnicotinamide[5]. The formazan produced after the incubation of the reaction mixture for 15 min. at 37° C. was extracted with petroleum ether and the colour measured in a Beckman quartz spectrophotometer at 480 mμ. N′-methylnicotinamide (7 × 10^{-3} *M*) was used instead of quinine hydrochloride since Knox[1] and also Lang and Keuer[1] demonstrated that this compound is the natural substrate for the enzyme. Blood plasma quinine oxidase was also measured by the increase in the absorption at 366 mμ of the carbostiryl oxidation product of quinine, using Baier's method[3,6]. Heparinized plasma was used throughout.

The enzyme could not be detected in the blood plasma of normal rabbits by the formazan reagent or by Baier's methods. It was, however, soon verified that a few hours after the injection of carbon tetrachloride the enzyme decreases in liver and appears in the blood. Table 1 summarizes this result.

Table 1. EFFECT OF INJECTED CARBON TETRACHLORIDE ON THE LIVER AND BLOOD PLASMA OF THE RABBIT

Conditions	No. of rabbits	Averages and standard deviations. Liver (μgm. formazan/gm. wet weight)	
			Blood plasma (Baier units)
Normal	10	21·5 ± 3·4	0
Carbon tetrachloride	10	9·2 ± 5·7	138 ± 42

Rabbits were dosed with carbon tetrachloride, 0·05 ml./100 gm. body-weight intraperitoneally and killed after 12 hr. Baier unit – increase of 0·001 in optical density at 366 mμ.

Some experiments were also performed to find the time of appearance and the level of this enzyme in blood plasma during the course of poisoning. A group of four rabbits weighing 600–920 gm. were injected intraperitoneally with 0·05 ml. of carbon tetrachloride/100 gm. body-weight and the blood withdrawn by heart puncture and analysed 3, 5 and 10 hr. after the injection. Four other animals were bled after 15 and 20 hr. Fig. 1 shows the average increase up to 20 hr.

Blood plasma of poisoned rabbits was saturated with ammonium sulphate solution (v/v) to find which fraction carries the enzyme. The protein precipitate was separated, dissolved in distilled water made slightly alkaline (*p*H 7·2) and dialysed in 'Cellophane' bags against distilled water at 4° C. The enzyme

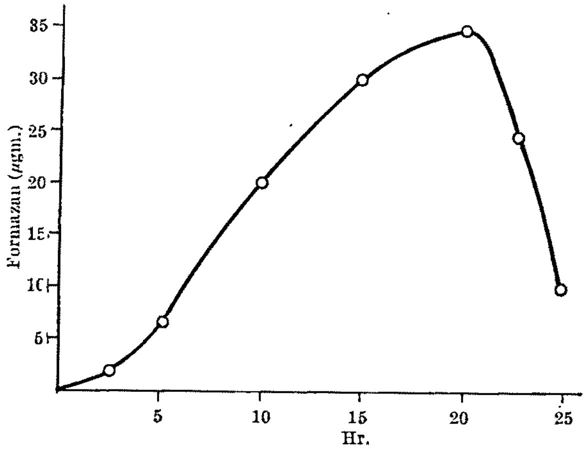

Fig. 1. Increase of plasma quinine oxidase in rabbits treated with carbon tetrachloride. Values expressed in μgm. formazan/1 ml. of plasma

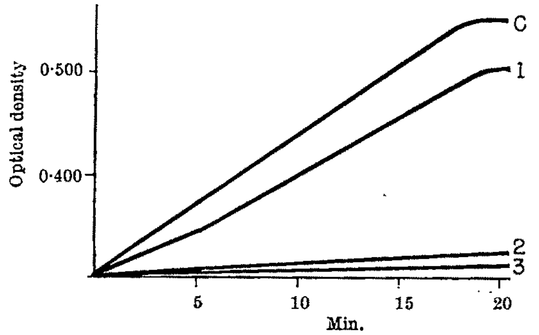

Fig. 2. Kinetics of the oxidation of quinine chloride. *C*, controls. 1, *p*-chloromercuribenzoate, 1×10^{-3} *M*. 2, crotonaldehyde, 7×10^{-3} *M*. 3, 0·1 ml. menadione, 0·4 *M*

activity was found only in the globulin fraction. A typical experiment is reproduced in Table 2.

Neither normal rats nor rats treated with carbon tetrachloride showed any quinine oxidase activity in the blood plasma. This suggests that in the rat the enzyme is not easily removed from the liver cells as in the rabbit. It appears, therefore, that this enzyme behaves differently from xanthine oxidase, which increases rapidly in the liver and blood of rats treated with carbon tetrachloride as previously reported by us[7]. It must be remembered that the liver of the rabbit is poor in xanthine oxidase and the blood is devoid of it. The localization in the liver cells of the rat and the association of this enzyme with lipids[8] may be responsible for the differences observed between their behaviour in carbon tetrachloride poisoning.

Liver quinine oxidase was inhibited by crotonaldehyde, *o*-iodobenzoic acid and 2-methyl-1,4-naphthoquinone(menadione), slightly inhibited by *p*-chloromercuribenzoate and not affected by 2-amino-4-hydroxy-6-pteridine aldehyde (Table 3). The kinetics of the oxidation of quinine chloride were followed in plasma by the increase in optical density at 366 mμ in the presence of *p*-chloromercuribenzoate, crotonaldehyde and menadione.

Table 2. Quinine Oxidase in Blood Fractions

	Activity*
Control plasma	150
Globulin fraction (corrected to the initial volume)	147
Albumin fraction	0

* Activity in μgm. formazan/100 ml. blood plasma.

Table 3. Effect of Inhibitors on the Quinine Oxidase of Cell-free Liver Homogenate

Inhibitors	Formazan produced (μgm.)	Inhibition (per cent)
Controls	30·8	—
6-Pteridyl aldehyde (30 μgm.)	30·0	0·9
p-Chloromercuribenzoate, 1×10^{-3} *M*	26·0	16
o-Iodosobenzoic acid, 2×10^{-3} *M*	13·0	58
Crotonaldehyde, 1×10^{-3} *M*	12·1	61
Menadione, 2×10^{-2} *M*	0	100

Liver homogenate 1:1 in phosphate buffer *p*H 7·4. Centrifuged 30 min. at 3,500 r.p.m. Total volume of the reaction mixture in the Thunberg tube, 2 ml. (ref. 5).

These results indicate that quinine oxidase is partly dependent to SH— groups for full activity. Work is now in progress to investigate the effect of other inhibitors.

Isolation of the Toxic Principle in *Acacia georginae*

Serious losses in livestock, apparently due to poisoning by natural fodder, have occurred in the Georgina River watershed since early settlement. These occur over an area of approximately 14,000 square miles of north-western Queensland and over an equally large area of the adjoining Northern Territory. *Acacia georginae* is widely distributed throughout the affected areas, and its pods, seeds and leaves have proved toxic to sheep and cattle[1,2].

The isolation and identification of the toxic principle in the seeds of *A. georginae* is now reported. Previous investigations[3] showed seeds to contain a complex mixture of carbohydrates, amino-acids and pinitol, but failed to characterize the toxic factor. This has now been identified as the fluoracetate ion.

Seeds were extracted with ethanol and standard procedures used to separate into acidic, basic and neutral fractions. The acid extract was purified by repetitive re-extraction from ether with sodium bicarbonate and finally by fractional distillation of the volatile acids so obtained. The toxic factor was identified as the fluoracetate ion by conversion to the butyl ester and the use of gas chromatography aided by an authentic specimen of butyl fluoracetate. Infra-red absorption spectra confirmed the identification.

Toxicity tests on laboratory animals and on sheep with potassium fluoracetate in quantities comparable with those found in the seeds of *A. georginae* produced identical symptoms.

The occurrence of fluoracetate has been reported in *Dichapetalum cymosum* (*Chailletia cymosa*) in South

Africa[4], this plant being responsible for serious stock losses.

Origin of β-Amino*iso*butyric Acid in Iris

Asen *et al.*[1] have recently added β-amino*iso*butyric acid (BAIB) to the growing list of amino-acids found in higher plants by isolating this compound from the roots of *Iris tingitana* var. Wedgewood. Fink *et al.*[2,3] have shown that BAIB can arise metabolically from thymine via dihydrothymine and β-ureido*iso*butyric acid in the rat. This discovery, taken in conjunction with our recent observation[4] that the higher plant *Brassica napus* (rape) forms radioactive dihydrothymine, β-ureido*iso*butyric acid and carbon dioxide from 2-^{14}C-thymine, strongly suggested to us that, in iris, thymine might well be the source of BAIB. This possibility was tested by supplying totally tritiated thymine to tissue sections of *Iris tingitana* var. Wedgewood.

Small disks (5 mm. diam., 1 mm. thick) were cut from the interior of a freshly dug iris root which had just finished blossoming. The disks (0·3 gm.) were incubated in air, at 28° C., in 1·0 ml. 0·03 *M* phosphate buffer, *p*H 5·0, which contained 5×10^{-3} μmoles of ^{3}H-thymine ($2{\cdot}4 \times 10^{7}$ c.p.m. counted as a weightless sample with a windowless Geiger counter). Following incubation for periods of 2, 4, 6 and 20 hr. the incubation mixtures were homogenized in a Potter–Elvehjem homogenizer with sufficient 75 per cent ethanol to yield a final volume of 5·0 ml. and filtered. The filtrates were taken to dryness in a stream of nitrogen, freed of lipoidal materials by extraction with petroleum ether and dissolved in a small quantity of water. The extracts were chromatographed on Whatman No. 1 filter paper employing solvent No. 5 of Fink *et al.*[3]. The radioactive regions on the developed chromatograms were located with a recording windowless scanning device (Forro radioscanner). In all cases the scanning records revealed the presence of a radioactive area corresponding precisely with authentic BAIB, the presence of which was revealed with ninhydrin. To establish further the identity of the putative BAIB, the radioactive product in question was eluted and portions thereof re-chromatographed on Whatman No. 1 paper, with three additional solvents: solvent No. 1 and No. 2 of Fink *et al.*[3] and *n*-butanol/acetic acid/water, 6 : 1 : 2 (v/v/v), of Asen *et al.*[1]. Correspondence between the radioactive area and the position of authentic unlabelled BAIB was satisfactory.

Still other portions of the eluate were converted to the N-dinitrophenyl derivative by treatment with fluoro-2,4-dinitrobenzene[5]. Since the quantities of the suspected BAIB were too small to yield sufficient dinitrophenyl derivative to be visibly yellow when applied to the paper chromatogram a small quantity of authentic unlabelled BAIB (100 μgm.) was added to the dinitrophenylation reaction mixture. The product was isolated and chromatographed on paper which had been previously treated with phthalate buffer[6]. Development was carried out with water-saturated butanol. On scanning the chromatogram for radioactivity, the dinitrophenyl derivative of the unknown was found to coincide with the yellow dinitrophenyl-BAIB. BAIB was detected in all the incubation experiments.

It is, therefore, reasonable to assume that the breakdown of thymine can account for the presence of BAIB which Asen *et al.* discovered in iris. ^{3}H-thymidine also yielded BAIB under similar conditions although it was a much poorer source than thymine. The thymidine was contaminated with a trace of thymine too slight to account for the BAIB formed. Presumably the free base is liberated from thymidine by a phosphorylase or hydrolase.

It is quite likely that the route to BAIB formation is via the Fink pathway[3], that is, through dihydrothymine and β-ureido*iso*butyric acid, since these two substances were found to be radioactive in the extracts obtained in the above experiments with thymine. These compounds were identified as described elsewhere[4] using slight modifications of the procedures of Fink *et al.*[3]. Still further evidence for the participation of this pathway comes from the observation that when the radioactive thymine was diluted 5,000-fold with unlabelled dihydrothymine (25 μmoles), no radioactive BAIB could be detected after 20 hr. incubation.

This work was supported by the North Central Regional Research Project *NCM*–23.

A Supplement to the Kober Reaction for Urinary Œstrogens

Ittrich[1] has shown that the pink colour given by natural œstrogens in the Kober reaction with sulphuric acid can be extracted by chloroform when the acid is diluted to 20–30 per cent. The colour fades, but can be stabilized somewhat by using a 2 per cent solution of *p*-nitrophenol for extraction. Other workers[2] have preferred tetrachloroethane to chloroform.

The Kober colour could be extracted more readily if dilution were performed with aqueous trichloroacetic acid instead of water, and was then more resistant to fading. Under these conditions, *p*-nitrophenol was not needed. Because of the favourable partition ratio, the colour can be concentrated in a small volume of organic phase, and much of the 'background colour' remains in the diluted sulphuric acid. The extracted Kober colour absorbs maximally at a longer wave-length than in sulphuric acid.

Colorimetric measurement of œstrogen in male and post-menopausal urine is frequently near the limits of sensitivity of the method. Concentration of feeble colours by extraction into chloroform–trichloroacetic acid should enable low levels of œstrogen to be measured spectrophotometrically with greater confidence, and the spectral shift is a check on the authenticity of the Kober colour. It is suggested that the following type of procedure may be valuable as a supplement to the conventional analytical procedures for œstrogen utilizing the Kober reaction[3,4]. For œstrone or its methyl ether: dilute a 3-ml. aliquot of the Kober colour (after reading) with 1·8 ml. of 2 *N* trichloroacetic acid in a pointed centrifuge tube, stopper, mix, cool under the tap, add 1·2 ml. of chloroform, shake for 20 sec , centrifuge briefly, suck off top layer and discard, read the bottom layer in a 1 ml. cuvette at 502, 532, 562 m*M* (508, 538, 568 m*M* for the ether) in a spectrophotometer. This gives an Allen corrected value about three times as great as that derived from measurements on the original Kober colour. The chloroform extract fades about 3 per cent in ½ hr. Tetrachloroethane is objectionably toxic, though an excellent solvent.

I thank Dr. P. B. Hudson, Francis Delafield Hospital, New York, for the opportunity to do this work while a guest in his laboratories.

Controlled Use of Adsorbents in Enzyme Purification

Published methods for the purification of many enzymes specify the use of *C*γ-aluminium hydroxide gel[1] or calcium phosphate gel[2] as adsorbents, and Colowick[3] has reviewed the use of these methods.

The adsorbents may be used (*a*) preferentially to adsorb contaminants from solution or (*b*) preferentially to adsorb the enzyme from solution. These may be regarded as the two gross extremes of (*c*) a graded fractional adsorption, and Ochoa[4] has used all three procedures for the purification of the 'malic' enzyme from different sources.

However, the use of fractional procedures is reported only rarely in the literature, and most authors seem to make use of a technique which superficially resembles (*b*). This procedure is carried out in such a way as to afford little chance for investigating, and thus utilizing, the possibly fine resolving power of the adsorbents. The gel suspension is usually added in one or two large batches to adsorb all the enzyme and, after sedimentation, the gel is washed and eluted.

In this communication the behaviour is reported of two different enzyme preparations on different gels, and evidence is presented of differential adsorption of protein during the procedure. The results emphasize the importance of fractional adsorption in enzyme purification with gels, and indicate that this technique can lead to greater purification than is possible using the popular technique above.

The method requires titration of the enzyme remaining in solution after addition of small batches of adsorbent, and a rapid method for the assay of enzymatic activity is desirable for convenient working.

(1) *Preparation of glucose-6-phosphate dehydrogenase.* This enzyme can be conveniently prepared from dried baker's yeast, but is usually contaminated with hexokinase. In a method used in this laboratory (unpublished), the hexokinase activity is destroyed by mild-heat treatment of a yeast autolysate and nucleic acids are precipitated by protamine sulphate. Some impurities are removed by iso-electric precipitation and the crude enzyme is fractionated with ammonium sulphate. Treatment with *C*γ alumina results in further purification.

Table 1 shows the results obtained in this step by the popular procedure and the fractional method.

Table 1. FRACTIONATION OF GLUCOSE-6-PHOSPHATE DEHYDROGENASE WITH ALUMINA GEL

Method 1:

Enzyme adsorbed from 0·05 *M* acetate buffer *p*H 5·5 with 2·5 ml. of *C*γ alumina (11 mgm. solids/ml.). Gel precipitate collected by centrifugation, washed with 0·05 *M* acetate *p*H 5·5, eluted three times with 0·1 *M* phosphate buffer *p*H 7·4.

Volume of gel added (ml.)	Total units* of enzyme in solution	Total protein† (mgm.)	Specific activity (units/mgm. protein)
0	260	20	13
2·5	31	—	—
Alumina eluate	230	9·7	24

Method 2:

Enzyme solution in 0·05 *M* acetate buffer *p*H 5·5, 29·0 ml. of *C*γ alumina suspension added. Gel precipitate discarded, 30 ml. of *C*γ alumina added to enzyme solution. Gel collected by centrifugation washed and eluted as above.

Volume of gel added (ml.)	Total units* of enzyme in solution	Total protein† (mgm.)	Specific activity (units/mgm. protein)
0	2,430	200	12
29	2,300	—	—
30	36	—	—
Alumina eluate	2,010	34	59

* Determined by the rate of reduction of triphosphopyridine nucleotide ($0{\cdot}2 \times 10^{-3}$ *M*) in the presence of *tris* (hydroxymethyl)-aminomethane buffer (0·03 *M*, *p*H 7·4), magnesium chloride (3×10^{-3} *M*) and glucose-6-phosphate (10^{-3} *M*) in a Beckman *DU* spectrophotometer at 30° C. The unit of dehydrogenase activity is defined as an optical density change of 0·100 per min. at 340 mμ and 30° C.

† Determined by the biuret method (ref. 5).

These results indicate that the fractional procedure gives a superior purification factor in this case. In method 1, the specific activity of the enzyme increases by a factor of about 1·9, while in the second method the increase in the factor is about 5.

(2) *Preparation of uridinediphosphoglucose* (*UDPG*) *dehydrogenase.* This enzyme is prepared from fresh calf-liver by a modification of a method previously applied to acetone powders of liver[6].

Fresh calf-liver is treated in a Waring blender with 0·15 *M* potassium chloride and centrifuged. The supernatant solution is fractionated with ammonium sulphate, heat treated and fractionated again with ammonium sulphate. Calcium phosphate gel is then used in the fractional adsorption procedure.

In this step, the differential adsorption occurs of some other system (of unknown type) which interferes strongly with the assay method for UDPG dehydrogenase. This is demonstrated by the data in Table 2. As more gel suspension is added, the apparent activity of the dehydrogenase in solution rises to a peak value, and then begins to fall. At the peak value

Table 2. FRACTIONAL ADSORPTION OF UDPG-DEHYDROGENASE WITH CALCIUM PHOSPHATE GEL

Adsorption of enzyme from solution in 0·01 *M* phosphate *p*H 6·8

Total volume of gel added (ml.)	Total units* of enzyme in solution
0	12·4
9·0	36·3
18·0	49·5
30·0†	60·2
3·0	50·5
6·0	46·5
21·0	31·5
51·0	0

* Measured by the rate of reduction of diphosphopyridine nucleotide (7×10^{-4} *M*) in presence of glycine buffer (0·15 *M*, *p*H 8·7) and UDPG ($1·5 \times 10^{-4}$ *M*). Micro-cells with total volumes of 0·7 ml. were used in a Beckman *DU* spectrophotometer at 30° C. The unit of enzyme activity is defined as a change in optical density at 340 mμ of 0·100 per min. at 30° C.

† At this point all the added gel was discarded ; 23 per cent of the total protein had disappeared from solution.

in a typical experiment, 23 per cent of the total protein had been adsorbed to the gel.

It can be seen that the fractional procedure brings about removal of an interfering system as previously mentioned, together with a substantial amount of protein. During the latter part of the step, the enzyme is adsorbed to the gel. The gel is washed with 0·01 *M* phosphate *p*H 6·8 and the enzyme eluted with 0·1 *M* phosphate buffer *p*H 7·4. Quantitative recovery of the enzymes (peak values) have been obtained in these experiments.

The results indicate that in procedures for the purification of other enzymes or proteins which involve the use of adsorption-elution techniques, the fractional methods described here may be of considerable value. Such procedures are relatively easy to apply provided that rapid assay methods are available.

The Pasteur Effect in a Respiration-deficient Mutant of Baker's Yeast

THE respiration-deficient mutant of baker's yeast, *Saccharomyces cerevisiae R XII A*, induced by high-temperature cultivation, was used for examining the point of action of oxygen in the Pasteur effect. The mutant was identical with the *petite colonie* mutant described by Ephrussi[1] and Raut[2]. The argument was that, if oxygen acted directly on some enzyme involved in glucose degradation (for example, glyceraldehyde phosphate dehydrogenase), it would decrease the rate of glucose catabolism even in the mutant lacking essential components of the cytochrome system.

It was found that in the presence of glucose there was no demonstrable uptake of oxygen by the suspension and that the Q_{CO_2} (=100–130) was not affected by the introduction of oxygen into the suspension. The uptake of glucose, as measured by quantitative analysis as well as by distribution of radioactivity following application of universally labelled ^{14}C-glucose, revealed no differences between aerobic and anaerobic conditions. As another criterion of the Pasteur effect, the change of inorganic phosphate-level was examined. Here again no change due to oxygen could be observed to take place in the steady-state level in the presence of glucose (Table 1).

Table 1. INORGANIC PHOSPHATE AND LABILE PHOSPHATE LEVELS IN THE RESPIRATION-DEFICIENT MUTANT (μGM. PHOSPHORUS/MGM. DRY WEIGHT ± *S.E.*)

Incubation conditions	Inorganic phosphate	Labile phosphate
No substrate, anaerobically	4·24 ± 0·24	5·84 ± 0·31
No substrate, 10 min. aeration	3·63 ± 0·26	6·39 ± 0·67
5 per cent glucose, anaerobically	2·37 ± 0·23	7·15 ± 0·71
5 per cent glucose, 10 min. aeration	2·40 ± 0·21	7·26 ± 0·75

If these results can be generalized they may serve as a weighty support for the theory that oxygen brings about the Pasteur effect not by affecting directly any enzyme involved in the anaerobic breakdown of glucose but rather by making it possible for other catabolic pathways to function (much in line with Lynen's views[3,4]).

It was observed, however, that under conditions when no substrate was present in the medium, oxygen was effective in producing changes in the amounts or, at any rate, in the distribution of some metabolically active components of the mutant cell. Some of these changes (for example, in the penetration of free glucose into the cell) are dealt with elsewhere[5]. It was found here that oxygen decreased the level of inorganic phosphate in the absence of glucose, with simultaneous production of labile phosphate bonds (Table 1), the process being completely blocked by 10^{-4} *M* potassium cyanide but only partly inhibited (at most by 20 per cent of the steady-state level change) by 5×10^{-4} *M* 2,4-dinitrophenol. The generation of high-energy phosphate bonds was accompanied by only a minute oxygen consumption ($Q_{O_2} = 0·25–0·32$; $Q_{CO_2} = 1·09–1·48$) so that the apparent phosphorus : oxygen ratio reached values far exceeding those commonly reported for whole cells and even for purified enzyme systems. Thus endogenous phosphorylation in the mutant (and very likely in ordinary baker's yeast, ref. 6) appears to be qualitatively different from phosphorylation proceeding with glucose, and produces high-energy bonds at the expense of other energy sources (physicochemical state of proteins, nucleic acids ?) than those involved in oxidative phosphorylation known heretofore.

Detailed results will be published in *Folia microbiologica*.

Is *Mycobacterium phlei* Glutamotransferase endowed with Glutamine Synthetase Activity?

IN a previous paper[1] we reported the finding of glutamotransferase (an enzyme catalysing the transfer of the γ-glutamyl residue of glutamine to hydroxylamine)[2] in cell-free extracts of *M. phlei*. The enzyme required the presence of manganese ions, which could not be substituted by magnesium ions. No glutamine synthetase (an enzyme catalysing the synthesis of glutamine from glutamic acid and ammonia) activity was found in the *M. phlei* preparations, when tested in the presence of magnesium ions under conditions optimal for this enzyme in preparations of bacterial[2], plant[3] and animal[4] origin. The *M. phlei* extracts possessed only traces, if any, of glutaminase activity and did not hydrolyse glutamohydroxamic acid at all. On the other hand, these preparations showed very high asparaginase activity, lacking any aspartotransferase and asparagine synthetase activities. Aspartohydroxamic acid was very strongly hydrolysed by the *M. phlei* extracts; however, this activity was dissociated from asparaginase activity. We have, therefore, concluded that in *M. phlei* the reactions of transfer, synthesis and hydrolysis are due to the action of different enzymes.

IT was reported recently[5] that glutamine synthetase and glutamotransferase of sheep brain were activated by either manganese or magnesium. The *p*H optimum of the manganese activated synthetase was in the acid range (*p*H 4·5), while that of the magnesium reaction was 7·2. Increase of the cation concentration caused a shift to the left of the *p*H optima of the manganese-activated synthetase and transferase. Thus the same enzyme seemed to catalyse both the synthesis and transfer reactions.

In light of these findings, and in view of the fact that the *M. phlei* transferase showed a specific requirement for manganese, it was of interest to see whether this organism also possesses a manganese-dependent synthetase.

Table 1. TESTING FOR GLUTAMINE SYNTHETASE ACTIVITY OF *M. phlei* EXTRACTS WITH EMPHASIS ON CONCENTRATIONS OF MANGANESE, MAGNESIUM AND HYDROGEN IONS

Reaction mixture No.	$MnCl_2$	$MgSO_4$	*p*H
1	$2{\cdot}25 \times 10^{-2}$ *M*	—	4·5
2	$2{\cdot}25 \times 10^{-3}$ *M*	—	5·0
3	$4{\cdot}5 \times 10^{-4}$ *M*	—	5·5
4	$2{\cdot}25 \times 10^{-4}$ *M*	—	6·0
5		$2{\cdot}25 \times 10^{-2}$ *M*	6·0
6		$2{\cdot}25 \times 10^{-2}$ *M*	6·5
7		$2{\cdot}25 \times 10^{-2}$ *M*	7·0
8		$2{\cdot}25 \times 10^{-2}$ *M*	7·5
9		$2{\cdot}25 \times 10^{-2}$ *M*	8·0

The reaction mixture contained: L-glutamic acid, $2{\cdot}25 \times 10^{-2}$ *M*; hydroxylamine sulphate, $1{\cdot}10 \times 10^{-2}$ *M* (calculated as NH_2OH); ATP, $2{\cdot}5 \times 10^{-3}$ *M*; $MnCl_2$ and $MgSO_4$ as indicated; *p*H as indicated; *p*H values below 7·0 were obtained by the use of acetate buffer, 0·1 *M*, while *tris* (hydroxymethyl) aminomethane buffer, 0·05 *M*, was used for *p*H values of 7·0 and above; bacterial extract, 9·1 mgm. protein. Final vol., 2 ml. All solutions added were adjusted to the appropriate *p*H with sodium hydroxide. Experiments were performed in the absence and presence of L-cysteine, 0·04 *M*, which was added before sonication. The mixtures were incubated at 37° for 90 and 180 min.

The experiments were performed with cell-free extracts at various manganese, magnesium and hydrogen-ion concentrations as indicated in Table 1. All the experiments invariably gave negative results: no synthetase activity could be detected under any of these conditions employed. With manganese, but not with magnesium, these extracts showed high glutamotransferase activity as already reported[1]. The results confirm our previous assumption, that the glutamotransferase of *M. phlei* is not associated with any synthetase activity.

PHYSIOLOGY

Flow of Portal and Hepatic Blood in Normal and Cirrhotic Liver

HEPATIC blood-flow measured by the bromsulphthalein method, the colloidal radiogold method, or other methods is the sum of both portal blood-flow and hepatic arterial blood-flow. As to the relative portal and arterial blood-flow, one-third to one-fourth of the total hepatic blood-flow was estimated, in animal experiments, to be derived from the hepatic artery under basal conditions[1]. In some cases with cirrhosis of the liver, in which portocaval shunting operations were performed or portal venous collaterals were accessible, 25–75 per cent or 54 per cent of the total hepatic blood-flow was estimated to be from the hepatic artery[2,3]. It is desirable to develop a new method which enables the actual measurement of the portal blood-flow and the hepatic arterial blood-flow in normal subjects and cirrhotic patients, but there has been no report except that of Ueda[4].

Ueda was the first to describe a method of measuring portal and hepatic arterial flow of blood in clinical cases. His method was based on the fact that the hepatic arterial blood was diluted with the portal blood when the hepatic arterial blood appeared in the hepatic veins, and that a dye concentration curve of the peripheral arterial blood could be a substitute for that of the hepatic arterial blood. Relative portal and arterial flow of blood was calculated from T_{1824} concentration curves of the peripheral arterial blood, and of the hepatic venous blood after the injection of T_{1824} into the cubital vein. The ratio of the hepatic arterial blood-flow to the total hepatic blood-flow was calculated as the ratio of the area of the first (hepatic arterial) component of the hepatic venous concentration curve to that of the peripheral arterial concentration curve.

This method is theoretically attractive. However, it involves a difficulty in the actual measurement. According to our experience, the differentiation between the first (hepatic arterial) component and the second (portal) component in the hepatic venous curve, which is needed for the calculation, is impossible by the original method. Hence, we attempted to improve the method, and were successful in the actual measurement of the portal and hepatic arterial flow of blood by our improved method.

Instead of the original method of injecting a T_{1824} solution into the cubital vein, 50–100 μc. of radioactive iodinated human serum albumin is injected into the pulmonary artery by means of a venous catheter, and blood is taken at successive intervals of 2–3 sec. from the hepatic vein through a hepatic venous catheter and also from an arterial needle placed in the brachial artery. Injection into the pulmonary artery serves to reduce diffusion of the injected material before it reaches the hepatic vein. Radioactive iodinated human serum albumin is used, because a major part of T_{1824} which is not yet bound with serum albumin binds with proteins of liver cells and does not appear in the hepatic vein.

The portal flow of blood (P) and the hepatic arterial flow of blood (A) are calculated from the first half-area of the curve of radioactivity in the brachial artery (a), the first half-area of the first (hepatic arterial) component in the hepatic venous radioactivity curve (h), and the total hepatic blood-flow (T), according to the method of Ueda (Fig. 1).

$$\frac{P}{A} = \frac{a}{h} - 1$$

$$P + A = T$$

The total hepatic flow of blood is determined by the method of Bradley *et al.*[5].

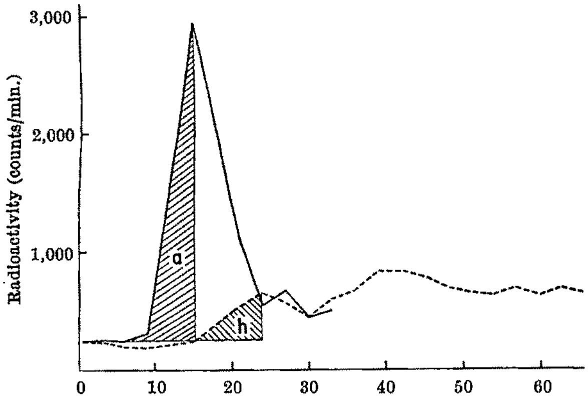

Fig. 1. Radioactivity in blood of a brachial artery (——) and hepatic vein (– – –) in a case with mild cirrhosis of the liver

In five normal subjects the portal flow of blood was 606–915 c.c./min./m.^{2} (66–83 per cent of the total hepatic blood-flow), and the hepatic arterial blood-flow 142–418 c.c./min./m.^{2} (17–34 per cent). In seven cases with cirrhosis of the liver, on the other hand, portal flow of blood was 203–802 c.c./min./m.^{2} (41–79 per cent), and the hepatic arterial blood-flow 179–355 c.c./min./m.^{2} (21–59 per cent).

Thus about one-fourth of the total hepatic flow of blood is derived from the hepatic artery in normal subjects, and the decrease of the total hepatic flow of blood in cirrhosis of the liver is ascribed mainly to the decrease of the portal flow of blood. These results are in agreement with the previous assumption based on the animal experiments and on the results of special cases with cirrhosis of the liver.

Purification of the Toxic Fractions from *Ascaris lumbricoides* and their Effect on the Guinea Pig

Shinamura and Fuji[1], Bier[2] and Rocha e Silva and Graña[3] were able to isolate from *Ascaris lumbricoides* an extract very active in producing an anaphylactic-like shock in guinea pigs and in dogs. On the other hand, Machebouef and Mandoul[4] showed a similar activity in extracts from *Ascaris megalocephala*. Nakajima[5], after heating at 80° C. an aqueous extract of *Ascaris lumbricoides*, purified it by alcoholic precipitation, obtaining an active fraction containing N and P. Recently, Högberg *et al.*[6], using 'Amberlite *IRC*–50' (*XE*–64), obtained a quite active fraction which released histamine from the perfused paw of the cat. The present communication describes the further purification and chemical analysis of the active fractions, and the effect of these fractions on the guinea pig.

Ascaris lumbricoides, collected from hogs, was treated by the method described by Rocha e Silva and Graña[3]. This extract, called fraction SB_1, was further purified by precipitation with ammonium sulphate to saturation at pH 5·2. The supernatant fluid was dialysed against distilled water for 48 hr., and alcohol then added to 95 per cent. The alcoholic precipitate, dissolved in distilled water, was run through a column of hydroxyapatite. The most active fraction was eluted with phosphate buffer, pH 7·5, 0·01 M ; under these conditions the column did not retain the active fraction. Elution with higher ionic strengths gave other protein peaks which contained some activity, and these fractions are still being studied in our laboratory. After dialysis for 48 hr. against distilled water, the active fraction obtained from the column was precipitated by adding alcohol to 95 per cent and dried *in vacuo*. This fraction was named SB_4. The chemical analysis of these two fractions is shown in Table 1. Passing it again through a column of 'Amberlite *IRC*–50' or zone electrophoresis on starch showed only one protein peak.

Table 1. CHEMICAL ANALYSIS OF FRACTIONS SB_1 AND SB_4 FROM *Ascaris lumbricoides*

	Protein (per cent)		Reducing sugars (per cent)*	Nitrogen (per cent)	Phosphorus (per cent)
	(Lowry)	280 mμ/ 260 mμ			
SB_1	27·4	33·3	21·3–23·3	7·7–8·7	1·18
SB_4	7·6	7·7	42	3·4–4·3	1·80

* Measured as glucose

From our results the active fraction of the *Ascaris lumbricoides* seems to be a complex substance containing sugars and protein.

For the biological assay of the *Ascaris* fractions, guinea pigs weighing 200–400 gm. were used. Intravenous injection of the active fractions caused in the majority of the animals an anaphylactic-like reaction. The activity of the fractions was determined by recording the ratio of deaths to survivals in a group of 6 animals, as shown in Table 2. Table 2 also shows an increase in the carbohydrate with a simultaneous decrease in the protein content when the SB_1 is purified.

Histological examination of the lungs of the animals which died in shock showed a reduction of 70–80 per cent in the number of the mast cells when compared with control animals. Furthermore, mast cells damage very similar to that noted by Mota and

Table 2. Relation of Dose (mgm./100 gm.) to Mortality for Guinea Pigs injected with SB_1 and SB_4 Fractions

Ascaris fractions	Total weight (μgm.)	Protein (μgm.)	Residue including glucide (μgm.)	Mortality ratio
SB_1	50 133 200	15 40 60	35 93 140	0/6 3/6 5/6
SB_4	132 264	10 20	122 244	4/6 5/6

Vugman[7] in anaphylaxis was observed. Perfusion of the isolated guinea pig lungs with 20–30 μgm. of SB_4 released histamine ranging from 1·35 to 5·85 μgm. The addition of 1–5 μgm. of the fraction SB_4 to the perfusing bath containing the guinea pig ileum evoked a strong contraction. A second addition of the same dose of SB_4 was either ineffective or produced a smaller effect, followed by a refractory state on further addition of the fraction. These experiments suggest that the ileum was desensitized by the first addition of SB_4. This desensitization was observed in 27 out of 30 different guinea pig ilea tested. Fig. 1 illustrates one of these experiments. On the other hand, when 7 guinea pigs were injected with sub-lethal dose of SB_4, and two days later the ilea were suspended in an organ-bath and tested with SB_4 as described above, none of them showed any response when the *Ascaris* fraction was added to the bath. On the basis of these findings, it is suggested that the guinea pigs are naturally sensitized to *Ascaris lumbricoides*.

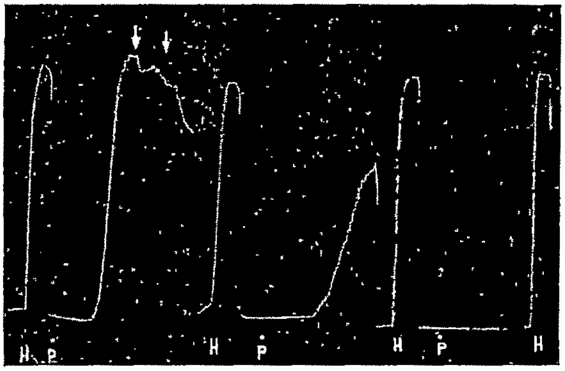

Fig. 1. Guinea pig ileum suspended in 10 ml. atropinized Tyrode solution. Effect of 5 μgm. fraction SB_4 (P) and 0·1 μgm. of histamine (H). The arrows indicate washings with Tyrode solution

Cholinergic Activity of Hyoscyamine

Many former and recent investigations, employing various clinical and experimental tests[1-4], have already revealed the synergic action of small atropine doses with acetylcholine. We were able to demonstrate quite an unexpected experimental correlation between hyoscyamine and cholinergic activity.

Fig. 1 shows an illustrative example of this correlation selected from a lot of thirty similar experiments. The 2 m. recti abdominis of a frog are suspended in Ringer fluid and their motor reactions are recorded on a slow-moving drum, one above the other, with a pair of vertical writing, isotonic levels having a two-fold amplification. The lower muscle only receives every 15 or 30 min. successive geometrically increasing, hyoscyamine concentrations which increase in geometrical progression with ratio 10 starting with C_{20} (C_{20} stands conventionally for $3{\cdot}16 \times 10^{-20}\ M$ and generally C_n for $3{\cdot}16 \times 10^{-n}\ M$; D_n stands for $5{\cdot}62 \times 10^{n}\ M$; 3·16 and 5·62 are the antilogarithms of 0·500 and 0·750 respectively). The first slightly active concentration (mark 7) is C_{14}. The next one gives a contraction of 5 mm., the third one 1·3 mm., the fourth only 0·1 mm. The concentration C_{10} produces no effect (mark 11). The same concentration, C_{10}, is also added to the upper muscle, also with no effect. At mark 12, the two muscles are washed three times and their responses to acetylcholine concentrations C_8 and C_6 tested. Both muscles show normal reactivity.

They are again washed and, after relaxing to their initial length, both receive paraoxon in concentration D_6 at mark 16, to block their acetylcholine esterase. At mark 17, the lower muscle receives again the series of increasing hyoscyamine concentrations, starting with C_{17}. The first contractile reaction arises at C_{15} and the higher concentrations increase the contraction

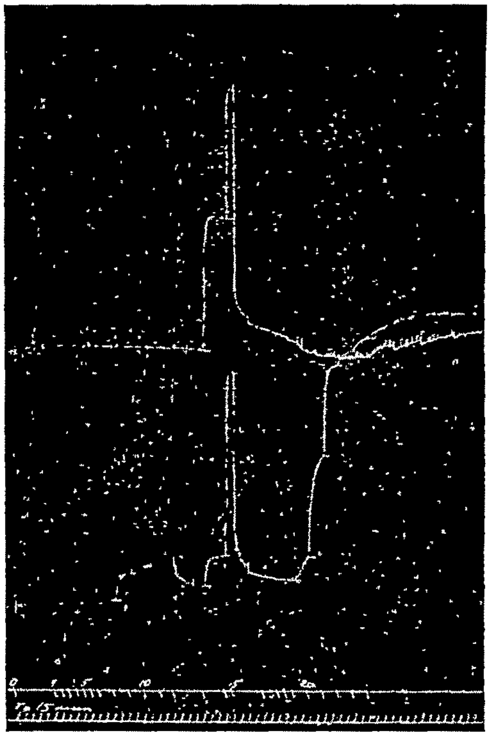

Fig. 1. Cholinergic activity of hyoscyamine

which is maximal at C_{10} (mark 24). At the same mark, the upper muscle receives hyoscyamine C_4 with practically no effect.

In my experiments the lowest active dose of hyoscyamine was C_{17}. It can be seen that hyoscyamine in very low concentrations contracts the frog's rectus, whereas concentrations of ten thousand up to one billion times greater fail to do so.

The amplitude of the maximal contraction produced by hyoscyamine increases by 6–10 times after paraoxon and is generally higher than that elicited by acetylcholine in concentration C_6 on untreated muscle. Concentrations of hyoscyamine, one million to one billion times higher than the threshold ones, are ineffective on treated, as well as on untreated, rectus muscles.

The contractions produced by small hyoscyamine concentrations are relaxed by stronger concentrations of this same alkaloid, by D-tubocurarine, in concentration C_6, and by magnesium chloride of concentration C_3.

These results suggest strongly that hyoscyamine acts on the rectus muscle as a contracting drug through a cholinergic mechanism, possibly by setting free an amount of acetylcholine at the level of its action. The closer pharmacological analysis of the site of this effect, details of which will be published elsewhere, demonstrates that these small concentrations of hyoscyamine act at the level of the neuromuscular junction and not on the contractile substance itself.

Methylatropine and scopolamine have no such effects. Other drugs may also act by releasing acetylcholine through a similar mechanism. I demonstrated it for barium chloride in concentrations between C_5 and C_3 and for neostigmine, in concentrations C_6 and C_5.

Serum Changes in the Rat following Oral Administration of Cadmium

The comparatively sudden and pronounced drop in hæmoglobin-levels and the resultant anæmia following oral administration of low doses of cadmium to rats has been reported by several workers[1–4]. Starch-gel electrophoresis was performed on the serum proteins of rats similarly dosed, using the apparatus described by Smithies[5], and a modification of the discontinuous buffer system described by Poulik[6], in which low melting point *tris*(hydroxymethyl)-aminomethane (m.p. 125° C.) was used instead of the usual form (m.p. 171° C.).

Sixteen male rats, Chester Beatty strain, aged three weeks and weighing 80–100 gm., were fed on diet 41*B* and allowed unlimited drinking water, containing 50 p.p.m. of cadmium as cadmium chloride. Blood specimens were taken from the tail at fortnightly intervals by rota, and severe anæmia was confirmed after four weeks. Despite continued oral administration of cadmium for a further three months, the degree of anæmia remained constant. Certain modifications of the normal serum protein pattern were observed after a similar time, but again, despite continued dosing, no further change was observed.

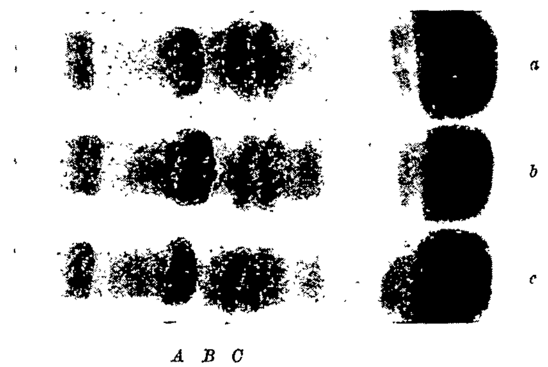

Fig. 1. Starch gel-electrophoresis pattern of the sera of rats given drinking water containing 50 p.p.m. of cadmium as cadmium chloride for four weeks. *a*, Cadmium rat serum; *b*, normal rat serum; *c*, cadmium rat serum. *A*, Unknown; *B* and *C*, transferrin bands

Two abnormalities in the serum protein pattern were seen to occur (Fig. 1). The component at point *A* was considerably diminished in the cadmium-dosed rats, compared with the control rats. The components at points *B* and *C* were noticeably enhanced by comparison with the controls and the possibility that they might be transferrin bands was examined, using the method of Giblett, Hickman and Smithies[7]. 1 μc. of radioactive iron-59 (as ferric chloride) was added to 0·2 ml. of normal rat serum and the specimen was subjected to starch-gel electrophoresis as before. The gel was sliced into two wafers, one slice being stained with a saturated solution of naphthalene black 10*B* 200 in methanol/water/glacial acetic acid (5:5:1) and the other slice, sealed in 'Saran Wrap', was placed in contact with Kodak 'No Screen' X-ray film for 12 hr., followed by development for 3 min. in Kodak *D*8 developer. Comparison of the stained gel and the final X-ray film showed that bands *B* and *C* had bound the radioactive iron exclusively. The result was confirmed by sectioning the starch block into the various bands, digesting the sections in 50 per cent nitric acid containing added carrier iron, and finally assaying the activity using an *M*6*H* liquid counter.

Benzidene staining of the gel revealed the presence of hæmoglobin in the space between the bands *A* and *B*, and further investigation indicated a 'ghost' band in this area, which was apparently the component which reacted positively to the stain.

Estimations of the copper oxidase-levels of the sera by the method of Ravlin[8] indicated no significant difference between the cadmium-dosed rats and the controls.

Absorption of Amniotic Fluid in the Gut of Fœtal Sheep

SWALLOWING movements are known to be made by the fœtus *in utero*, but the ability of the gut to absorb material from the amniotic fluid has received little attention. This latter aspect has been investigated in fœtal sheep over the age-range 80–145 days (full term).

Under spinal anæsthesia and sedation with sodium thiopentone the fœtus was exposed by Cæsarian section and its abdomen opened. Electrical potential differences were measured between gut contents and fœtal extracellular fluid at various levels, using a Vibron 33*B* electrometer, calomel electrodes and 3 *M* potassium chloride in agar salt bridges. Representative segments of the gut were used to study the absorption of amniotic fluid to which polyethyas a glycol, mol. wt. 3,300–4,000, was added to serve lene volume marker[1]. The segments used were abomasum, jejunum, ileum and colon; approximately 8 cm. lengths of these latter three segments were used. Each segment, isolated by ligation, with intact blood supply, was flushed and filled with the labelled amniotic fluid and then left unexposed for 1–3 hr. The initial volume was calculated from the final weight of the contents and the change in concentrations of polyethylene glycol.

All significant potential differences (greater than ± 3 mV.) showed the gut lumen to be electrically negative with respect to the fœtal extracellular fluid at all ages studied. The abomasal potential difference was 14 mV. at 80 days, 21 mV. at 107 days and 26–30 mV. after 120 days. The potential difference across the small intestine was close to zero prior to 120 days, after which values of 4–10 mV. were obtained. The potential difference across the colon was close to zero at 80 days. From 120 days the transcolon potential-difference was 4–24 mV. These values may be compared with those obtained in the adult which were of the same sign: abomasum 40 mV., small intestine 10–14 mV., colon 15 mV.

Control experiments on single segments showed that the recovery of polyethylene glycol using a turbidimetric method[2] was of the order of 60–80 per cent over the experimental period. Calculations based on an assumed recovery of 60 per cent showed a net absorption of water, sodium and fructose from all segments at all ages studied. The amount of water absorbed from any segment was greater than could be accounted for by the hypotonicity[3] of the amniotic fluid. Sodium absorption occurred against a gradient of concentration and electrical potential. Absorption of fructose took place down a concentration gradient (140–500 mgm./100 ml. in amniotic fluid, 80–120 mgm./100 ml. in fœtal plasma), the fructose concentration in the gut decreasing. The results obtained for water absorption were extrapolated to the whole gut. From this it was computed that the 100–110 day fœtus absorbed fluid at a rate of 120 ml. per day. At 120 days this was about one litre, falling to 500 ml./day at term. The total volume of fluid absorbed from 80 days to term is about 32 litres, which is of the same order of magnitude as the volume of urine produced during this time (about 40 litres[4]). At 100 days fructose absorption occurred such that 6·7–10·7 per cent of the fructose introduced into the small intestine was absorbed in 1 hr., 12·6 per cent/hr. being absorbed from the colon. At 107 days the rate of fructose absorption was 9·0 per cent/hr. from the abomasum, 26–40 per cent/hr. from the small intestine and 46–47 per cent/hr. from the colon.

The results suggest that absorptive powers of the gut are retained in this species from at least 80 days. The gut is capable of absorbing a considerable volume of amniotic fluid with active sodium absorption probably accounting for much of the water absorption. Fructose absorption occurs at a high rate, and this may be of some nutritional significance to the fœtus. The fœtal abomasum appears to bear a functional similarity to the stomach of the fœtal rabbit in its capacity to absorb sodium actively[5].

This work was aided by an M.R.C. grant to Prof. A. St. G. Huggett and a grant to one of us (G. H. W.) from the Central Research Fund, University of London. We thank the Shell Chemical Co., Ltd., for donating the polyethylene glycol.

Spontaneous Potentials from Explants of Chick Cerebral Hemisphere (Telencephalon) in Tissue Culture

USING techniques and supernatant similar to those used to demonstrate spontaneous potentials from explants of chick embryo cerebellum in tissue culture in Kahn tubes[1], spontaneous potentials have been demonstrated in explants from the telencephalon of 11-day chick embryo brain. The explants were thin slices of the full thickness of the lateral aspect of the telencephalon. The control used was dead chick cerebellum tissue (explanted into a Kahn tube in the same manner as the telencephalic tissue and then killed by heat). The Kahn tube containing the control tissue was placed side by side with the living culture material in the same incubator with identical amplification and recording apparatus. The living brain tissue gave the same form and magnitude of potentials on every recording channel which was tried; whereas the control tissues gave no potentials on any channel.

The form of the potentials are shown in Fig. 1 (26 hr. in culture). The typical activity is a combination of series of spikes of varying complexity. The simplest of these spike potentials arises sharply from the background and has a relatively uncomplicated form and an amplitude of between 20 and 30 μV. The time-interval between them varies somewhat but many recur at nearly 16½ sec. intervals. A second and more complex form is seen to occur almost independently of this first type and consists of a group of smaller potentials having amplitudes between 10 and 15 μV. Each group lasts about 7 sec. and they are about 2 min. apart. This behaviour is unlike the behaviour of spontaneous potentials already reported from explants of cerebellum and medulla oblongata[1,2], but has some similarity to that reported from explants of human cerebellum[3]. The explant continued to show this type of spontaneous electrical potentials until

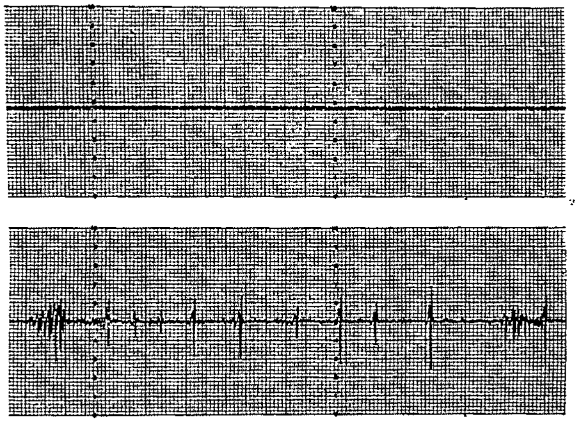

Fig. 1. Lower trace. Spontaneous potentials from an explant of 11-day chick telencephalon 26 hr. after explantation. Vertical lines, ½ sec. apart. Amplitude scale, distance between two horizontal lines equals 1½ μV. The photograph embraces one of the groups of potentials described in the text. Potentials at right-hand side of trace occurred before those at left-hand side. Upper trace. Control of dead cerebellar tissue under identical conditions with identical time and amplitude scales

after 72 hr. in culture. No record of spontaneous potentials from foci in the telencephalon in tissue culture has been found in the literature. Further investigations on these potentials are now in progress.

This work was done under a U.S. Navy Contract, *NONR* 1598 (04).

RADIOBIOLOGY

Increase of Aldolase Activity in Blood Serum following Irradiation

Sahasrabudhe, Nerurkar and Baxi[1] have found that 2 hr. after whole-body irradiation with 600 r., the aldolase activity of rat liver and scelet muscle decreased by 25–30 per cent.

Experiments were conducted to investigate whether this decrease of aldolase activity in liver and muscle makes any difference to the aldolase activity of blood serum.

As decrease of aldolase activity in the liver and muscle may influence aldolase activity in serum only after some time has elapsed and, as Albaum[2] described, decrease of aldolase activity in rabbit serum 6 hr. after whole-body irradiation with 750 r., the aldolase activity in the serum of guinea pigs was determined 2, 4, and 6 hr. after irradiation with 500 r. (Siemens Stabilivolt apparatus, 180 kV., 10 m.amp., 0·5 copper, 50 cm. distance without a tube, 36·3 r./min. dose-rate). The determinations were undertaken only in serum—in some cases in plasma—samples without any visible sign of hæmolysis by the method of Tovarnicky and Voluyskaya[3] modified by Ananyev and Obouchova[4] using a Unicam *SP.* 500 spectrophotometer. Blood was withdrawn from the heart to avoid any admixture of tissue fluids.

The aldolase activity in the serum of 29 healthy guinea pigs was found to be 34·1 units (ranging from 22·7 to 45·0). In the plasma of 20 healthy animals it was found to be 33·1 units (ranging from 23·7 to 45·1).

The aldolase activity of serum samples 2. 4 and 6 hr. after irradiation was determined in the serum fo 44, 21 and 22 animals. It was stated that the activity reached its maximum 4 hr. after irradiation (Table 1).

Table 1. Serum Aldolase Activity in Healthy and Irradiated Animals

Healthy animals	After irradiation of 2 hr.	4 hr.	6 hr.
34·1 (22·7–45·0)	34·9 (23·1–52·8)	64·4 (41·9–109·3)	53·3 (41·0–72·3)

These results show that aldolase released from liver, and perhaps muscle cells damaged by irradiation appears in serum 1–2 hr. later, that is, 3–6 hr. after irradiation. Thus the determination of aldolase activity in serum may help to detect radiation damage.

Our preliminary investigations on persons suffering from malignant tumour diseases and receiving therapeutic whole-body irradiation gave similar results with the remarkable difference, however, that while in guinea pig the same aldolase activity was found both in whole blood and in plasma, in man the aldolase activity in whole blood was several times greater than in plasma.

Results of investigations to elucidate the cause of this difference and to establish the connexion between dose of irradiation and increase of aldolase activity in serum will be published later.

Effect on Biological Nitrogen Fixation of Nitrogen Gas treated with Ultra-violet Radiation

Many different theories on nitrogen fixation by *Azotobacter* cells have been presented, among them the proposition of Wilson and Burris[1] that the nitrogen molecules, which are absorbed and take part in the reactions leading to nitrogen fixation, are in an activated state. These authors also suggest that this activated form might comprise a molecule possessing an energy greater than some unknown critical value.

If this suggestion is valid, it might be possible to increase the degree of nitrogen fixation by increasing artificially the energy of the nitrogen gas.

We are recording here some experiments based on this assumption, using ultra-violet light as a means of bringing about an increase in the energy of the nitrogen gas.

The organism used was *Azotobacter vinelandii*, strain *O*. The bacteria were grown in a nitrogen-free medium[2], modified to contain 30 gm. of glucose instead of 10 gm. of sucrose. 0·05–0·2 l./min. of air was passed into the cultures through sintered glass cylinders 20 mm. long and 10 mm. thick (maximal pore diameter 40–60μ). The rate of oxygen transfer for all the cultures was 150 mM O_2/l./hr., as measured by the sulphite method[3]. Separately, 0·4 l./min. of nitrogen was passed into the cultures through a

Table 1. THE EFFECT OF IRRADIATED NITROGEN GAS ON FIXATION OF NITROGEN IN CULTURES OF *Azotobacter vinelandii*, STRAIN *O*

In each experiment eight cultures were run simultaneously under identical conditions except for the variance in the irradiation of the nitrogen gas. All the cultures were gassed with the same amount of nitrogen and at the same oxygen transfer-rate. The nitrogen fixed by the bacteria is expressed as mgm. nitrogen fixed per gm. glucose consumed. The increase of the nitrogen fixation obtained in cultures gassed with irradiated nitrogen gas is expressed in per cent of the mean value of the controls

Total mean					22·8			7·1			14·8

capillary of 1·5 mm. diameter. Arrangements were made to wash the nitrogen with pyrogallol and water, and to dry the gas with calcium chloride before it entered the cultures.

Eight cultures were run simultaneously. In six of them the washed and dried nitrogen gas passed through glass-mantled ultra-violet lamps before entering the cultures. The ultra-violet lamps used were Philips' 6 W., 15 W. and 30 W. germicidal lamps marked *TUV* 6, *TUV* 15 and *TUV* 30. The distance travelled by the nitrogen through the capillary from the glass mantle to the open end was 150 mm. The end of the capillary tube was 50 mm. below the surface of the culture. Precautions were taken to avoid direct or indirect irradiation of the cultures by ultra-violet light. The cultures were run for 30 hr. and the growth estimated by dry-weight determinations. The glucose was determined by the anthrone method[4,5]. After digesting 1 ml. of each culture in sulphuric acid and oxidizing the solution with perchloric acid, the nitrogen was determined colorimetrically[6].

Using nitrogen gas, treated with ultra-violet radiation, as a partial nitrogen source, the nitrogen uptake increased by 7–23 per cent.

Table 1 shows that the 6-W. lamp increased the nitrogen uptake by 23 per cent, the 15-W. lamp by 7 per cent and the 30-W. lamp by 15 per cent, compared to the non-irradiated control cultures. Controls run in tubes fitted with the ultra-violet equipment—lighted but not flushed with nitrogen—gave roughly the same values as the ordinary growth tubes. In this case the nitrogen was added through an extra capillary.

Further work on the influence of irradiated gases on bacterial cultures is in progress in this laboratory and will be reported later.

We thank Miss K. Erixson for her helpful assistance and Statens Tekniska Forskningsråd for financial support.

HÆMATOLOGY

Hæmoglobins of Fœtal *C57BL*/6 Mice

THE existence and nature of differences within species between adult and fœtal hæmoglobins have attracted much attention[1-7], but until very recently a distinct fœtal hæmoglobin type had not been demonstrated in the mouse. Filter paper[8,9], starch block[10] and starch-gel electrophoresis of hæmoglobins of adult mice from different inbred strains and inter-strain crosses have shown inherited strain specificity for either of two general types of electrophoretic pattern, 'diffuse' (two or more components) or 'single' (discrete single band). Tests of hæmoglobin of new-born mice from several different inbred strains have given electrophoretic patterns indistinguishable from those of adults of the same strain[11,12]. However, starch-gel electrophoresis of adult and fœtal hæmoglobins in the *CBA* strain of mouse has shown the presence in early fœtal samples of a slowly moving component which disappears after 15 days gestation[11]. The *CBA* adult mouse has 'diffuse' hæmoglobin (three bands on starch-gel)[11], which renders interpretation of variations in the pattern rather difficult. The concept of a change in hæmoglobin type in mid-fœtal life rather than at birth is sufficiently novel to warrant repetition of the experiment with more favourable genetic material. Starch-gel electrophoresis of hæmoglobin of adult *C57BL*/6 mice reveals the presence of only one component, which provides a simple background against which to analyse variations in pattern. The present communication is a comparison of the starch-gel electrophoretic pattern of hæmoglobin from early and late fœtal and adult *C57BL*/6 mice.

In obtaining timed fœtuses, duration of the mother's pregnancy was timed from observation of vaginal copulation plugs. Blood collected from each fœtus of a litter, by cutting across the umbilical cord, discarding the placenta, and transecting the thorax, was pooled in a Petri dish containing heparinized saline. The adult and fœtal samples thus obtained were subjected to identical means of preparation: the cells were washed twice in 0·9 per cent saline and the packed cells lysed with their own volume of distilled water. One volume of molar phosphate buffer, *p*H 6·8, was added to precipitate the stromal proteins and other contaminants. The mixture was then centrifuged and the clear hæmoglobin solution removed and stored in the cold until required. Each sample was used on the day on which it was prepared,

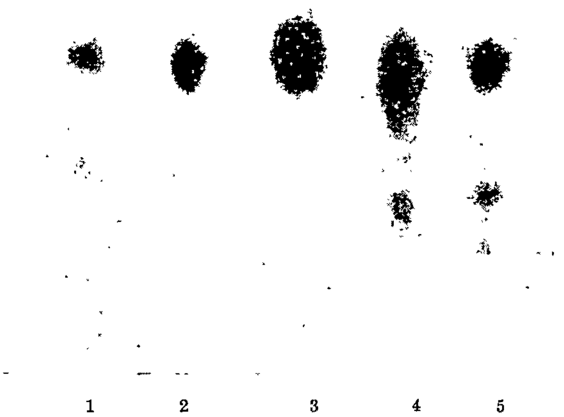

Fig. 1. Starch-gel electrophoresis (Poulik's discontinuous buffer system) of cyanmethæmoglobins prepared from 14-day fœtal and maternal *C57BL/6* blood and from a mixture of these two. 1, Fœtal; 2, mixture; 3, adult; 4, mixture; 5, fœtal

though results using hæmoglobins stored over several days in the cold showed that there was no appreciable alteration in the electrophoretic patterns.

The hæmoglobins were converted to the cyanmethæmoglobin forms and starch-gel electrophoresis carried out as described in a previous communication[11], except that a stronger solution of hæmoglobin was run for 4 hr. The gel was stained as before with an *o*-dianisidine–hydrogen peroxide mixture.

The electrophoretic patterns of hæmoglobins obtained from several groups of fœtuses of all ages from 12 days of intra-uterine life to birth were studied. At 12 days each of four tested litters showed three components, with the slowest moving present in a concentration (judged by intensity of spots) at least equal to that of the most advanced component. At 13 days (four litters) the fastest moving component was increased in intensity while the slowest moving one was diminished ; at 14 days (three litters) this slowest moving spot was disappearing (Fig. 1), and at 15 days (three litters) it was not discernible. The second spot, which had also been diminishing, though more slowly, was still seen at 15 days but was scarcely visible at 16 days. From 17 days on to birth and into adult life, only the first rapidly moving component was seen. In order to determine whether the fastest-moving component observed in these early fœtal samples corresponded in any way with the single hæmoglobin found in the adult animal, an additional sample, composed of two parts of fœtal to one part of adult hæmoglobin, was applied to a gel together with the standard fœtal samples and maternal control. It was felt that if one of the fœtal components corresponded with the adult hæmoglobin, three spots would be visible in the mixture, whereas non-correspondence might result in an indistinct blur or the presence of four components. The mixture separated well into three components with the first component in line with the single adult spot of the control (Fig. 1). It seems, therefore, reasonable to assume that the first fœtal component has the same electrophoretic mobility as the adult component ; however, such mobility may be due to interaction between the two hæmoglobins and does not in itself demonstrate complete correspondence of the two.

These results are similar to observations previously made on the *CBA* strain of mouse[11] in that the adult pattern replaced the fœtal pattern in late intra-uterine life of the mouse rather than at birth as in many other species. The observed transition in hæmoglobin patterns occurred at a time when the proportion of nucleated red cells in the fœtal circulation falls rapidly. From the 14th day to the 16th day the numbers of nucleated erythrocytes have been reported to fall from 21 to approximately 1 per cent[13]. Although at the present time it is not possible to state any specific physiological reason for a shift in hæmoglobin pattern in mid-fœtal life, it is tempting to conjecture some relationship with the shift in proportion of nucleated erythrocytes.

We wish to thank Drs. E. S. Russell and K. B. Roberts for their generous help and advice. This investigation was supported by grant *E*–76 to the Roscoe B. Jackson Memorial Laboratory from the American Cancer Society, and much of the work was carried out while one of us (J. B.) was holding a pre-doctoral fellowship from U.S. Public Health Service Grant *CRT*–5013 to the Roscoe B. Jackson Laboratory.

PATHOLOGY

Anti-tumoral Action of New Sarcomycin Derivatives

The anti-tumour effect of sarcomycin-2 methylen *cyclo*-pentanon-3 carboxylic acid was reported so long ago as 1953 (ref. 1), and since then this substance has been widely employed for its broader chemotherapeutic effect on cancer. Recently one of us[2] proposed new procedures for the synthesis of compounds of sarcomycin type, and the preparation of several new sarcomycin derivatives is now possible.

In this communication we report on the action of some sarcomycin derivatives on the growth of the Ehrlich ascites tumour. The tetraploid Lipschutz IV strain of Ehrlich tumour has been used. The following procedure was adopted : from a donor mouse selected from mice with rapidly growing ascites, at 10 days after inoculation of cancer cells, 4 ml. of milky ascitic fluid were withdrawn. The cells were counted in a Spencer chamber and diluted with physiological saline buffered at *p*H 7. 0·2 ml. of the fluid

containing approximately 3 million cancer cells was injected intraperitoneally into the lower abdominal region into each of a number of young Swiss albino mice, weighing about 20 gm.

In each set of experiments the animals were divided in two groups, one treated with the compound, and the other used as control. The compounds to be tested were dissolved as calcium salt with saline and the resulting solution was adjusted to *p*H 7. Before the inoculation, the solutions were filtered through a Berkefeld candle, and aseptic precautions were maintained during the procedure. Each animal received one single administration of 4 mgm. immediately after the injection of cancer cells. The effectiveness of the compounds against the growth of the ascites tumour was recorded by the determination of survival-rate of treated animals, by measurements of the amount of ascites fluid after treatment (weighing the mice), and by cytological examinations of ascites tumour cells.

Table 1 shows the main results of the treatment with dihydrosarcomycin and with sarcomycin derivatives.

After early administration of the compounds, inhibition of ascites tumour is clearly shown, in some cases, on the basis of survival-rate and of increase of body-weight. The most effective compounds were found to be SB_5, SB_6, SB_7, SB_8 and SB_{15}, in each of which the CH_3CH_2 radical had been introduced; these are derivatives of omodihydrosarcomycin[3].

Further to clarify the chemotherapeutic action of those compounds, inhibition of the ascites tumour has been also evaluated by means of other parameters, as reported in Table 2.

The results in Table 2 clearly indicate that the sarcomycin derivatives really affect the growth of

Table 2

Compound	Mitotic rate	No. of cells/μl.	Mean total volume of fluid	Mean percentage living cells (Schrek)

Control	28	$7 \cdot 3 \times 10^4$	6·2	100

Ehrlich ascites tumour. It is also evident that the dihydrosarcomycin is less active than its derivatives.

It must be emphasized that in the evaluation of chemotherapeutic results, the dose and time of administration of the drug are very important. Under our conditions, one single dose only was given, whereas it is well known that a bigger effect can be obtained when several doses are given after the injection of cancer cells.

Detailed results of the anti-tumoral action of sarcomycin derivatives will be reported elsewhere.

Reversible Nature of Liver Cell Damage due to Carbon Tetrachloride as demonstrated by the Use of Phenergan

Rees, Sinha and Spector[1] have suggested a possible sequence of events in the rat liver following the administration of carbon tetrachloride. Thus at 6 hr. there is a large increase in liver fat and liver cell damage verging on necrosis. In addition, the hepatic enzymes, malic and *iso*citric dehydrogenase, can be detected in the blood. By 12 hr., histological examination shows early hepatic necrosis and massive fatty change, and glutamic dehydrogenase can be detected in the serum. As glutamic dehydrogenase is wholly a mitochondrial enzyme, this latter observation is indicative of mitochondrial injury. By 24 hr. the concentration of hepatic enzymes in the blood is maximal, as is the quantity of the fat in the liver. Histologically, there is widespread parenchymal cell necrosis. Recknagel and Anthony[3] have emphasized that the accumulation of fat in the liver occurs before mitochondrial injury becomes demonstrable by *in vitro* enzymological study, and have suggested that the initial effect of carbon tetrachloride on the liver occurs at about 3 hr.

In previous experiments it was found that the administration of phenergan ('Promethazine HCl') at 0 and at 6 hr. to animals poisoned with carbon tetrachloride modifies considerably the above sequence of events[4]. In rats receiving both phenergan and carbon tetrachloride, there was no significant liberation of hepatic enzymes into the blood and hepatic necrosis was almost absent in the first 24 hr. On the other hand, the hepatic fatty change was unaltered both in appearance and in quantity.

In the present investigation, these observations have been extended. It was found that if animals given carbon tetrachloride and phenergan at 0 and 6 hr. were given no further doses of phenergan in the period 24–48 hr., liberation of hepatic enzymes into the circulation was demonstrable from 24 hr. onwards, and by 48 hr. there was hepatic necrosis of the same order as found in the liver of a rat not treated with phenergan 24 hr. following poisoning with carbon tetrachloride. However, if the poisoned animals received additional treatment with phenergan during the 24–48 hr. period, hepatic necrosis and release of hepatic enzymes into the blood were prevented almost completely, and even at 72 hr. these changes were not observed (Table 1).

Table 1. Degree of Liver Necrosis and Level of Serum *iso*citric Dehydrogenase following Carbon Tetrachloride Poisoning in Rats with and without Phenergan Treatment

Time after carbon tetrachloride poisoning (hr.)	Time of phenergan treatment (hr.)	Serum *iso*citric dehydrogenase (μl. oxygen per ml. per hr.)	Degree of necrosis	Comment
0	nil	1 (0·6–1·7)	0	—
24	nil	153 (144–180)	+ + + +	Active necrosis
24	0 and 6	12 (9–15)	+	—
48	nil	35 (28–40)	+ + + +	Healing necrosis
48	0 and 6	78 (60–84)	+ + + +	Active necrosis
48	0, 6, 24 and 30	11 (2–17)	+	–
72	nil	3 (1·5–4)	+ + +	Healing necrosis
72	0, 6, 24 and 30	1·0 (0·6–1·7)	+	–

The animals were dosed with 1·25 ml. carbon tetrachloride/kgm. body-weight. When phenergan treatment was given, the dose at 0 hr. was 25 mgm./kgm. body-weight and all subsequent dosage was at 12·5 mgm./kgm. body-weight level. Albino female rats (120–200 gm. body-weight) were used.

Active necrosis denotes areas of eosinophilic coagulative necrosis of liver cells. Healing necrosis denotes extensive infiltration of these areas by chronic inflammatory cells.

Since phenergan fails to prevent fatty accumulation in the liver, it is clear that the drug does not act by detoxicating carbon tetrachloride. In addition, the development of hepatic necrosis at 48 hr. after administration of carbon tetrachloride to animals given only two doses of phenergan would also suggest that phenergan had not detoxicated the carbon tetrachloride but rather prevented a secondary 'necrogenic' reaction in the liver cell.

Carbon tetrachloride reaches its maximum concentration in the liver about 3 hr. after administration, and thereafter the concentration falls rapidly[4]. 24 hr. following poisoning with carbon tetrachloride, chemical estimation discloses that the concentration of the latter in the liver has dropped to zero, and in the present investigation using carbon-14 tetrachloride it was not possible to detect any radioactivity in the livers of animals 24 hr. after poisoning.

Thus, the delayed appearance of hepatic necrosis 24 hr. after administration of carbon tetrachloride in rats given phenergan at 0 and 6 hr. only occurs in the absence of carbon tetrachloride as demonstrable by chemical and radiochemical techniques.

The simplest explanation of these results is to assume that carbon tetrachloride irreversibly damages a reaction that is non-essential in the short term for the survival of the cell, and that as one consequence of this primary injury there is a secondary disturbance, for example, the entry of sodium and water into the cell. It is this secondary disturbance which is prevented so long as phenergan is present. It seems that the primary injury caused by carbon tetrachloride will continue in force, after its concentration has dropped, until the vital constituents of the damaged system are re-synthesized. This process appears to take up to 48 hr.

The hypothetical secondary disturbance could be associated with the breakdown of phosphoprotein, a system which Judah[5] has shown to be sensitive to the action of phenergan and has postulated as part of the mechanism controlling cellular water and electrolyte movements.

The reason for stating that the primary site of attack of carbon tetrachloride is a system not immediately essential for the life of the cell is that, in the presence of phenergan, the damage caused by carbon tetrachloride is reversible. It is clear that this conclusion carries with it some important implications, including therapeutical possibilities.

We are grateful to Sir Roy Cameron and Prof. C. Rimington for their advice and encouragement. One of us (K. R. R.) is indebted to the Medical Research Council for a grant for assistance.

Alloxan and Hypersensitivity

During the course of another investigation, it was found that a diabetogenic dose of alloxan (175–200 mgm./kgm.)[1] protects approximately 50 per cent of rats sensitized to horse serum and later injected intravenously with this antigen. The time of death was lengthened in those rats suffering lethal shock. Controls consistently showed 0–10 per cent survivors.

Rats were of Sprague–Dawley strain, sensitized by a single intraperitoneal injection of a mixture of horse serum and *H. pertussis*. Alloxan was injected subcutaneously into the sensitized rats just prior to, or four days before, challenge with horse serum. Of the various routes tested, the subcutaneous route for injection of alloxan proved the least toxic. The purpose of this communication is to describe some aspects of the effect of alloxan on hypersensitivity reactions in the rat and guinea pig.

One unit of insulin, injected subcutaneously into alloxan-treated sensitized rats 1 hr. before challenge, partially reversed the protective effect of the alloxan. This amount of insulin also increased the speed with which death occurred in untreated sensitized controls (Fig. 1). Ganley[2] recently reported similar findings in mice.

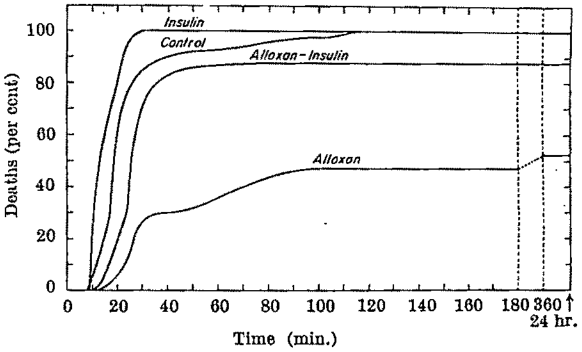

Fig. 1

In the guinea pig, alloxan injected either intraperitoneally or subcutaneously at 300 mgm./kgm. body weight four days prior to challenge reduced the size and intensity of the skin reaction to PPD in animals sensitized by injection of killed *M. tuberculosis* in paraffin oil emulsion. Long, Miles and Perry found a similar action of alloxan in guinea pigs infected with living *BCG* [3]. Alloxan did not protect against either 'immediate' or 'delayed' type anaphylaxis. However, it did appear to give protection during the first 24 hr. to the type of shock induced by intraperitoneal challenge with old tuberculin. Failure to protect from anaphylactic shock in the guinea pig may be due to the very swift occurrence of emphysema of the lungs and death from bronchospasm.

The protective effect of a diabetogenic dose of alloxan in rat anaphylaxis and delayed skin hypersensitivity in the guinea pig, with its reversal in the rat by insulin, suggests the involvement of a lack of insulin or an excess of glucose. We have evidence that large amounts of glucose (4 gm./kgm. × 2) injected intraperitoneally prior to challenge gives at least some degree of protection.

ANATOMY

Function of the Fœtal Thyroid of the Rabbit with regard to Cholesterol Metabolism studied by Fœtal Thyroidectomy

In earlier communications, it was reported that the fœtal pituitary–thyroid system influenced cholesterol and fat metabolism. Following removal of this system, a significant rise in the serum cholesterol occurred[1], and also in the fat content of the fœtal liver[2]. The technique for removing the fœtal pituitary and thyroid involves decapitation of the fœtus either through the neck to remove both the thyroid as well as the pituitary, or through the mouth to preserve the thyroid. It has already been shown that this operation has no significant effect on the weight development of the fœtus[2–4], but it may be objected that the metabolic changes may be the result of removing structures other than the pituitary and the thyroid, such as the brain.

To overcome this objection and to investigate this problem further, the fœtal thyroid was removed surgically on the twenty-second to twenty-third day of pregnancy and each operated fœtus then allowed to continue development within the uterine cavity. These experimental fœtuses with their litter mates for controls were recovered just before term on the twenty-ninth to thirtieth day of pregnancy by Cæsarian section. The serum cholesterol-levels were determined (as indicated in ref. 1) and the results are shown in Table 1.

Table 1. SERUM CHOLESTEROL IN THYROIDECTOMIZED AND CONTROL RABBIT FŒTUSES

Fœtuses	Age at investigation	No.	Mean serum cholesterol (mgm./ 100 ml. ± *S.E.*)	
Thyroidectomized (at 22–23 days)	29–30 days	7	129*	± 7·7
Litter-mate controls	29–30 days	32	86*	± 3·5

* These differences are significant, $P < 0.001$.

There is no significant difference in weight development of thyroidectomized and control fœtuses. The operated fœtuses all show a significant increase in serum cholesterol, and this indicates, therefore, that the fœtal thyroid plays a part in fœtal cholesterol metabolism. In addition, these results indicate that the maternal thyroid secretions are unable to compensate for the absence of the fœtal thyroid.

One of us (J. G. B.) expresses his indebtedness to Prof. A. Jost for his help in developing techniques for intra-uterine surgery of the fœtus, and to the Medical Research Council for a grant towards apparatus.

We are indebted to Prof. E. W. Walls and Prof. A. C. Dornhorst for their interest and guidance in this investigation.

BIOLOGY

Transport of Carbon in Fungal Mycelium

INTEREST in the problem of translocation by fungi has been stimulated by Schütte's paper[1], and this communication is concerned chiefly with the movement of carbon compounds through an established mycelium.

We have investigated three aspects of translocation by fungi:

(1) Ability to grow from a 'complete' nutrient medium on to a 'deficient' medium (distilled water-agar) using the dish method of Schütte. Of 20 species representing all classes of the fungi, 10 were able to grow on to the deficient medium ('translocating' fungi *sensu* Schütte), 6 were unable to do so ('non-translocating' fungi) and 4 were indeterminate.

(2) The ability of growing mycelium to transport labelled carbon compounds using the dish technique with sucrose-^{14}C in the centre dish. All 'translocating' fungi were capable of moving compounds labelled with carbon-14 as the mycelium grew on to either deficient or complete media. However, 'non-translocating' species were also able to move labelled compounds when their mycelium grew out on to a complete medium; the possibility of respired $^{14}CO_2$ being re-absorbed by the growing mycelium was examined and rejected. This observation is at variance with Schütte's hypothesis that growth on to a deficient medium was evidence for translocation by a fungus.

(3) Movement of compounds labelled with carbon-14 through an established mycelium. Three species were used; two were selected as exemplifying the behaviour of 'translocating' fungi (*Rhizopus stolonifer* (Ehrenb. ex Fr.) Lind. and *Pellicularia filamentosa* (Pat.) Rogers) and one as a 'non-translocating' fungus (*Saprolegnia ferax* (Gruith.) Thuret) in the sense of Schütte.

The dish technique was used, there being a distance of approximately 4·6 cm. between the edge of the centrally placed, inner dish and the circumference of the outer dish. The complete medium, potato dextrose +0·1 per cent peptone, was chosen because it supported better growth of a wide range of fungi than any simple, synthetic medium; replication was achieved by using only a single batch of Oxoid dehydrated potato extract. The deficient medium was distilled-water agar containing Oxoid 'Ionagar No. 2'.

Complete liquid medium (approx. 15 ml.) was placed into the inner dish, and the outer dish poured with either deficient or complete agar medium. After inoculation of the inner dish and incubation at 25° C. for 14 or 16 days, some of the medium was withdrawn from the inner dish and replaced with 5-ml. fresh, complete liquid medium containing glucose-^{14}C having an activity of 5 μc. By this time the mycelium had usually completely covered the medium in the outer dish.

Incubation was continued, and at intervals the mycelium on the agar medium was sampled by cutting 3 disks (area 1 cm.^{2}) along a radius, the innermost close beside the central dish, the outermost at the circumference of the outer dish, and the third sample at a point midway between these two. The samples were counted and the results are presented in Table 1.

Some activity could be detected in the mycelium one hour after the glucose-^{14}C had been supplied. Thereafter, activity increased progressively at the innermost and central sampling sites up to about 78 hr., but there was little indication of accumulation at the outermost site, possibly because of more rapid catabolism in the physiologically younger part of the mycelium. The aerial mycelium of *R. stolonifer*

on the lid of the dish at the edge of the colony was also active.

Recently, Lucas[2] showed that compounds labelled with phosphorus-32 are not transported through an established mycelium, and suggested that their movement was normally concomitant with growth of the hyphal tips. Possibly a sink for carbon is maintained by respiration in the younger part of the mycelium, whereas a similar sink for phosphorus would not exist. Consequently, we do not consider our results are in conflict with those of Lucas, but that they reflect different metabolic patterns for carbon and phosphorus. However, when considered together, Lucas's results and our own are contrary to a 'mass flow' hypothesis of translocation in mycelium.

This work is being extended to include a study of the movement of phosphorus, and the forms in which carbon and phosphorus move in the mycelium.

Prevention of Manganese Deficiency in Oat by soaking the Grain in Solutions of Manganous Chloride

TRACE element deficiencies in crops are normally overcome by applying the required element to the soil or by spraying the plant with a solution containing it. However, it has been found that soaking seed in a solution of a salt of the required element is an effective way of preventing the development of deficiency symptoms in the crops grown from soaked seed[1–4]. Grey speck of oat, caused by manganese deficiency, is prevalent in many areas of west Scotland due usually to induced manganese deficiency associated with high soil *p*H. To our knowledge, the possibility of preventing this condition by seed soaking has not been reported before. The following investigations were carried out to determine the possible usefulness of such treatments.

The effects of different soaking treatments on the germination capacity of oat were determined. 5-gm. samples of oat grains (*Avena sativa* L. var. Victory) were soaked in 100 ml. of water or solutions of manganous chloride ranging in concentration from 0·2 per cent to 10·0 per cent w/v. After surface drying, the grains were germinated at 10° C. on moist filter paper in Petri dishes. With all soaking treatments longer than 36 hr., there were reductions in the rate of germination, and the final germination percentage. The magnitude of the effects was proportional to the concentration of the manganous chloride solution. With soaking periods less than 24 hr., and solutions less than 2 per cent manganous chloride, there was little adverse effect on germination.

The full requirement of manganese for a crop of oats has been reported to be 7 ounces per acre[5]. To meet this requirement, it is necessary for the grain to have a manganese content of 1,450 mgm. per lb. at the time of sowing, on the basis of an effective sowing-rate of 140 lb. per acre. The manganese content of the grains used in our experiments was 21·5 mgm./lb. In order to be successful there would need to be a considerable uptake of manganese during the soaking period, and at the same time, germination must not be affected adversely. An estimate of the amounts of manganese taken up during soaking was obtained by measuring the amount of manganese left in solution at the end of treatment using the colorimetric method of Sideris[6]. Some of the results obtained are given in Table 1.

Table 1

Length of soaking period (hr.)	Concentration of manganous chloride solution (percentage w/v)	Manganese content of grains (mgm./lb.)	Final germination (percentage)
0	0	21·5	100
8	2	1,290	94
24	2	2,290	91
24	10	5,920	15

From these figures it can be seen that the manganese content of the grain can be raised to a level which, without compromising germination, provides the full crop requirement. This was tested by growing plants from treated and untreated grain in nutrient solutions with and without manganese.

Twenty plants grown from grains treated by soaking in water or manganous chloride solution were supplied with modified Hoagland's solution[7] with or without manganese. Half of each sample was gathered after 63 days, and the remainder at maturity, after 114 days. The average dry weights of the plants are shown in Table 2.

Table 2

Length of soaking period	Soaking solution	Nutrient solution	Average dry weight (gm.) at 63 days	Average dry weight (gm.) at 114 days
24 hr.	distilled water	Complete	0·59	5·05
24 hr.	distilled water	manganese-free	0·26	3·27
8 hr.	2 per cent $MnCl_2$	manganese free	0·40	4·99
24 hr.	2 per cent $MnCl_2$	manganese-free	0·73	4·41

Grey speck was observed on the control plants grown in manganese-free solutions before the 63-day stage, but was not observed at any time on any of the plants in the other treatments. The dry-weight figures bear out the contention that the method is a feasible way in which to provide the oat crop with its manganese requirement.

The possible use of seed-soaking treatments to overcome manganese deficiency under field conditions was investigated on a preliminary basis during 1959 using soil rich in shell sand from the Island of Tiree. Manganese-deficiency symptoms were not obvious in plants from treated grain, while plants from untreated grain showed typical grey speck and considerably reduced growth. Full-scale trials will be carried out this year and reported elsewhere.

Nucleic Acids and Sexual Differentiation in *Allomyces*

THE finding that thymine is the most effective nucleic acid base in inducing proliferation of male gametangia in *Allomyces*[1] is of special significance for an understanding of the biochemical basis of sex differentiation in these water-moulds.

A first step towards understanding the nature of the thymine effect in *Allomyces* can be derived from recent demonstrations that this nitrogen base induces a selective, stimulatory effect on nuclear multiplication, with concomitant increase of the deoxyribonucleic/ribonucleic acid (DNA/RNA) ratio in the related mould *Blastocladiella*[2]. Consequently, we could expect a similar effect in *Allomyces* and safely predict that in promoting increased DNA synthesis relative to RNA (higher DNA/RNA ratios) in the cytoplasm of differentiating hyphæ, thymine automatically favours male differentiation, with its attributes of high rate of nuclear multiplication and low RNA basophily.

The gametophytic strains of *Allomyces* have been grown 8–10 days on Emerson's 'YpSs'[3] agar medium (Difco) in Petri dishes at 25° C. and the gametes collected by mild centrifugation 2–3 hr. after flooding the plates with Machlis's 'DS' solution[4]. Pellets of gametes were carefully washed twice with distilled water before their dispersal in 0·4 *N* potassium hydroxide for a 1 hr. extraction at 100° C. Two aliquots were then withdrawn and used according to McIntire and Sproull's[5] analytical procedure : (1) for selective DNA precipitation with salamine (protamine sulphate, supplied by Gen. Biochem. Inc., U.S.A.) 0·05 per cent at 4° C. overnight, followed by sodium chloride 10 per cent–sulphuric acid 0·1 *N* hydrolysis (30 min.) of the precipitate, previously washed with ice-cold distilled water ; (2) for direct, sodium chloride 10 per cent–sulphuric acid 0·15 *N* hydrolysis at 100° C. (30 min.) to get the total purines and pyrimidines fraction. Measurements of both fractions at 268 and 330 mμ with a model *DU* Beckman spectrophotometer gave the basis for final calculations of the quantities of DNA and total purines and pyrimidines, using McIntire and Sproull's formulæ. RNA (ribonucleic acid) was considered as total purines and pyrimidines less DNA (negligible, soluble pool of purines and pyrimidines in the RNA nuclear cap-containing gametes of Allomyces). Proteins were determined with the biuret reaction[6].

As shown by my results summarized in Table 1, I have measured consistently a higher DNA/RNA ratio in the mixed populations of gametes liberated from the gametophyte of *Allomyces macrogynus* Emers. grown in the presence of additional thymine. Of importance is the fact that uracil, the corresponding RNA base, was ineffective in *Allomyces* as previously shown in *Blastocladiella*[2]. Such higher DNA/RNA ratios measured in the gametes of thymine-treated *Allomyces* conform to the expected higher proportion of male gametangia (minimal 75 per cent) differentiated under such conditions, and to the relatively smaller RNA nuclear caps[7] of the predominantly male gametes liberated. Incidentally, these determinations provide chemical confirmation of earlier microscopic data on the smaller value of the nuclear cap/nucleus volume ratio in the male compared to the female gametes in *Allomyces*[8]. Similar verification was obtained : (1) for the gametes of a male colchicine mutant[1] in comparison with the composite population of female and male gametes of the wild-type of *A. macrogynus* ; (2) for the gametes of a male, hybrid strain (*A. macrogynus* × *A. arbuscula*[9]) compared with the gametes of a female, similar hybrid strain (Table 1).

Table 1

Cultures (8–10 days, at 25° C.)	♂/♀ gametangia	DNA/RNA* in gametes liberated
1. *Allomyces macrogynus* Emers.:		
Wild-type on 'YpSs' 'Difco' medium	1/1	9·6
Wild-type on peptone-glucose† ('PYG Cantino' 'Difco' medium)	1/2	8·4
Wild-type on 'YpSs' + thymine (2×10^{-3} *M*)	4/1	10·9
♂ Colchicine mutant on 'YpSs' medium	3/1	10·7
2. *A. macrogynus* × *A. arbuscula:*		
♀ hybrid strain	2/98	6·9
♂ hybrid strain	92/8	12·8

* Average values from three experiments.

† Feminizing medium.

Moreover, the higher proportion of DNA in the male gametes could also be verified on a protein basis :

male hybrid strain	12·0 μgm. DNA/mgm. protein
female hybrid strain	6·4 μgm. DNA/mgm. protein

The use of nucleic acid antagonists has tended to confirm the importance of the DNA/RNA balance in the biochemical basis for sex differentiation in *Allomyces* : at relatively high concentrations (10^{-2}–10^{-3} *M* in solid 'YpSs' 1/2 medium) all compounds favouring an increased DNA/RNA ratio in *Blastocladiella*[2]—that is, thiouracil, bromouracil, *iso*cytosine and (paradoxically) aminopterin—induced a significant increase in the male/female ratio (up to 75 per cent males on 10^{-2} *M* thiouracil) in *A. macrogynus*. Inversely, pteropterin, which tended to lower the ratio in *Blastocladiella*, showed a feminizing effect in *Allomyces*.

In conclusion, it appears as if differentiation of male sex organs in *Allomyces* is associated with the genetically controlled, polar accumulation of a biochemical system favouring more active DNA synthesis in the prospective male territory of the cytoplasm of differentiating hyphæ. Conversely, the prospective female territory is characterized by polar segregation, in this region of the cœnocytic cytoplasm, of a more 'vegetative' type of nucleic acid metabolism which favours RNA synthesis and—with its potential role in protein synthesis—confers on the future female gametes their well-known capability for parthenogenetic development.

I am indebted to Prof. Ralph Emerson, University of California at Berkeley, for his generous gift of the two hybrid strains of *Allomyces*. Thanks are also expressed to Prof. E. C. Cantino in whose Laboratory at Michigan State University, East Lansing, my first nucleic acid determinations were made.

Determination of the Volume and Weight of Living Animals

WHEN accurate measurements of the weight of aquatic animals are necessary, most authors remove the adherent water by towelling the body with filter paper and weigh quickly and repeat until a constant weight is obtained. The method is defective since, apart from possible damage to the animals, the degree of dryness reached may not be the same each time. These difficulties increase when the animals are small and several have to be used at a time. Similarly, determinations of volume necessitate an elaborate procedure or the use of complicated apparatus.

For small marine Crustacea I find the following procedure better than the volumometer which I described[1]. A basket is suspended by a nylon thread from one arm of a balance and immersed in a definite volume of sea-water in a beaker. The apparent weight of the basket and the thread is determined. The animals are then transferred to the basket and weighed. Next, a fourth of the sea water in the beaker is removed and distilled water is added, stirred and the animals weighed again. The animals are removed and the empty basket is weighed in the 75 per cent sea-water. The difference in apparent weights of the animals in sea-water of two densities will thus help to calculate the volume of sea-water displaced and also the weight in air.

It has been found that determinations of apparent weight are not vitiated by osmotic transport, since most Crustacea take more than 10 min. to respond to changes in media. This method is particularly suitable for making continuous observations on the rate of water transport in animals left in anisotonic media.

β-Galactosidase Changes in the Developing Intestinal Tract of the Rat

IN some micro-organisms β-galactosidase (lactase) is an adaptive enzyme, that is, its biosynthesis is induced by external agents such as lactose or lactose-related substances[1]. Apparently this is not the case for the intestinal β-galactosidase of the rat, since a lactose-rich diet does not modify the intestinal specific activity[2]. In the work reported here, the behaviour of this enzyme has been investigated in the albino rat, starting from the last third of the intra-uterine life until adult age.

Homogenates of the small intestine from the duodenal flexure to the ileo-cæcal valve were used. The enzyme was determined by the *ortho*-nitrophenol released from the *ortho*-nitrophenyl-β-galactoside, at 38° C. and *p*H 3·5[4]. The age of fœtuses was estimated according to the histo-differentiation shown in the duodenal, ileo-cæcal and umbilical regions[3], independently of the biochemical values. This technique allows a very close correlation between histological and biochemical data.

The changes in β-galactosidase activity during the end of pregnancy, new-born period and adult age of the rat are plotted in Fig. 1.

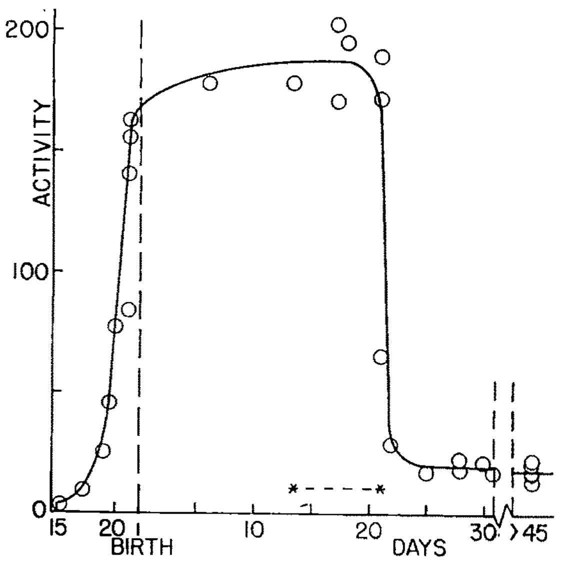

Fig. 1. Intestinal β-galactosidase activity expressed as mμmoles of *ortho*-nitrophenol released per mgm. of tissue (wet weight) in 1 hr. *----* Transition from lactation to adult diet; gestation, 22 days

The enzyme activity was also examined in different physiological and dietetic conditions: in adults on a lactose-rich diet, in pregnant rats, in nursing mothers, and in young rats kept after weaning on a complete diet with lactose (25–30 per cent) as the only carbohydrate (lactose-rich diet). The results are recorded in Table 1 together with the values for the normal adult and suckling rats.

Table 1. INTESTINAL β-GALACTOSIDASE ACTIVITY EXPRESSED AS MμMOLES *ortho*-NITROPHENOL RELEASED PER MGM. OF TISSUE (WET WEIGHT) PER 1 HR.

Diet	Condition	No. of animals	β-galactosidase activity	Increase
Normal	Adult	5	18 ± 2·9	×1·00
Normal	Pregnant	4	18·6 ± 1·0	×1·03
Normal	Nursing	3	18·4 ± 2·4	×1·02
Mother's milk	1–20 days old	14	183 ± 8·8	×10·0
Lactose*	Adult	3	19·3 ± 2·1	×1·07
Lactose	25–27 days old	3	19·8 ± 3·0	×1·10

* 'Lactose' means a complete diet with lactose 25–30 per cent as the only carbohydrate.

The features which became apparent from these results are: (1) The specific activity does not change on the diet rich in lactose (no induction in a strict sense), confirming discoveries of other authors[2]. (2) There are no significant changes either in the pregnancy or in the nursing period. (3) Activity increases rapidly at the end of fœtal life until birth, parallel to the very fast histo-differentiation of the digestive tract[3]. The high level remains rather constant in the new-born. (4) At the time of weaning (21–22 days) the activity decreases abruptly to the low adult-value. (5) This net decrease in the activity also occurs when the new-born is kept on the lactose-rich diet.

Several authors have shown that lactose hydrolysis is necessarily previous to its intestinal absorption; the somewhat low β-galactosidase adult activity makes its action a limiting step in lactose assimilation, and therefore laxation and diarrhœa occur[2]. An activity ten times higher in the new-born, as compared with the adult animal, is in agreement with the expected great efficiency as regards milk lactose assimilation in the sucklings. The 'physiological immaturity of the new-born' seems to be in this case rather a physiological adaptation (in a broad sense) to a milk diet. In any event, β-galactosidase belongs to the few biochemical systems showing an activity in this period, generally marked by enzyme deficiencies[5], higher than in adult age.

Conchie *et al.*[4] have shown a considerable increase for this and other mammalian glycosidases in the epididymis, apparently associated with sexual development. The enzyme activity from other tissues remains about the same during and after growth, and this finding has been confirmed by us for the pancreas and liver in all the conditions mentioned here.

It should be noted that the fall in β-galactosidase activity is observed at the time of weaning, where other authors have found a loss of permeability to macromolecules, such as insulin and anticorps[6]. This age seems to be peculiar in the evolution of the gastro-intestinal tract of the rat.

Avian Schistosomes in Hertfordshire

Limnaea stagnalis collected from three sources in the vicinity of Winches Farm Field Station of the London School of Hygiene and Tropical Medicine were found to be shedding furcocercous cercariæ. On emergence from the snail, the cercariæ swam freely for a short time with either the head- or tail-end forward and then attached themselves to the side of a beaker nearest the light. The cercariæ were apharyngeal, possessed a pair of eyespots and had six pairs of flame cells in the body and one pair at the base of the tail. The posterior part of the body was taken up by five pairs of penetration glands, the two anterior pairs having coarsely granular and the three posterior pairs having finely granular contents. In its behaviour and morphological characters the cercaria is identical with that described as *C. ocellata* by Rees[1] and Taylor and Bayliss[2], who have given a detailed description of the cercaria which will not be repeated here. At one site (Verulamium Lake) a small percentage of *Limnaea ovata* were occasionally found to be shedding this cercaria. In both hosts the sporocysts were located in the digestive gland.

Several attempts were made to infect domestic ducks, by single and multiple infections, by cutaneous and oral routes with pooled cercariæ from a large number of infected snails. Droppings were examined for eggs at weekly intervals, and at 4–6 months post-mortem examinations for worms were made. All results were negative. It has been observed that the birds common to all three locations are duck, moorhen and coot.

Diapause, Neurosecretion and Hormones in Copepoda

DESPITE the great advances made during the past decade in the investigation of the endocrinology of the Crustacea Malacostraca[1], little or nothing has been published on the endocrine organs or hormones of the lower Crustacea. Neurosecretory cells have been observed in barnacles[2], but nothing is known for certain of any hormonal emanations from these cells.

Calanus finmarchicus and *C. helgolandicus* pass through three generations a year, in southern populations at least, overwintering as the last larval instar (the fifth copepodid stage)[3]. It has recently been shown (Smyly, W. J. P., personal communication) that *Cyclops leuckarti* has a similar life-history, and that, in this species, the overwintering copepodid penetrates to a depth of some 15 cm. into the mud of lake bottoms, passing the cold season in a quiescent state. This condition has obvious analogies with the diapause of many species of insects, which is known to be controlled by the endocrine system, especially by the neurosecretory system of the brain. We have therefore embarked on an investigation of the equivalent system of copepods.

The endocrine structures of the cerebral region of *Calanus* include a pair of lateral groups of neurosecretory cells at the front edge of the brain. From these the neurosecretory fibres pass forward and outward, skirting round the anterior blood sinus to reach the frontal organ. In adult and juvenile copepodids taken during the summer months these neurosecretory cells contain an abundant granular secretion. In the overwintering larvæ, however, this secretion is grossly depleted or even absent. By analogy with insects, therefore, we conclude that the secretion of these cells is probably playing some part in the control of the diapause, moulting and the overwintering metabolism and behaviour.

In the Crustacea Decapoda the same endocrine structures which are concerned with the control of moulting and metabolism also govern colour change. It therefore seemed reasonable to look for chromactivating hormones in copepods, even though they may possess no chromatophores. Accordingly, extracts of whole *Calanus finmarchicus* and of whole *Euchaeta norvegica* were assayed for chromactivating substance *A* (ref. 4) on *Leander adspersus*. One unit of this substance was found in 7·2 whole *Calanus*, while 6·5 units were found in one whole *Euchaeta*. The whole of the activity was found to be present in the cerebral region of the body in *Euchaeta*, and in the brain plus frontal organ of *Calanus*. It seems likely, therefore, that this hormone is secreted, as in decapods, by the neurosecretory cells of the brain.

This work is continuing, and a fuller account will be published elsewhere. We are grateful to Dr. F. S. Russell, Dr. S. M. Marshall, Mr. W. J. P. Smyly, Dr. B. Swedmark, the National Science Foundation and

the Browne Fund of the Royal Society for the various ways in which they have helped advance this investigation.

Verification of the Gastropod Golgi Cycle with an Electron Microscope

THE Golgi cycle of the gastropod (*Navanax*) was detailed[1], based on osmicated preparations and studies of living embryos vitally stained with methylene blue. However, because of the scepticism that has surrounded vital-dye observations, particularly since the neutral red controversy of the early 'thirties, these studies with methylene blue have never enjoyed complete acceptance by cytologists and have been severely criticized in some quarters.

It is particularly important, therefore, to report that our recent investigations of gastropod (*Crepidula*) development, by means of the ultra-thin sectioning technique, confirm substantially the earlier findings with methylene blue. Taken together, these two independent approaches to the Golgi body problem offer what we consider to be strong evidence that :

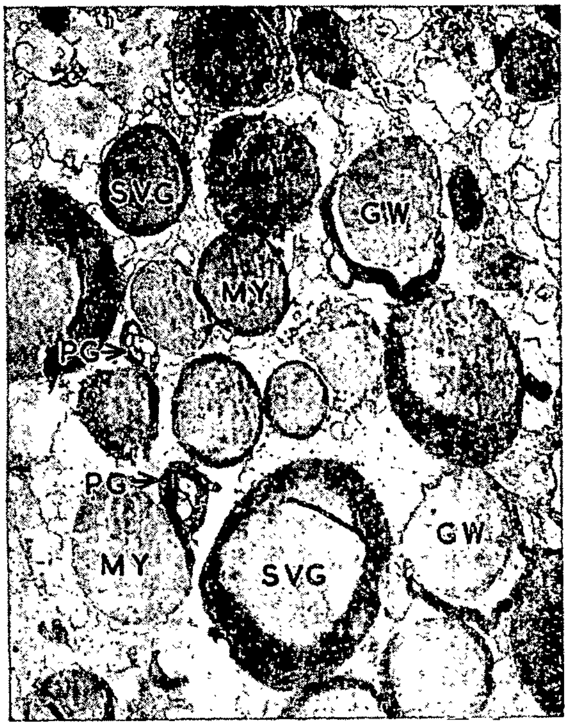

Fig. 1. Electron micrograph (× 3,400) of yolk-laden cell of *Crepidula veliger* showing three stages in the elaboration of protein yolk. Simple vesicular Golgi bodies (*SVG*), consisting of chromophilic cortices and chromophobic centres, eventually release the latter (*GW*) as mature secondary yolk spheres (*MY*). Following this withdrawal of the chromophilic envelope (*GW*), the Golgi material lies temporarily at the side of the yolk sphere as a hollow, pycnotic Golgi remnant

(1) The Golgi 'apparatus' in the gastropod veliger exhibits a cycle in which certain stages can be identified consistently by both methods; these stages are Golgi granules (droplets), simple vesicular Golgi bodies (Fig. 1, *SVG*); compound vesicular Golgi bodies, pycnotic Golgi bodies (*PG*), as well as disintegrating plates of primary yolk and newly formed mature secondary yolk spheres (*MY*).

(2) The Golgi system engages in the elaboration of protein yolk which makes its initial appearance as the chromophobic component of the Golgi body, increases greatly in size during the embryonic stages, and is eventually released as a mature yolk plate by virtue of the withdrawal from its surface of the chromophilic Golgi envelope (Fig. 1, *GW*).

(3) The Golgi complement of these cells is a series of spheres, presumably chiefly phospholipoidal in chemical composition[2], but such phospholipid spheres, through their ability to release their cores as formed cell products, play a dynamic part in the economy of the cell.

(4) Under appropriate control the microscopically visible chromophilic components of the Golgi elements in these living cells are selectively stained by methylene blue and are thus revealed in essentially unaltered form comparable with identical stages observed by means of the electron microscope.

These observations, which will be reported in detail elsewhere, indicate that in these, and perhaps in many animal cells, the function of the Golgi 'apparatus' is the continual building up of formed energy reserves from the raw nutritive materials present in the cytoplasm.

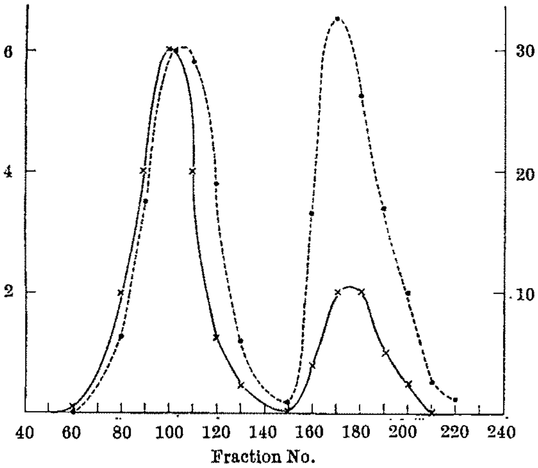
A 'Natriferic' Principle other than Arginine–Vasotocin in the Frog Neurohypophysis

IT has been shown that neurohypophyseal extracts from amphibians and teleosts stimulate the active sodium transport across frog skin more markedly than do extracts from mammalian pituitaries, and this led to the hypothesis that they contain a new hormone, differing from either oxytocin or vasopressin[1,2]. Its chemical constitution being unknown, this principle has been provisionally called 'natriferin'. Its possible identity with Heller's 'water-balance principle'[3] was of interest.

A synthetic peptide, arginine–vasotocin, prepared by Katsoyannis and du Vigneaud[4], has been shown to possess the pharmacological properties ascribed to the 'water-balance principle'[5,6], and to exhibit a high natriferic activity[7,8]. Moreover, a hormone having the same amino-acid composition and the same pharmacological properties as arginine–vasotocin has been extracted from the neurohypophysis of the chicken[9], the frog[10], and a teleostean[11].

According to Sawyer[7], the natriferic activity of the frog neurohypophysis should be entirely attributed to arginine–vasotocin. The results described below, however, indicate that arginine–vasotocin accounts only for approximately one-half of the total natriferic activity of the neurohypophysis of the frog, *Rana esculenta*. The remaining half must be ascribed to an active principle, differing from either oxytocin or arginine–vasotocin and of as yet unknown chemical constitution; this principle has not been found in the chicken.

The neurohypophyseal hormones of the frog, *Rana esculenta*, were purified by a method described previously[5,9,10,12], and treated by means of a gradient elution technique with an 'Amberlite *IRC*–50' column[12]. Fig. 1 shows the chromatographic profile obtained for the oxytocic activity (tested on the rat uterus) and the natriferic activity (tested on the 'short-circuited' frog skin[1]) of the eluate fractions. Natriferic activity was tested using synthetic oxytocin ('Syntocinon', Sandoz) as a standard. By definition, one natriferic unit corresponds to the effect produced by one I.U. of oxytocin. The complete analysis was carried out three times with separate batches of glands and comparable profiles were obtained.



←(0·1 *M*, *p*H 5 →0·5 *M*, *p*H 7·7)→ (0·75 *M*, *p*H 7·7) →

Fig. 1. Chromatographic profile of the frog neurohypophyseal principles. The hormones are separated on 'Amberlite *IRC*-50' by a gradient (of *p*H and ionic strength) elution technique (ref. 12). Concentrations and *p*H of the ammonium acetate buffer are shown below the figure. The oxytocic (left-hand scale) and natriferic (right-hand scale) activities of the effluent fractions are expressed in units/ml. Note that different scales are used. The right-hand natriferic peak corresponds to arginine–vasotocin and the left-hand natriferic peak to an unknown principle
×, Oxytocic activity; ●, natriferic activity

A study of the effluent fractions corresponding to the right-hand side of the chromatographic profile reveals coincident peaks of oxytocic and natriferic activities (25 per cent and 50 per cent of the total recovered activities respectively), corresponding to a substance which exhibits also a strong vasopressin activity[10]. This substance has the same amino-acid constitution and the same pharmacological properties as arginine–vasotocin[10], which is also present in the chicken neurohypophysis[9].

The left-hand side of the profile shows other peaks of oxytocic and natriferic activities (75 per cent and 50 per cent of the recovered activities, respectively). The peak of natriferic activity must necessarily be attributed to an unknown principle for the following reasons: (1) The strong natriferic activity as compared with the oxytocic activity (3–15 times higher, according to the region of the peak), eliminates the possibility that this substance is oxytocin, although oxytocin appears as a rule in this region of the chromatogram. (2) Its position on the profile and the absence of associated vasopressic activity[10] distinguish it from arginine–vasotocin. (3) The 'water-balance' activity of the pooled effluent fractions number 110–130, determined by means of Sawyer's gravimetric technique[6] on *Rana esculenta* bladder, was found to be ninety times higher than oxytocin itself and about 2·5 times less active than arginine–vasotocin. (4) The pooled effluent fractions, number 110–130, have no antidiuretic activity in both the rat and the frog. This contrasts with the high antidiuretic activity exhibited by arginine–vasotocin[8].

In the chicken, however, the effluent fractions corresponding to the left-hand side of the profile show only a low peak of natriferic activity coincident and equivalent to the peak of oxytocic activity. Oxytocin has been characterized chemically in this region of the chromatogram[12]; its presence accounts entirely for the observed natriferic activity.

Enhancement of Intraperitoneal Staphylococcal Virulence for Mice with Different Bile Salts

The intraperitoneal injection of a 1 per cent mixture of equal parts of sodium taurocholate and sodium glycocholate followed by an inoculum of *Staphylococcus aureus* has been previously found to enhance virulence of the latter for mice[1]. In the light of this observation, effectiveness in this respect of other individual bile salts, as well as the minimal effective concentration of those salts possessing such activity, was investigated.

Sodium taurocholate, sodium glycocholate, sodium glycotaurocholate and sodium dehydrocholate were obtained from Nutritional Biochemicals Co., sodium cholate from K. and K. Laboratories and sodium deoxycholate from the Fisher Scientific Co. All were readily soluble in distilled water and were sterilized by autoclaving at 15 lb. for 15 min. 0·5 ml. of the indicated concentration of each bile salt was injected intraperitoneally into groups of 10 albino, male Swiss mice weighing 15–20 gm., followed immediately by 0·3 ml. of an 18-hr. culture of a strain of *Staphylococcus aureus* grown in trypticase soy broth at 37° C. The latter had been isolated from a purulent lesion and was highly pigmented, hæmolytic, coagulase-positive, and fermented mannitol. All deaths occurring within 48 hr. as well as the number of positive post-mortem heart-blood cultures for *Staphylococcus aureus* in the animals that died were noted. In addition, one group of 10 mice received 0·5 ml. of 5 per cent gastric mucin and another group of 10, 0·5 ml. of physiological saline immediately prior to the intraperitoneal bacterial injection, as controls. A mortality of 10 out of 10 deaths within 48 hr. with 10 positive post-mortem heart-blood cultures was produced with the gastric mucin adjuvant whereas there were no fatalities with the saline solution. Intraperitoneal toxicity of 0·5 ml. of different concentrations of each bile salt *per se* was also determined. Sodium deoxycholate, 0·25 per cent, elicited a mortality of 3/10 with all post-mortem heart-blood cultures negative ; 0·1 per cent was innocuous. 4 per cent was found to be the maximum non-lethal concentration of sodium dehydrocholate. No fatalities occurred with a 1 per cent concentration of the remaining bile salts.

The number of fatal bacteræmias produced by the intraperitoneal staphylococcal inoculum with the aid of different concentrations of each bile salt investigated is contained in Table 1. As may be observed from Table 1, complete to almost complete mortality accompanied by bacteræmia was obtained with 0·25 per cent sodium deoxycholate and with a 1 per cent concentration of the remaining bile salts tested except sodium dehydrocholate. Lesser concentrations produced lower mortalities. The same intraperitoneal bacterial inoculum without bile salts, on the other hand, had resulted in no deaths. The maximal tolerated concentration of sodium dehydrocholate, 4 per cent, failed to elicit any mortality. Since the failure of the latter might conceivably have been due to a bactericidal activity on its part against the injected *Staphylococci*, the following experiment was performed. 0·3 ml. of an overnight culture of the test strain was distributed into each of two series of tubes. 0·5 ml. of 4 per cent sodium dehydrocholate was added to the tubes of one series, 0·5 ml. of physiological saline to the other. All were placed in a shaker water bath at 37° C., oscillating at approximately 120 per minute and comparative colony counts upon similar aliquots from both series at intervals of 2, 4, 6, 8 and 24 hr. were performed. No significant reduction in the number of viable bacteria was observed following exposure to sodium dehydrocholate as compared with physiological saline even up to 24 hr., so that the ineffectiveness of sodium dehydrocholate as a virulence-enhancing substance could not be attributed to any sterilizing effect upon the bacterial inoculum in the peritoneum.

Many chemically diverse substances, including certain anionic and non-ionic surfactants, have been found capable of converting ordinarily innocuous intraperitoneal staphylococcal infections in mice into rapidly fatal ones associated with septicæmia[1,2]. All possess one property in common, namely, the ability to lower surface tension. A substance possessing this characteristic might conceivably interfere with contact between peritoneal phagocytes and the bacteria so that the former are no longer able to envelop, engulf and destroy the latter. Furthermore, permeability of the peritoneal barrier between the abdominal cavity and the blood might also be increased by the surfactant and thus facilitate passage of the intraperitoneal organisms directly into the blood stream, thereby permitting them to circumvent the protective action of peritoneal phagocytes and minimize their exposure to the bactericidal action of peritoneal fluid. The surface tension-lowering ability of each bile salt was determined by means of the capillary tube method[3], with the following results: values expressed in dynes/cm. at 25° C. for physiological saline was found to be 66·2 ; that of 1 per cent sodium taurocholate, sodium glycocholate, sodium glycotaurocholate and sodium cholate 41·6, 40·4, 38·0 and 45·3 respectively ; of sodium deoxycholate 0·25 per cent, 45·3 ; while that of 4 per cent sodium dehydrocholate was 61·3. The lack of effectiveness of the last bile salt provides additional evidence to indicate that an association exists between the ability of a substance to lower surface tension and its ability to enhance virulence of intraperitoneally injected *Staphylococci* for mice.

This investigation was supported by Research Grant No. *E*–2687 of the U.S. Public Health Service, National Institutes of Health.

Paper Chromatography of Natural Saponins

APART from an early attempt by other authors[1–3] to adapt a method of paper chromatography for the examination of natural saponins, the potentialities in this field do not seem to have been investigated. The present communication deals with the application of paper partition chromatography to the identification of natural saponins and the separation of the constituents present, with particular reference to saponins of the important medical plants.

Such a separation was found to be readily achieved using the system *n*-butanol/acetic acid/water (6 : 1 : 3) as mobile phase. Good separation requires a 3-hr. conditioning of the Whatman No. 1 filter paper strip with substances applied in the chromatograph chamber, saturated with vapour of the solvent (the walls are lined with the paper). About 0·2 mgm. of the saponin dissolved in 50 per cent ethanol (primulic acid in 95·5 per cent ethanol) is spotted at the origin, and an ascending chromatogram is run at 19–20°. The solvent front moves slowly, usually about 30 cm. in 15–18 hr.

The strips are then exposed to a stream of warm air for 5 min. After evaporation of excess acetic acid, the chromatograms are heated at 105° for a further 30 min.

The detection reagent which yielded the best results was a 25 per cent ethanolic solution of phosphotungstic acid[4,5]. Other solvent systems and reagents are being tested. Characteristic colours reach optimum intensity in about 2 min., by which time very little background colour has developed. Each of the saponins examined so far yields a characteristic chromatogram distinguishable by the number, colour and R_F values of the coloured zones.

The colours obtained are: blue in daylight and ultra-violet light with *Herniarias glabra* saponosides; blue in daylight and pink in ultra-violet light with saponosides of *Saponaria officinalis* L. and *Gypsophila paniculata* Fisch. (Caryophyllaceae); magenta with primulic acid; cherry-red with the saponosides of *Calendula officinalis* L. (Compositae); violet with saponosides of *Polygala senega* L. (Polygalaceae); grey-green with escinol from *Aesculus hippocastanum* L. (Hippocastanaceae) and saponosides of *Quillaja Saponaria molina* (Rosaceae). The saponosides yield spots of the same colours as their aglycones when treated with phosphotungstic acid[4–6].

Full details will be published in *Dissertationes Pharmaceuticae*, Cracow, Poland (in English).

MICROBIOLOGY

A Diurnal Cycle for Holotrich Protozoa of the Rumen

In the last decade the study of the ciliate protozoa of the rumen has emphasized the investigation of individual species, rather than the ciliate population as a whole.

Several outstanding biochemical differences between Oligotrichs and Holotrichs have now been established *in vitro*[2–4]. However, *in vitro* work can delineate biochemical capabilities only. It cannot predict with certainty the activity of these organisms *in vivo*, and therefore if any attempt were made to estimate the value of the organism of the host animal, some knowledge of the ecological factors concerned is necessary.

Initial investigations into factors affecting the concentration of protozoa *in vivo*[5] have demonstrated a diurnal cycle for *Entodinium*. This cycle is in agreement with that obtained by other workers[6,7]. In the work described here a diurnal cycle for the holotrich protozoa was demonstrated.

Two merino wethers, fitted with rumen fistulæ, were fed a ration consisting of 500 gm. oaten chaff and 150 gm. lucerne chaff daily at 0900 hr. After 25 days on this ration, rumen samples were taken at 0, 1, 2, 3, 4, 6, 8, 10, 12, 16 and 20 hr. after feeding for 3 consecutive days. Samples were taken from the bottom of the rumen, and protozoal counts were made by the method described by Purser and Moir[5]. The holotrich species consisted entirely of *Dasytricha*.

Variations between sheep and between days were not significant, but statistical analysis revealed the highly significant ($P<0{\cdot}001$) regression $y=2132{\cdot}8-192{\cdot}3x+5{\cdot}1x^2$ between holotrich concentration (y) and the time in hours after feeding (x). This curve and the mean values are presented in Fig. 1.

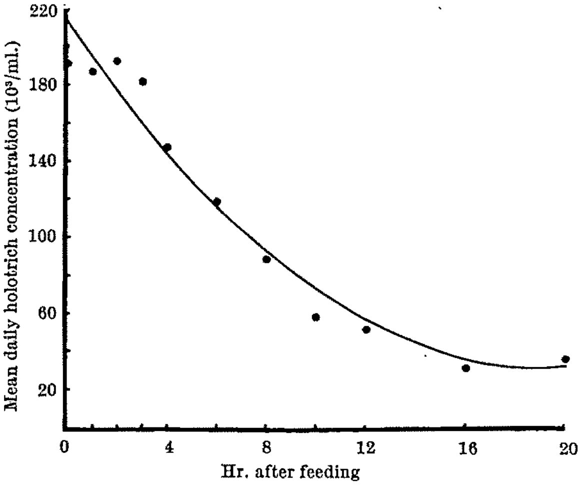

Fig. 1. Mean daily holotrich concentration (●) and the regression $y = 2132{\cdot}8 - 192{\cdot}3x + 5{\cdot}1x^2$ ($P < 0{\cdot}001$) between holotrich concentration (y) and the time in hours after feeding (x)

This diurnal cycle differs substantially from that exhibited by *Entodinium*. Whereas the concentration of holotrichs diminishes gradually until 20 hr. after feeding and then builds up rapidly to the original concentration, the recovery of *Entodinium* begins only 8 hr. after feeding. It has been suggested that the *Entodinium* cycle is controlled largely by physical dilution factors such as those due to feeding and salivation[5]. This would not appear to be the case for the holotrichs.

It is possible that the holotrich cycle is a reflexion of site differences, for the cycle implies a five-fold increase in the concentration in 4 hr. Boyne *et al.*[8], however, have failed to demonstrate a site difference and it is difficult to understand why a sudden change in site distribution should occur immediately before feeding.

This cycle has been confirmed afterwards in experiments under different nutritional régimes, but the factors governing it have not been explained. It is important, however, that this difference between holotrichs and oligotrichs *in vivo* is recognized, when samples are taken from animals for population analysis or for *in vitro* work.

Multiplication of Hansen's Bacillus in Complex Symbiosis *in vitro*

The work reported here followed a chance observation made while attempting, without success, to grow *Mycobacterium leprae* in a culture of *Entamoeba terrapinae*.

A fragment of leproma (*L*.II), about 1 c.c. in size, had been incubated for eight days, at 25° C., in saline buffered at *p*H 7·0 with phosphates. It was thereafter inoculated into the following culture medium, called *M-E-R* : (*a*) 30 gm. of powdered skimmed milk were suspended in 200 ml. distilled water ; this was autoclaved at 115° C. for 20 min. and cooled. (*b*) A whole egg (about 60 ml.) was aseptically homogenized either by hand-shaking in a flask containing glass beads or by the use of a mechanical mixer. (*c*) Milk (*a*) and egg (*b*) were mixed together and the mixture aseptically distributed (18 ml.) into sterile test tubes (dia. 25 mm.). (*d*) 2 ml. of an autoclave-sterilized solution of reductose (2·5 per cent in water) were aseptically added to each tube.

(A variant of medium *M-E-R*, used later on and called *M-E-R-M*, differed from it only in that solution (*a*) contained, in addition to the milk powder, 0·6 gm. gastric mucin.)

After incubation at 25° C. for several weeks, the microscopic examination of medium *M-E-R* inoculated with leproma *L*.II revealed the presence of an exceedingly large number of bundles of acid-fast bacilli recalling the typical 'globes' seen in the cells of lepromatous lesions.

However, only one out of three identical tubes inoculated likewise with fragments of the same leproma *L*.II gave such positive results. This suggested that contaminating microflora might be involved. From the single tube in which a multiplication of *M. leprae* had apparently occurred, four micro-organisms were isolated by standard procedures. Two were aerobes, an anthrax-like bacillus and a species of *Neisseria*. Two were anaerobes, an agar-liquefying organism and a gas-producing *Clostridium*.

My initial observation was repeated with three other specimens (*L*.I from the same patient as *L*.II, *L*.III and *L*.IV from two other patients) using the following procedure : (*a*) incubation of the fragment from leproma (about 1 c.c.) at 25° C. during at least 8 days in buffered saline (*p*H 7·0) ; (*b*) inoculation of the four micro-organisms together in a tube of medium *M-E-R* (or *M-E-R-M* in the case of specimen *L*.IV) and incubation during about 24 hr. (the medium is then clotted) ; (*c*) introduction of the macerated fragment (*a*) on the surface of (*b*) and incubation at 25° or 34° C., the tubes being tightly capped.

After one week, the clotted medium was liquefied and the proliferation of the symbionts could be stopped by the addition of either 'Sigmamycine' (a platinum loop of the dry product) or malachite green (1 ml. of a 0·5 per cent sterile solution in water) or both. However, this step was optional since it did not influence at all the evolution of *M. leprae* as observed monthly in Ziehl-stained smears.

In primary cultures, bundles of acid-fast bacilli increased and diminished in number alternately several times. They were preferably localized at the surface of the medium and in the ring which was progressively formed on the glass just over the surface. When occurring singly, bacilli were granular in appearance, but this happened very rarely as they were mostly seen in three-dimensional dense bundles or in one-plane clumps. Sometimes the agglomerates were rather loose and sometimes disintegrated into separate individuals in the immersion oil. There was no macroscopic difference between a culture in which *M. leprae* were multiplying and one inoculated with the symbionts only. Some observations, which, however, required further confirmation, led me to believe that the anthrax-like bacillus is the organism responsible for making medium *M-E-R* suitable for the growth of *M. leprae*.

Secondary cultures from the primary tubes were obtained in two ways. Either in medium *M-E-R*, using then a large inoculum representing at least one-fifth of the volume of culture, or on agar-media of various composition containing malachite green, using such an inoculum that, after partial desiccation, it left a heavy and creamy layer on the surface. Further sub-cultivation has so far been unsuccessful.

I now have on hand four suspensions very rich in bundles of *M. leprae* and aged respectively 12 (*L*.II), 11 (*L*.I and *L*.III) and 8 (*L*.IV) months. The possibility of subcultivating from them on an agar-medium gives us the hope of devising a method for the easier preparation and standardization of large amounts of lepromin.

Rhamnose for Detection and Isolation of *Azotobacter vinelandii* Lipman

During investigations on the utilization of pentoses by *Azotobacter* spp., *A. vinelandii* proved to be the only species able to utilize rhamnose as sole carbon source. The experiments were carried out with a nitrogen-free nutrient solution containing mineral salts, 0·1 per cent agar and 1·0 per cent rhamnose as source of carbon and energy. The growth was estimated by comparison with check cultures without carbon source, and in a few cases the nitrogen fixation was determined by Kjeldahl analysis.

Twenty-eight strains of *A. chroococcum* and nine strains of *A. beijerinckii* were tested, and all were found completely unable to utilize rhamnose. Of *A. vinelandii* ten strains were tested, and nine grew as well or better with rhamnose as sole source of carbon as with glucose. One strain showed only slight, but unmistakable, growth with rhamnose as carbon source. In the nitrogen fixation experiments 14·1–15·8 mgm. nitrogen was fixed per gm. of rhamnose decomposed, and 13·3–14·4 mgm. per gm. of glucose by the same strains.

This exclusive ability of *A. vinelandii* can be used for enrichment and isolation of this species from soils and other sources, where other *Azotobacter* species are present at the same time. In the presence of *A. chroococcum*, *A. vinelandii* cannot be detected or isolated by means of the ordinary enrichment cultures with glucose or mannitol as carbon source, because *A. chroococcum* always will be entirely dominant in such cultures. In nitrogen-free enrichment cultures with rhamnose as sole carbon source, however, *A. vinelandii*, when present, will develop profusely in 3–5 days. In the absence of *A. vinelandii* other *Azotobacter* species may develop, but only after a considerably longer incubation period (1–2 wk.).

A considerable number of cultivated soils has been tested by this technique, but *A. vinelandii* was found only in a few garden soils, and always together with *A. chroococcum*. It seems to be restricted to the most fertile soils, and to occur much more sparsely than the other *Azotobacter* species. It was not possible, however, to establish more precisely the factors determining the occurrence.

VIROLOGY

Mutation in Tobacco Mosaic Virus induced by a New Carcinogen, 4-Nitroquinoline N-Oxide

SEVERAL reports on the mechanism of mutation induced by nitrous acid in tobacco mosaic virus (TMV) phages T_2, T_4, $\varphi \times 174$, and in transforming deoxyribonucleic acid (DNA), have been published. These indicate that, with nitrous acid treatment, inactivation and mutation occur at the same time, and therefore either may be due to a single chemical alteration in nucleic acid.

Recent experiments on the effects of 4-nitroquinoline-N-oxide (4-NQO) on TMV have demonstrated that this new type of powerful carcinogen[1,2], within a certain wide range of concentrations: (1) does not inactivate TMV, although inactivating its ribonucleic acid in proportion to the concentration; (2) induces mutation in both TMV and TMV–RNA, but at a much higher rate in the latter than in the former. That 4-NQO may induce mutation without involving a change in the infectivity of TMV suggests the possibility of considering inactivation and mutation separately, and leads us to believe that the mutagenic mechanism of 4-NQO may be basically different from that of nitrous acid.

Inactivation tests. Aliquots of 1 γ/ml. TMV solution and of 290 γ/ml. solution of TMV–RNA extracted with phenol, both in 10^{-2} *M* phosphate buffer of *p*H 7·4, were each mixed with equal volumes of 4-NQO solutions in such final concentrations as shown in Table 1, and the mixtures were allowed to stand at room temperature for 60 min., after which infectivity of each mixture was assayed. For the assay 20 half-leaves of *Nicotiana glutinosa* were used, and the infectivity was judged by the number of typical lesions per half leaf. TMV used in this experiment was the ordinary mosaic strain of the Hatano Tobacco Experiment Station. The purification of the virus was made by three cycles of differential centrifugation (Spinco model *L*) of expressed sap from the diseased leaves of *Nicotiana tabacum* L. variety White Burley, which were gathered 3–4 weeks after the virus inoculation.

The results of this experiment are shown in Table 1, in which changes in infectivity according to the concentrations of 4-NQO are expressed by the variation of the mean number of local lesions per half leaf.

Table 1. EFFECTS OF 4-NQO ON THE INFECTIVITY OF TMV AND TMV–RNA

		Concentration of 4-NQO (mol.)				
		0	0.5×10^{-6}	1×10^{-6}	0.5×10^{-5}	0.5×10^{-4}	0.5×10^{-3}
TMV	4-NQO		46·0		46·0	38·4	42·0
	Solvent only (vol. per cent ethanol in water)	44·5	43·1 (0·002)		45·2 (0·02)	37·2 (0·2)	38·2 (2)
RNA	4-NQO	57·6		68·7	40·5	19·4	6·7

In another experiment, at a fixed concentration of 4-NQO (0.5×10^{-4} *M*), the incubation time was changed from 0 to 1 and 3 to 6 hr., and the infectivity expressed by the average number of local lesions produced in 16 half leaves was found to be almost constant, being 22·5, 22·4, 28·3, and 28·5 respectively.

Mutagenic effect. In this experiment, the mutagenic action of 4-NQO was estimated by the number of necrotic lesions produced in the leaf of *Nicotiana tabacum* L. variety *xanthi*. It is well established that the necrotic lesion is specifically produced by a mutant of TMV.

Aliquots of 0·45γ/ml. TMV solution and 400γ/ml. TMV–RNA solution, both in 10^{-2}*M* phosphate buffer of *p*H 7·4, were each mixed with 4–NQO in such final concentrations as listed in Table 2, kept at room temperature for 60 min., and then assayed. The total number of necrotic lesions produced in 15 leaves varies according to the concentrations of 4-NQO as shown in Table 2.

Table 2. PRODUCTION OF MUTANT LESIONS IN TOBACCO LEAVES BY 4-NQO

	Concentration of 4-NQO (mol.)			
	0	1×10^{-6}	0.5×10^{-4}	0.5×10^{-3}
TMV*	0	3	5	2
TMV	0	4	3	5
RNA	3	18	22	15

* Refers to an experiment in which 0·45 mgm./ml. TMV solution was incubated with 4-NQO for 60 min. and assay was made by diluting the mixture to 1 : 1,000 in order to avoid any possible effect of 4-NQO itself on the leaf

Control experiments in which 4-NQO solution alone was applied to tobacco leaves proved that no necrotic reaction was caused by this substance.

From the chemical point of view, it may be stated that the carbon at position 4 of the 4-NQO molecule forms a highly reactive centre, through the polar effect of the N-oxide and nitro groups, and can easily substitute with nucleophilic reagents with production of nitrous acid. Therefore, deamination by this nitrous acid also might be considered as a possible mechanism in the mutation of RNA induced by 4-NQO. As has been already reported[3,4], however, 4-NQO reacts rapidly only with SH groups at neutral *p*H and at room temperature, and under these conditions the ultra-violet absorption of this chemical is not affected when kept mixed with any other possible cellular nucleophilic group.

Also, when TMV–RNA is treated with 4-NQO, no change could be detected in ultra-violet absorption of either substance up to 24 hr. after mixing. Further investigations on the interaction between RNA and 4-NQO are under way.

It is well known that mutagenic and carcinogenic actions are often found in one and the same substance, and the fact that 4-NQO, besides its potent carcinogenic action, possesses also remarkable mutagenicity on *Aspergillus niger*[5] and *Streptomyces griseoflavus*[6] has been reported. 4-NQO, with its characteristic chemical reactivity, may eventually serve as a unique tool in the analysis of the mechanism of mutation on the molecular basis.

Hæmagglutinating Sub-units released from Newcastle Disease, Para-influenza 1 and Mumps Viruses by Treatment with Ether

IT was shown originally by Hoyle[1] that influenza viruses can be split by treatment with ether into sub-units, hæmagglutinin and soluble (nucleoprotein) antigen. Recently, a study on the sub-units of Newcastle disease and mumps viruses has been published, which indicated that these viruses do not liberate hæmagglutinin on treatment with ether, but only filamentous particles of nucleoprotein nature, exhibiting complement-fixation activity[2]. Working with the Blacksburg strain of Newcastle disease, the Sendai strain of para-influenza 1 and the Enders strain of mumps viruses, we found that these viruses, on treatment with ether, released both nucleoprotein antigen and hæmagglutinin.

The viruses were isolated from infectious allantoic fluids by two cycles of alternate low- and high-speed centrifugations. Concentrated preparations containing 10^4–10^5 hæmagglutination units per ml. were stirred and treated with a half volume of ether at 15° C. for 90 min. The aqueous phase was separated by low-speed centrifugation and, after removal of the water-soluble ether, clarified by centrifugation at 17,000g for 45 min. to remove the intact or only partially split virus. On electron microscopic examination of the supernatant, predominantly spherical particles of about 30 mμ diameter and, in the case of Newcastle disease and mumps viruses, also long filaments, similar to those described by Schäfer and Rott[2] and Horne *et al.*[3], were seen. The highest yield of hæmagglutinin was obtained with Newcastle disease virus, the number of the hæmagglutination units recovered indicating that the particle of this virus contains at least four hæmagglutinating sub-units.

The hæmagglutinins were isolated from the suspensions of sub-units by repeated adsorption on to fowl erythrocytes and by subsequent elution. In the case of Newcastle disease virus, however, this procedure did not assure the complete removal of hæmagglutinins from the suspension of sub-units. The hæmagglutinin could be concentrated and further purified by sedimentation at 145,000g for 90 min.

The hæmagglutinins of the viruses investigated were non-infectious; they agglutinated fowl and guinea pig erythrocytes to the same dilution, although the virus preparations, from which they were derived, showed higher hæmagglutination titres with fowl than with guinea pig erythrocytes. They exhibited neuraminidase activity and liberated from virus hæmagglutination inhibitor, isolated from bovine serum, about the same amount of sialic acid, calculated per hæmagglutination unit, as the corresponding viruses. They did not exhibit hæmolytic properties, although the viruses investigated are all hæmolytic[4]. They were precipitated quantitatively on dialysis against distilled water, but the precipitate could not be re-dissolved in the original solvent (phosphate buffered saline pH 7·2). They could be stored at 3° C. for several months without any decrease in hæmagglutination activity. They were not pelleted under conditions (36,000g for 45 min.) sufficient for almost quantitative sedimentation of the viruses. On electron microscopic examination of samples of hæmagglutinin, spherical particles of about 30 mμ were predominant (Fig. 1).

Immune guinea pig sera were prepared against the three viruses investigated, their hæmagglutinins and, in the case of the Sendai strain of para-influenza and mumps viruses, also against the nucleoprotein antigens, respectively. The viruses did not show any relationship by cross-neutralization, hæmagglutination inhibition and complement-fixation tests. The

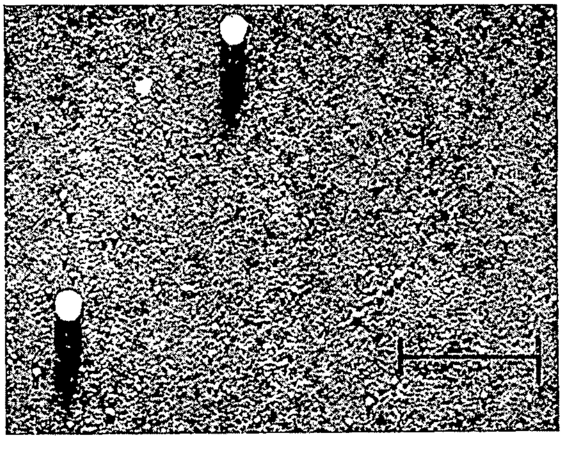

Fig. 1. Electron micrograph of para-influenza 1 virus hæmagglutinin. Scale, 1μ

same holds for their sub-units, as estimated by cross complement-fixation reactions, and in the case of hæmagglutinin also by cross-hæmagglutination inhibition tests.

CYTOLOGY

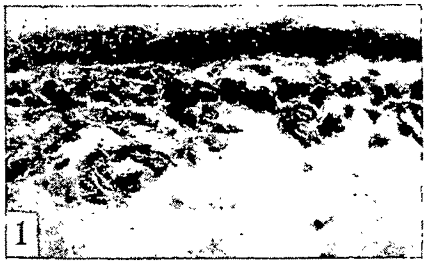
The Stainable Mucin of Joint Tissues and Synovial Fluid

Joint synovial fluid is considered to be a dialysate of blood with added mucin, which consists of hyaluronic acid[1]. The source of the latter is uncertain, but the belief is current that the synovial membrane is the likely site of formation. Articular cartilage is said to contain no hyaluronic acid, and the sulphated mucopolysaccharide it does contain is not found in appreciable quantity in synovial fluid. Synovial membrane is not lined by an epithelium, but is composed of fine, compact connective tissue of variable cellularity[2], the cells being indistinguishable from fibroblasts by electron microscopy[3]. Claims have been made that the 'membrane', especially in its superficial part, stains with mucicarmine[4-6], and also reacts with the periodic acid – Schiff technique[3]. Metachromasia, which might indicate the presence of hyaluronic acid in the membrane, has not been unequivocally demonstrated; some claim that the membrane is metachromatic[6,7], but others deny it[3,5].

In the present work, specimens of synovial membrane were removed immediately after death from the parapatellar region of the knee-joint of 5 rats, 10 guinea pigs, 10 rabbits, 10 cats, 5 dogs, 5 sheep and 4 monkeys, and from 4 human subjects at post-mortem. In addition, specimens of articular cartilage were taken from the distal femoral condule, and of fibrocartilage from the articular disks of rats, guinea pigs, rabbits, cats, dogs and monkeys. The fixative most often employed was 80 per cent alcohol, but Heidenhain's 'susa' was also used; the results were similar with both fixatives. Paraffin sections from each specimen were stained with hæmatoxylin and eosin, Southgate's mucicarmine and 0·5 per cent aqueous toluidine blue, whereas others were treated by the periodic acid – Schiff technique. A hyaluronidase (bovine, testicular) control was used with all the mucin-staining methods and a saliva (diastase) control as well with the periodic acid – Schiff technique.

The results obtained with each technique were precisely the same in all species examined. The distribution of mucinous material in the tissues, as shown by mucicarmine staining, was similar to that of the metachromatic material revealed with toluidine blue, but was different from the mucopolysaccharide distribution shown by the periodic acid – Schiff technique.

In synovial membrane, the only staining observed with mucicarmine was a faint coloration of the intercellular material, similar to that of connective tissue fibres generally, and with toluidine blue no metachromasia was observed, except in mast cells in the deeper part of the membrane. With the periodic acid – Schiff technique, some specimens of mucous membrane showed a weak reaction in the fibrous groundwork between the cells; but it was no greater than that given by connective tissue fibres in other parts of the section, and normally was weaker than the reaction seen in the walls of blood vessels. In a few instances, a fairly thick layer of precipitated synovial fluid was present, in contact with, or slightly separated from, the synovial membrane, and this material stained strongly with mucicarmine (Fig. 1), and stained metachromatically with toluidine blue. Only a weak reaction was given with the periodic acid – Schiff technique. The results obtained with all three techniques were uninfluenced by pre-treatment of the section for 24 hr. in buffered hyaluronidase at *p*H 6·9.



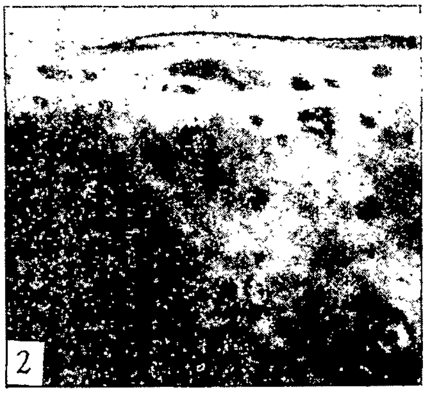


Fig. 1. Mucicarmine and hæmatoxylin preparation of human synovial membrane. Layer of precipitated synovial fluid is strongly stained with mucicarmine. (× 360)

Fig. 2. Mucicarmine and hæmatoxylin preparation of rabbit articular cartilage. General matrix is irregularly stained, but perilacunar haloes strongly stained; less staining near free surface. (× 460)

It is generally appreciated that articular cartilage contains stainable mucin, and that the distribution of the material shown with the periodic acid – Schiff technique differs from that revealed with mucicarmine. This was confirmed in the present work. With the periodic acid – Schiff technique, the whole matrix reacted moderately and evenly throughout, but no reaction was seen in the shrinkage spaces within the lacunæ. The cartilage cells, as is well known, contain glycogen, and it was confirmed that they give a positive periodic acid – Schiff reaction, which is abolished by pre-treatment with saliva. The distribution of material stainable with mucicarmine was found to be similar to that of metachromatic material, but was quite different from that of periodic acid – Schiff positive material. The matrix immediately around the lacunæ stained strongly, in the form of haloes, but the staining of the general matrix was blotchy and irregular: towards the free surface of the cartilage there was a marked decline in the amount of stainable material in both the general matrix and in the perilacunar haloes, but small amounts were present here and there, even adjacent to the free surface (Fig. 2). The claim that cartilage cells contain stainable mucin was not confirmed; under oil immersion, it was observed that the material stainable with mucicarmine and metachromatic with toluidine blue occupies the shrinkage space between the cell and lacunar margin, and is often seen to be drawn into strands where the cell has shrunk away from the lacuna. The histological picture suggests that the cell secretes a mucinous material into the lacuna, whence it is incorporated into the perilacunar matrix, and thence passes into the general matrix, where it has an irregular distribution, and declines in amount towards the free surface of the cartilage. In articular disks, the cartilage is usually of the hyaline variety towards their free margins, and here the stainable mucin showed the same distribution as that described here. As in synovial fluid, pre-treatment with hyaluronidase did not influence the periodic acid – Schiff reaction, nor the mucicarmine or the metachromatic staining.

From the present work, it is concluded that there is insufficient evidence to show that the stainable mucin of synovial fluid is produced, at least in any quantity, from normal synovial membrane. Regarding articular cartilage, it can be said that it contains an appreciable quantity of material which stains with mucicarmine and is metachromatic with toluidine blue, and also contains material with a different distribution, which gives a positive reaction with the periodic acid – Schiff reagent. Precipitated synovial fluid also contains such material, and in neither site was the staining result influenced by hyaluronidase. Although cartilage may not contain hyaluronic acid, it seems conceivable that mucinous material of some kind may be added to synovial fluid from the wear and tear of cartilage, though present chemical evidence is not in accord with this view.

Nucleic Acid Content of Haploid and Diploid Cells of *Protomyces inundatus*

Protomyces is a fungus of uncertain taxonomic position and its life-history is incompletely known. In particular, previous investigators[1,2] have been unable to determine satisfactorily the position of meiosis. In the course of a taxonomic investigation into the genus *Protomyces*, a number of standard staining techniques was employed in an attempt to demonstrate meiosis, but up to now none has proved satisfactory. In view of the recent demonstration of a linear relationship between deoxyribonucleic acid (DNA) content and ploidy in a polyploid series of *Saccharomyces*[3], we decided to use DNA estimation as the basis of a method for distinguishing between haploid and diploid stages in *Protomyces*.

Stock cultures of *P. inundatus* were established on its natural host *Apium nodiflorum*, in the greenhouse: chlamydospores formed readily in such infections. Single-spore cultures were established by means of a dummy objective from: (*a*) unfused endospores obtained from germinating chlamydospores; (*b*) fusion bodies formed by the conjugation of two endospores; (*c*) cultures of budding cells obtained from mycelium within the host by plating out sterilized fragments of leaf tissue containing only vegetative mycelium.

Cultures obtained by all three methods were grown on a basal semi-synthetic liquid medium[4] with glucose as carbon source on a shaker at 20° C. The results were converted to a per cell basis by counting the cells in a small aliquot by means of a hæmocytometer. Nucleic acids were determined by the method of Ogur *et al.*[3]. RNA, together with metaphosphate, was extracted in 10 per cent perchloric acid overnight at 3° C. Labile and total phosphate were determined colorimetrically using ammonium molybdate and stannous chloride, and from the values obtained metaphosphate and RNA phosphate[5] were calculated. RNA was also determined by the orcinol method of ribose estimation[6] and gave results in good agreement with those obtained by phosphorus estimation. DNA was extracted in 5 per cent perchloric acid at 70° C. for ten minutes and determined as total phosphate. Insoluble nitrogen was determined by the semi-micro Kjeldahl's method. Cell volume was calculated from measurements of major and minor axes of a hundred cells, assuming the shape of the cells to be that of an ellipsoid.

The results obtained are presented in Table 1. In a second experiment, confined to the determination of nucleic acids, the relative amounts of DNA and RNA in unfused endospores and fusion bodies were similar to those found in the first experiment. Different values on a per cell basis were obtained, however, possibly because the cultures were gathered 12 days after inoculation as opposed to 25 days in the first experiment; the cells were probably in a more actively dividing condition than those analysed in the first experiment.

Table 1. NUCLEIC ACID CONTENTS AND OTHER CHARACTERISTICS OF CELLS FROM THREE STAGES OF *P. inundatus*

	Cultures derived from:		
	(*a*) Unfused endospores	(*b*) Fusion bodies	(*c*) Mycelium in host
DNAP/cell (μgm.)	$1{\cdot}42 \times 10^{-9}$	$2{\cdot}85 \times 10^{-9}$	$2{\cdot}84 \times 10^{-9}$
RNAP/cell (μgm.)	$1{\cdot}70 \times 10^{-8}$	$1{\cdot}85 \times 10^{-8}$	$1{\cdot}84 \times 10^{-8}$
Meta-P/cell (μgm.)	$2{\cdot}19 \times 10^{-8}$	$2{\cdot}35 \times 10^{-8}$	$2{\cdot}34 \times 10^{-8}$
Insoluble N/cell (μgm.)	$1{\cdot}59 \times 10^{-7}$	$1{\cdot}97 \times 10^{-7}$	$1{\cdot}77 \times 10^{-7}$
Dry weight/cell (μgm.)	$5{\cdot}77 \times 10^{-6}$	$5{\cdot}68 \times 10^{-6}$	$5{\cdot}62 \times 10^{-6}$
Vol./cell (μ^3)	53·21	55·43	54·77

The above results indicate that there is a doubling of the DNA content following fusion and that this is maintained throughout the rest of the life-cycle up to chlamydospore formation. There is thus a strong suggestion that meiosis occurs in the chlamydospores, in the stage preceding the formation of the endospores. Having now ascertained where meiosis is likely to occur, and by concentrating cytochemical investigations on this stage, it should be possible to find out if this is the case or not. The metaphosphate content of the cell is high, and this may be the reason why most nuclear stains tried, stained the cytoplasm as well as the nucleus. By growing single spore colonies on a medium devoid of phosphorus it has been possible to show the nucleus. One of the striking features of the results is that the RNA content of diploids is only very slightly greater than that of haploids. This situation is in contrast to that found by Ogur *et al.*[3] in yeast, where the RNA content, like that of DNA, was an indication of ploidy. The values of metaphosphate, dry weight, insoluble nitrogen and volume, like that of RNA, are all similar in haploid and diploid cells of *P. inundatus* and the only significant difference detected is in the DNA content.

The measurement of DNA content appears to be a valuable method of determining the position of meiosis in cases where cytological methods give unsatisfactory results. While the DNA content in both *Protomyces* and yeast appears to be a reflexion of ploidy, the RNA content appears to be related to the metaphosphate, insoluble nitrogen, dry weight and volume of the cell. *Allomyces*[7] and *Enteromorpha*[8] like *Protomyces* are examples of natural diploids the cells of which are about the same size as those of haploids. In most cases where diploids are produced artificially, for example *Aspergillus*[9] and *Aspidium*[10], they are double that of the haploids. Yeast is one of the few cases found in Nature in which diploids are twice the size of haploids. A knowledge of the RNA contents of haploid and diploid cells of other types of organisms would be of great interest.

Giant cells have been obtained in our cultures by the use of camphor[11] and are being examined biochemically. By comparing these giant cells, which may be diploids, with naturally occurring ones we hope to elucidate the contrast between diploid cells of *Protomyces* and those of yeast.

GENETICS

Pulmonary Tumours, Group VII and Sex in the House-Mouse

Although the exact number of factors concerned in the inheritance of susceptibility to pulmonary tumours in the house-mouse is still unknown, experiments by various workers[1-4] have suggested the presence of one major factor in linkage group VII: this factor is here termed *Tm*. A series of experiments has been undertaken to confirm the existence of this factor and to obtain an estimate of its position in group VII. The following is a preliminary report of the results of the first experiments in the series.

Mice of the following stocks were used: high susceptibility—strain *A/Cam*; low susceptibility—vestigial tail–wavy-2 (*vt–wa*-2); homozygous Rex (*Re*); *CBA/FaCam*

Strain *A* animals of both sexes were mated to the two mutant stocks, and the F_1, again of both sexes, were back-crossed to multiply recessive, low susceptibility stocks. The offspring, which totalled more than 1,000, were injected intraperitoneally at eight weeks of age with 0·5 mgm. 1 : 2 : 5 : 6-dibenzanthracene suspended in 0·5 ml. horse serum. They were killed six months later and their lungs placed immediately in Tellyesniczky's fluid. The number of nodules present on the surface was counted 24 hr. later. This number was taken as a measure of susceptibility. For a preliminary analysis all animals without tumours were classified as non-tumourous and animals with tumours, whether one or more were present, were classified as tumourous.

wa-2, *vt* and *Re* were chosen as markers to represent group VII as they have minimal effect on weight. This is of importance, because weight is known to affect susceptibility, and interaction between weight and susceptibility can mimic linkage in linkage experiments that only involve one of the linkage phases.

The recombination values obtained for *wa*-2–*Tm* and *vt–Tm* were different from 50 per cent at the 1 per cent level of probability (Table 1). These values, and the others involving *Tm*, are calculated from coupling-phase data only. Further experiments in this series will provide repulsion-phase data, thus giving balance and allowing corrections for disturbed viability and misclassification. However, the data related to *Tm* and sex are balanced (that is, there are approximately equal quantities from both phases), and controls are available in the form of data from females heterozygous for *Tm*. The significantly low value for *Tm*–sex† is heterogeneous from a 'linkage' point of view and is due to the homogeneously higher susceptibility of females[4].

Table 1. Recombination Values involving *Tm*

Pairs of factors	Phase balance	n	r	χ^2 (1 : 1)	$\frac{r}{r+n}$
vt — *Tm*	*U*	415	334	8·76*	44·593
wa-2 — *Tm*	*U*	421	328	11·55*	43·792
Tm — sex	*B*	134	159	2·13	54·266
Tm — sex †	*B*	255	201	6·39‡	44·079
Tm — sex	*U*	58	69	0·95	54·331
Tm — *Re*	*U*	60	67	0·39	52·756

n, non-recombinants; *r*, recombinants; *U*, unbalanced data; *B*, balanced data.

* Significant at the 1 per cent probability-level.

† Significant at the 5 per cent probability-level.

‡ Data from heterozygous females.

The significant recombination values confirm the association between susceptibility and group VII and clearly demonstrate the existence of a susceptibility locus (or loci) in this region of the linkage group. As the order in group VII is known to be *wa*-2–*vt*–*Re*, and as *Re* gives a value close to 50 per cent with *Tm*, *Tm* is best accommodated on the opposite side of *wa*-2 to *Re*: the tentative order being *Tm*–*wa*-2–*vt*–*Re*. The order is tentative because misclassification of *Tm* certainly occurs to some degree in these results. An excess of *Tm* can occur when mice with any number of tumours are classified as *Tm*+, and this may be severe enough to mask the true position. This diffi-

Table 2. RECOMBINATION VALUES FOR THE GROUP VII MARKERS AND SEX

Pairs of factors	Phase balance	n	r	χ^2 (1 : 1)	$\frac{r}{r+n}$
vt — *wa*-2	*U*	1,346	459	435·88*	25·429
vt — sex	*B*	386	383	0·01	49·805
vt — sex†	*B*	606	594	0·12	49·500
wa-2 — sex	*B*	370	353	0·40	48·824
wa-2 – sex†	*B*	525	557	0·95	51·479
Re — sex	*U*	78	90	0·86	53·571

The data not involving *Tm* are twice as large as the rest because they include all the mice that were classified at birth for sex, *wa*-2, *vt* and *Re* and which died before classification for *Tm* was possible.

* Significant at the 1 per cent probability-level.

† Data from heterozygous females.

culty should be cleared up when repulsion-phase linkage data are available.

The experiments also give data on the partial sex-linkage of group VII (Table 2), a matter about which there has been some doubt. There is no indication of partial sex-linkage such as Wallace[5] found for *wa*-2 and shaker-2 (*sh*-2) or as Carter and Phillips[6] found mimicked in the offspring of heterozygous females.

More detailed discussion and analysis of these results are to be published elsewhere.

I thank Dr. M. E. Wallace for constant advice and encouragement and much helpful discussion. Part of this work was supported by a scholarship from the Medical Research Council.

Existence of Multiple Sex Genotypes in the Hermaphrodite Polychaete Worm *Ophryotrocha puerilis siberti*

IT was demonstrated in 1951 that *Ophryotrocha puerilis* shows a marked sex variability, as the age when each individual passes from the male to the female sex phase is highly variable. *O. puerilis* can thus be considered as an unbalanced hermaphroditic species[1].

It was shown later that individuals of *Ophryotrocha puerilis* collected in the Bay of Naples and individuals of the same species collected in Plymouth Sound belong to two different sub-species[2]. Small oocytes first appear in isolated Naples individuals at a mean size of eighteen chætigerous segments, whereas in isolated Plymouth individuals they appear at a mean size of twenty chætigerous segments and therefore the two sub-species differ in the relative duration of the male and female phases. The former hypothesis of a genetical basis for sex variability inside each population is thus strongly supported.

The genetic nature of such variability was later demonstrated by the successful selection for the prolongation of the male phase and for the anticipation of the female phase[3]. Individuals that never passed to the female phase or which began to show oocytes at the mean length of 25 segments only were obtained at the fourth generation from a strain which passed to the female phase at a mean length of about 18 segments in the first generation. Selection against duration of the male phase produced individuals which began to show oocytes at 11 segments in a generation the individuals of which passed to the female phase at a mean length of 13 segments.

This series of experiments, which was interrupted in 1955, lead to a revision of the traditional interpretation of sex determination in hermaphrodites, and it has been resumed using the same technique but examining groups of more numerous individuals in each generation. Individuals have been examined three times a week.

Experiments are still going on, and their results are confirming and extending results obtained in the first series of experiments.

Crosses have started from one pair of individuals which were collected at Roscoff and thus belong to the Atlantic sub-species *O. puerilis siberti*. Their sons ($n = 148$), which form the 0 generation, pass from the male to the female phase at a mean length of 18·8 segments, which is a little lower than the mean which is characteristic for the sub-species. In the following generation the sons of the specimens that were selected for maleness ($n = 350$) begin to show oocytes at mean values of 20·9 segments, the sons of the specimens selected for femaleness ($n = 340$) pass to the female phase at about 18 segments and the mean falls a little below 17 segments in the second generation ($n = 285$, $\overline{m} = 16{\cdot}85$). Selection for the anticipation of the female phase at generation 3 has given a mean value of 16·44 in 170 individuals examined so far.

The mean lengths for the appearance of oocytes in the groups selected for the duration of male phase rise in generation 2 to about 22 segments ($n = 291$, $\overline{m} = 21{\cdot}75$) and they rise again very nearly 23 segments at generation 3.

Crosses between individuals of the second generation, which showed oocytes at 15 segments, and individuals of the first generation, which showed oocytes at 23 segments, produced groups of individuals (370 individuals altogether) which passed to the female phase at mean lengths between 18·64 and 18·69 segments, which scarcely differ from the mean obtained in the 0 generation (18·79).

This last result was to be expected on the basis of the crosses published in 1955. It falls in line with results obtained in classical research work on polygenic determination. Present experiments are showing the efficiency of selection in the next generations, which are now being investigated.

The various types of crosses and the various results inside the two lines selected for maleness and for femaleness, which may be called arrhenogenous and thelygenous lines[4], will be discussed in detail in a forthcoming paper. The existence of multiple sex genotypes is nevertheless wholly confirmed in *Ophryotrocha*. The so-called polyfactorial sex determination was demonstrated some time ago for some gonochoric cyprinodont species by Breider and by Kosswig[5], for the hermaphrodite polychæte worm *Ophryotrocha* in 1955. This mechanism now awaits application to the phenomena of sex variability in heterogonic cycles[4], and also to the phenomena of relative sexuality as defined by Hartmann.

AGRICULTURE

Amines in Silage

In 1908 Russell, referred to by Watson[1], reported that silage contained "in addition to ammonia, amines such as pentamethylene diamine, betaine, adenine, and other unidentified purin bodies". Barnett, in his book about silage fermentation[2], expressed the opinion that putrescine and cadaverine would be present in very poor silages as products of putrefaction.

In the course of work on the chemical composition of grasses and legumes during the ensiling process, silage was prepared in plastic jars (each jar containing about 2 kgm. fresh material) from fresh green maize and lucerne. After 83 days, the maize silage had a *p*H of 3·8 and showed all the characteristics of normal fermentation. The presence of tyramine was established by chromatography[3]. Further proof of its identity was obtained by cutting out an area corresponding to the tyramine spot on the chromatogram which was not developed by ninhydrin, and eluting with warm 95 per cent ethanol. The ethanol was evaporated *in vacuo*, and the residue tested for tyramine by the 1-nitroso-2-naphthol reagent[4].

When fresh green maize was tested for amines before ensilage, no tyramine was found.

Silage from fresh green lucerne was prepared under the same conditions with the further addition of 1·0 per cent sugar. In addition to tyramine at least two more amine spots appeared to be present. One had R_F 0·81 and is possibly phenylethylamine (blue colour when developed with ninhydrin); the other one had R_F 0·50 (brown colour), and might be serotonin. The eluting solvent used was butanol/acetic acid/water (120 : 30 : 50).

Tyramine and serotonin are known to exert strong physiological effects in the animal body. The possibility that these amines might interfere with consumption of silage by cattle is under investigation.

MATHEMATICS

Relationship between the True and Mean Anomalies

For an elliptical orbit, we have the following relations[1]:

$$r = \frac{a(1 - e^2)}{1 + e\cos\nu} \qquad \frac{\mathrm{d}M}{\mathrm{d}\nu} = \frac{r^2}{a^2\sqrt{(1 - e^2)}}$$

whence,

$$\frac{\mathrm{d}M}{\mathrm{d}\nu} = \frac{(1 - e^2)^{3/2}}{(1 + e\cos\nu)^2} \tag{1}$$

where r, a, and e have their usual meanings, and ν and M are the true and mean anomalies, respectively.

The solution of equation (1) has been obtained in various ways[2,3] giving[2]:

$$M = \nu + 2\sum_{n=1}^{\infty}(-1)^n\left\{\frac{1}{n} + \sqrt{(1 - e^2)}\right\}\varkappa^n \sin n\nu \tag{2}$$

where $\varkappa = \frac{1}{e}\left\{1 - \sqrt{(1 - e^2)}\right\}$, which gives[4], by Lagrange's Expansion Theorem[5],

$$\varkappa^n = \left(\frac{e}{2}\right)^n\left\{1 + n\sum_{\lambda=1}^{\infty}\frac{(2\lambda + n - 1)!}{\lambda!(\lambda + n)!}\left(\frac{e}{2}\right)^{2\lambda}\right.$$

As far as terms in e^4, equation (2) gives[3]:

$$M = \nu - 2e\sin\nu + \left(\frac{3e^2}{4} + \frac{e^4}{8}\right)\sin 2\nu - \frac{e^3}{3}\sin 3\nu + \frac{5e^4}{32}\sin 4\nu$$

A simplified version of the solution to equation (1) enables this expansion to be derived rather quickly.

This solution may be obtained as follows:

We have, from equation (1),

$$\frac{\mathrm{d}M}{\mathrm{d}\nu} = (1 - e^2)^{3/2}(1 + e\cos\nu)^{-2}$$

$$= (1 - e^2)^{3/2}\left\{1 + \sum_{n=1}^{\infty}(-1)^n(n + 1)e^n\cos^n\nu\right\} \tag{3}$$

Now

$$2^{n-1}\cos^n\nu = \sigma + \sum_{\lambda=0}^{\left[\frac{n}{2}\right]}\binom{n}{\lambda}\cos(n - 2\lambda)\nu,\ n > 0$$

$$\text{where, } \sigma = \tfrac{1}{2}\binom{n}{\frac{n}{2}}, \text{ for } n \text{ even}$$

$$= 0, \text{ for } n \text{ odd}$$

and $\left[\frac{n}{2}\right] \equiv$ integral part of $\frac{n}{2}$.

Hence, equation (3) becomes:

$$\frac{\mathrm{d}M}{\mathrm{d}\nu} = (1 - e^2)^{3/2}\left[1 + 2\sum_{n=1}^{\infty}(-1)^n(n + 1)\left(\frac{e}{2}\right)^n \left\{\sigma + \sum_{\lambda=0}^{\left[\frac{n}{2}\right]}\binom{n}{\lambda}\cos(n - 2\lambda)\nu\right\}\right] \tag{4}$$

But,

$$1 + 2\sum_{n=1}^{\infty}(-1)^n(n + 1)\left(\frac{e}{2}\right)^n\sigma = (1 - e^2)^{-3/2}$$

Hence, equation (4) becomes:

$$\frac{\mathrm{d}M}{\mathrm{d}\nu} = 1 + 2(1 - e^2)^{3/2}\sum_{n=1}^{\infty}\sum_{\lambda=0}^{\left[\frac{n}{2}\right]}(-1)^n(n + 1)\left(\frac{e}{2}\right)^n\binom{n}{\lambda}\cos(n - 2\lambda)\nu$$

Integrating with respect to ν, we obtain the solution in the form:

$$M = \nu + 2(1 - e^2)^{3/2}\sum_{n=1}^{\infty}\sum_{\lambda=0}^{\left[\frac{n}{2}\right]}(-1)^n(n + 1)\left(\frac{e}{2}\right)^n\binom{n}{\lambda}\frac{\sin(n - 2\lambda)\nu}{n - 2\lambda} \tag{5}$$

since M and ν vanish together.

From this equation, it can be seen that the coefficient of $\sin\nu$ is:

$$2(1-e^2)^{3/2}\sum_{n=1}^{\infty}(-1)^n(n+1)\left(\frac{e}{2}\right)^n\sigma' \qquad (6)$$

$$\text{where, } \sigma' = \begin{pmatrix} n \\ \frac{n-1}{2} \end{pmatrix}, \text{ for } n \text{ odd}$$

$$= 0, \text{ for } n \text{ even.}$$

Extracting $\left(\frac{e}{2}\right)$ from equation (6) we obtain the expression :

$$e(1-e^2)^{3/2}\sum_{n=1}^{\infty}(-1)^n(n+1)\left(\frac{e}{2}\right)^{n-1}\sigma'$$

But,

$$\sum_{n=1}^{\infty}(-1)^n(n+1)\left(\frac{e}{2}\right)^{n-1}\sigma' = -2(1-e^2)^{-3/2}$$

Hence, the coefficient of sin ν is $-2e$ for all n, and the solution (5) may be expressed as :

$$M = \nu - 2e\sin\nu + 2(1-e^2)^{3/2}\sum_{n=2}^{\infty}\sum_{\lambda=0}^{\left[\frac{n}{2}\right]}(-1)^n(n+1)\left(\frac{e}{2}\right)^n\binom{n}{\lambda}\frac{\sin(n-2\lambda)\nu}{n-2\lambda}$$

where $n \neq 2\lambda + 1$.

As from equation (2), we obtain as far as terms in e^4, the usual expression :

$$M = \nu - 2e\sin\nu + \left(\frac{3e^2}{4}+\frac{e^4}{8}\right)\sin 2\nu - \frac{e^3}{3}\sin 3\nu + \frac{5e^4}{32}\sin 4\nu$$

The Complete *n*-Point Graph

A COMPLETE n-point graph consists of n points in a plane (or on the surface of a sphere), each joined to all the others by lines, not necessarily straight. The problem of determining the minimum number of intersections, m, for various values of n is being investigated.

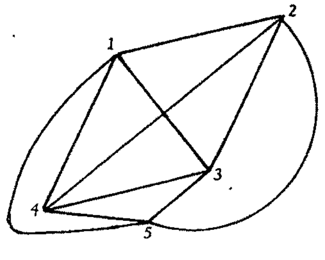

Fig. 1

Fig. 1 shows a complete 5-graph which has 1 intersection, this being the minimum for $n = 5$.

The problem does not appear tractable analytically, so it was programmed for the University of London *Mercury* computer. The programme was written on the assumption that a minimum for $n + 1$ points can be obtained by adding an extra point in a suitable place on a minimum solution for n points. However, the computations have proved that this apparently natural assumption is false : two different minimum configurations for $n = 7$, $m = 9$ were taken and one led to the true minimum $n = 8$, $m = 18$, while the other led to $n = 8$, $m = 19$.

I thank Dr. A. D. Booth for help and encouragement.

STATISTICS

A Basic Notion in the Theory of Cognitive Systems

IN a previous communication[1] a network was described which would resolve linear relations among continuous input signals. It was indicated that for times greater than the resolution time (for some intrinsic error criterion) this net could follow changing relations and thus, by means of other nets, one could observe the relations between relations and so on. The process described is essentially that of ascending a scale of logical types. To characterize this more generally, consider a binary time series $y(t)$ of discrete time t. If this contains $2^r \leqslant 2^m$ structures of length it can be described by a logical function :

$$y(t+1) = f\{y(t)\ \ldots\ y(t-m),\ x_1(t)\ \ldots\ x_r(t)\} \qquad (1)$$

where it is supposed that the variance $\mu(x)$ has been minimized. The x's then describe, roughly speaking, which of the 2^r structures is under consideration. But this by no means determines the function uniquely; there is an enormous redundancy of something like $2^{2^r}(2^m/m)$ possibilities (as examination of the periodic case, $r = 0$, shows). However, for realization of logical functions it is well known that there are nets which are minimal with respect to number $v(f)$ of connexions required. In this case one may expect to obtain effective unicity by requiring the minimization of a function such as :

$$H(f, x) = \log v(f) + \log \mu(x) \qquad (2)$$

If $H(f, x)_{\text{min.}} < \log \mu(y)$ we say that (1) is a resolving transformation $f^{(1)}$ of type 1, written formally as :

$$y = f^* x^{(1)} \qquad (1')$$

Clearly the process could be repeated on the variables x to obtain higher types, but this requires a notion, in a certain sense dual to resolving transformation, which I call selective punctuation, $y^{(1)}$. This is the insertion of a sequence $y^{(1)}$ of length m into the signal and may be regarded as the formalization of an experiment to test whether the $x^{(1)}$ so generated by the natural continuation of $y^{(1)}$ can be resolved into an $f^{(2)}$, and so on.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, May 29

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. David Attenborough: "Travels in Madagascar".

Tuesday, May 30

Laboratory Animals Centre (at the Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2), at 10 a.m.—Symposium on "Hazards of the Animal House".

Institution of Chemical Engineers (at the Royal Commonwealth Society, Craven Street, Strand, London, W.C.2), at 2.30 p.m.—Symposium on "Biochemical Engineering".

Tuesday, May 30—Friday, June 2

Seventeenth Radio and Electronic Component Show (at Olympia, London).*

Wednesday, May 31

British Association for Commercial and Industrial Education (at County Hall, London, S.E.1), at 9.30 a.m.—Exhibition and Conference on "Successful Instruction".

University of London (in the Physiology Lecture Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Dr. David B. Sprinson (Columbia University): "The Reactions of Aromatic Biosynthesis".*

Institute of Information Scientists (at the Swedenborg Society Hall, 20 Bloomsbury Way, London, W.C.1), at 6.15 p.m.—Annual General Meeting. 7.30 p.m.—Miss M. Webb: "Some Thoughts on the National Science Reference Library".

Thursday, June 1

Institute of Physics and the Physical Society (in the Physics Department of Imperial College, Prince Consort Road, London, S.W.7), at 2.30 p.m.—Dr. R. W. Twiss: "On Re-designing Michelson's Stellar Interferometer"; Mr. K. Hacking: "Secondary Flare in Lenses".

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. D. W. Dresser: "A Study of the Adaptive Secondary Response to a Protein Antigen in Mice"; Mr. J. G. Howard and Mr. M. F. A. Woodruff: "Effect of the Graft-versus-Host Reaction on the Immunological Responsiveness of the Mouse".

Thursday, June 1—Saturday, June 3

British Society for Immunology (in the Edward Lewis Theatre of the Middlesex Hospital Medical School, Cleveland Street, London, W.1)—Spring Meeting.

Friday, June 2

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 10 a.m.—Dr. H. E. M. Kay: "Some Relevant Problems of Homotransplantation".*

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 6 p.m.—Mr. P. D. MacMahon: "Development of Stabilizing Equipment for Helicopters".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Experimental Officers (2) (with a university degree in agriculture or in pure science with main subject botany or bacteriology) in the Department of Agriculture and Fisheries for Scotland, for research work in the field and in the laboratory on potato black-leg disease—The Establishment Officer, Room 73, Department of Agriculture and Fisheries for Scotland, St. Andrew's House, Edinburgh 1 (May 31).

Assistant Lecturers (with particular interests in physical chemistry, inorganic chemistry or organic chemistry) in the Department of Chemistry—The Secretary, The University, Edinburgh (May 31).

Lecturer in the Department of Pathology—The Secretary, The University, Glasgow (May 31).

Lecturer or Assistant Lecturer in Pure Mathematics—The Secretary and Registrar, University College of North Wales, Bangor, North Wales (June 3).

Research Demonstrator in the Department of Physics—The Registrar, The University, Leicester (June 3).

Tutorial Assistant in the Department of Geography—The Registrar, The University, Leicester (June 3).

Assistant Lecturer in Organic Chemistry—The Registrar, The University, Manchester 13 (June 5).

Lecturer (Grade II) in the Department of Organic Chemistry—The Registrar, The University, Bristol 8 (June 5).

Lecturer or Junior Lecturer in Applied Mathematics—The Registrar, Trinity College, Dublin 2 (June 5).

Lecturer or Assistant Lecturer (preferably qualified to carry out research in electrophysiology) in Marine Zoology at the Marine Biology Station—The Registrar, University College of North Wales, Bangor, North Wales (June 6).

Chair of Physics; and Chair of Chemistry (from 1962)—The Registrar, University College of Sussex, Stanmer House, Stanmer Road, Brighton (June 8).

Research Fellow in the Nuclear Physics Group of the Department of Physics, to prepare and participate in experiments on the 7 GeV. proton synchrotron at the Rutherford High Energy Laboratory of the National Institute for Research in Nuclear Science—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (June 8).

Assistant Lecturer and a Lecturer in Physics—The Registrar, The University, Nottingham (June 10).

Demonstrator in Zoology—The Registrar, The University, Nottingham (June 10).

Lecturer or Assistant in Geology—The Secretary of University Court, The University, Glasgow (June 10).

Research Fellow in the Department of Biochemistry—The Assistant Registrar (Science), The University, Edgbaston, Birmingham 15 (June 12).

Assistant Lecturer or Lecturer (honours graduate) in Mathematics—The Secretary, Bedford College, Regent's Park, London, N.W.1 (June 17).

Lecturer (graduate in science with special qualifications in botany or agricultural botany) in Botany—The Secretary, The West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (June 17).

Lecturer (physicist or physical chemist, with some background in the biological sciences) in Radiation Physics and Biology in the Isotopes Laboratory—Joint Clerk to the University Court, Queen's College (University of St. Andrews), Dundee (June 17).

Research Assistant (chemist, preferably with two or three years research experience), for work on volatile inorganic compounds in collaboration with Dr. L. H. Long—The Secretary, The University, Exeter (June 17).

Lecturer in Physical Chemistry at Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (June 22).

Assistant Lecturer or Lecturer in the Department of Mathematics—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (June 24).

Demonstrator or Assistant in the Sub-Department of Pharmacology, University College of the West Indies—The Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1 (June 28).

Head (with wide experience of research on plant diseases caused by fungi and bacteria, and preferably a special interest in microbiological problems, for example, as associated with soil or mushroom composts) of the Mycology and Bacteriology Department—The Secretary, Glasshouse Crops Research Institute, Worthing Road, Rustington, Littlehampton, Sussex (June 30).

Chair of Philosophy; and Senior Lecturers or Lecturers in Mathematics at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, July 3).

Lecturer in Geography in the Department of Metallurgy The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

Lecturer in Mathematics; and a Senior Lecturer or Lecturer in Physics at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, July 15).

Lecturer in Prehistory in the Department of Anthropology, University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, July 15).

Postgraduate Research Assistant (with a knowledge of X-ray diffraction methods), for studies of liquid structure under the personal supervision of Prof. J. D. Bernal—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1.

Senior Research Assistant (preferably with a special interest in pharmacology or physiology) in the Animal Laboratory of the Department of Psychology, for work on variables affecting conditioned behaviour—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1.

Technician for biochemical work in the Department of Cancer Research—The Administrative Officer, Mount Vernon Hospital, Northwood, Middlesex.

PHYSICS DE[illegible]

SCIENTIFIC AND TECHNICAL MAN-POWER IN BRITAIN

IN the recent debate in the House of Commons on the economic situation in Britain, no attention was given to the situation as regards scientific and technical man-power, though this is at least as important as the question of mobility of labour between industry and industry and skill and skill. Nor is it reflected in the report by Political and Economic Planning (see *Nature*, April 15, p. 199), which was so freely quoted in the debate. That report indeed suggests that the chief impediment to a faster growth of the British economy is that we do not want it enough. The British worker is not sufficiently prepared to take risks, to move to a new job and fight for advancement; and in the British business-man also the aggressive, dynamic, restless spirit is less in evidence than the desire for an easy life with safe but small profits.

Political and Economic Planning does not suggest that these natural desires for security should be condemned or ignored; rather they must be faced as valid human needs, which may limit the pace of technological advance and the rate of growth of the economy, but are susceptible to deliberate measures to overcome them. It criticizes the lack of flexibility in industry, and the wasteful hoarding and inefficient use of labour, to which attention was directed in the House of Commons, and it emphasizes the need for Britain to rely on the skill and brain-power of the population to maintain and even improve the standard of living. For that reason alone, social investment, and particularly capital expenditure on education, is regarded as among the most urgent calls on the investment resources of the nation; but in the same connexion, referring to the distribution of public investment, stress is laid on the importance of increasing more rapidly the productivity, and so lowering the cost of coal mining, as well as increasing the efficiency of the railways. Although it is not disputed that heavy taxation does cause some distortion of the economy, and in particular the allowances for depreciation of capital assets are criticized, the PEP study found insufficient evidence to support the more sweeping assertions about the harmfulness of the present taxation system. The allocation of resources, however, is the vital matter, especially where production cannot be immediately increased, and it is admitted that consumption expenditure has not been restrained sufficiently to keep the economy in a healthy condition and to permit a satisfactory steady rate of growth.

One of the reasons for the inadequate rate of growth of the British economy since the Second World War may have been the absence of an objective of growth at which to aim, but PEP can only propose that all efforts should be made by the Government, the employers and the trade unions to increase co-operation in economic life. The rate of growth of productivity could be improved by stepping up the amount of investment; but within this general aim of increasing the level of investment, priority should be given to encouraging labour-saving investments. Attention must also be directed towards increasing the mobility of labour and achieving the maximum flexibility in the labour force; and since the shortage of skilled man-power of all kinds is likely to persist as industry expands, technical education will continue to be a priority and one in which shortage of teachers is likely to be as great a problem as lack of buildings. Apart from this, however, general education at all levels is an important factor in economic progress and the report reiterates that investment in education, apart altogether from its social value, can make a great contribution to production.

What is particularly obvious from the PEP report, without being explicitly stated, is the need for education, scientific research, defence and fiscal policy to be effectively integrated if proper use is to be made of the resources of Britain. It is encouraging to note that there is already some evidence that this is recognized to some extent in the machine-tool industry, where the manufacturers accept that constant work is needed in design, research and development to enable British products to be competitive. The shortage of technically qualified men cannot be overcome by the manufacturers alone; although the industry has provided for scholarships, time will be required before the schools of research and higher training in machine-tool technology now being developed at the Manchester College of Science and Technology, the University of Birmingham, the Royal Technical College, Salford, and the College of Aeronautics, Cranfield, with research grants of more than £100,000 from the Department of Scientific and Industrial Research, or from the special courses at the Birmingham, Loughborough and Salford Colleges of Advanced Technology. Nor can the manufacturers alone solve the problem of improving delivery dates or secure the full benefits of adopting electronic techniques to the control of machine tools without the co-operation of the trade unions.

It is not sufficient, however, for such co-operation and co-ordination to be secured in respect of a single industry. The improved facilities for higher technical education that it needs must form part of a considered policy and programme for expanding technological and technical education in Britain, just as the expansion of its research effort must form part of a considered programme for research and development generally. Further, the demands made for scientific and technological man-power alone interlock the expansion of research and development with that of technological and university education generally.

Obviously many of the necessary decisions have to be taken at the highest possible level. Many of them clearly fall within the sphere of the Minister for Science, but other Ministers are also involved—those of Education, of Power, of Labour, for example, as well as the President of the Board of Trade and the Chancellor of the Exchequer. The ultimate decisions can be taken only at Cabinet-level, but the Minister for Science bears a large responsibility to see that the scientific and technological issues are clearly and forcefully formulated, especially in respect of the demands they make for scientific and technical man-power and provision for its training. The Advisory Council for Scientific Policy, as its last annual report shows, is already clarifying some of the requirements, and the research councils are also examining some of the issues, notably the Council for Scientific and Industrial Research. Some, however, like the Nature Conservancy, appear to lack the resources required even for preparatory exploration, and it should be a first priority on the part of the Minister for Science to see that the task of elucidating all the factors that bear on the distribution of Britain's scientific and technological effort is carried out with the utmost urgency. Only when the results of such a survey are fully available can really sound decisions be taken; in the meantime, it is only too likely that action may have to be taken to strengthen the country's economic position before the full facts are known. The recent debates in Parliament have demonstrated the critical importance of some of the inquiries now being made into particular aspects of Britain's scientific and technological effort, and the urgent need to complete these inquiries at the earliest possible moment.

Mr. Albu, in a recent broadcast talk, suggested that one reason for the backwardness of some sections of British industry is their failure to adapt themselves to the changed educational system and to employ university-trained scientists and engineers not only in research but also in design and production. Possibly Mr. Albu makes too light of the contribution which should also be coming from the colleges of technology, and he may rather over-stress the part that the Government could play in changing the situation. Undoubtedly, however, the Government could ensure that the board of every nationalized industry includes a first-class scientist or technologist, and it could stimulate the backward industries by detailed inquiries such as those made by the Department of Scientific and Industrial Research. It has considerable powers which could be exercised through the research associations, and its authority as a large-scale purchaser could also be used to encourage research. These powers, once again, can only be exercised wisely on the basis of knowledge and not on political theory, and Mr. Albu's suggestions once again really illustrate the decisive position of the Minister for Science and of the Advisory Council for Scientific Policy. On the wisdom and urgency with which Lord Hailsham and his advisers address themselves to these problems depends more than on any other single factor the success of Britain's effort to adjust itself to the world situation of to-day.

THE. AGE OF CONFERENCES

Communication or Conflict

Conferences—Their Nature, Dynamics, and Planning. Edited by Mary Capes, with the collaboration of A. T. M. Wilson. Pp. xi + 228 (London: Tavistock Publications, 1960.) 30*s*. net.

EVERY year, tens, and possibly hundreds, of thousands of people congregate in groups, both large and small, in many different lands. For the most part the purpose of these meetings is the exchange of knowledge and ideas, but some others are held to attempt agreement between delegates whose vital interests may be influenced by any resolutions which may be adopted. Most participants arrive in various conditions of hope and apprehension and depart in varying degrees of despair, stimulation or exhaustion, each with his own opinion of the success or otherwise of the conference.

The book under review is concerned with the factors which make for success or failure. It seems that an "international conference on the functioning of international conferences" was held at Eastbourne during 1956 at some unspecified date, which, from the reference in the foreword to prevailing snow and ice, I can only conclude was within the period January–April. This omission is characteristic of the imprecision of much of the text. The meeting was convened by the World Federation for Mental Health, presided over by Dr. Brock Chisholm (formerly director-general of the World Health Organization) and attended by a mixed bag of social scientists, numbering twenty in all, in which psychiatrists were the most numerous. Three pre-circulated working papers were prepared for the conference entitled: "The Cultural Perspective" (by Margaret Mead), "The Appreciation of Individual Idiosyncrasies" (by Otto Klineberg) and "Historical Development of Group Work" (by T. A. Ratcliffe) and these form Part 1 of the book. Discussion of these papers in plenary sessions led to the setting up of four groups, each having five members who were responsible for leading discussions on a particular topic of the conference. The record of these discussions comprises Part 2. Part 3 consists of four appendixes dealing chiefly with the organization and running of conferences for different purposes.

It is difficult to know what purpose this book will serve. The stated object was "not to provide a rigid set of blue-prints on conference management but to sensitize those interested in small conferences, whether as sponsor or participator, to the subtleties involved when people come together in discussion". Some of the supposed subtleties are so obvious as to be axiomatic, as for example, the cautionary tale on p. 53 of which the moral is to avoid large dormitory accommodation (30 to a room). Some are so masked by verbiage as to be barely discernible, while others are plainly nonsensical. To a physical scientist the notion (p. 14) that "In any conference it is desirable to discount as many as possible of the disadvantages of previous experience or unequal experience—this means that it will be *desirable to equalize language background by having each participant speak in a language not his own*" (my italics) is patently silly.

Scientists are notoriously avid conference goers, and have had to devise semi-empirically sets of rough-and-ready rules appropriate to the successful conduct of their meetings, whether these be large jamborees or small groups of experts discussing narrow fields, as in the Gordon research conferences, or the informal Faraday Society Discussions, or international delegate conferences charged with specific duties such as agreement on nomenclature or atomic weight standards. The learned societies of Britain and other countries have, among their senior officials, persons with very wide experience of all these types of meetings and of the problems of mechanics, procedure, differences of language and cultural background of the participants, and it is therefore all the more remarkable that apparently not one of these officials was invited to participate in this meeting. One is tempted to think that it would have been difficult for such an official to sit patiently through the "widely exploratory discussion", extending over *three* of the seven days of the meeting, which was apparently necessary before 21 participants could frame the agenda and "draw up an integrated programme of work acceptable to every member". Even then the device of setting up four groups had not been agreed on.

The organizers of international scientific conferences who peruse this book will, despite its many shortcomings, be able to learn some lessons—not all of which may be those intended by the author and contributors. In particular, it is useful to be reminded that each participant arrives with his own characteristic attitudes and preconceptions and his own particular responses towards external problems with which he is presented and which may include a strange language, strange procedures and the establishment of understanding with conference-members of different characteristics and cultural background, and that a prime function of the organizing committee must be to devise machinery which will effectively minimize the barriers which may thereby be created. It might be a salutary exercise for a conference-organizing committee at its first meeting to make a précis of these and related problems and the devices which have been, and might be, adopted to solve them. As a preliminary to this exercise the committee members might read this book with some profit, though, at the conclusion of their reading, they might well turn to the opening sentence of the foreword in which it is written that the international conference of which this book is the outcome "was perhaps unique" and be forgiven for hoping that it will remain so.

F. S. Dainton

CELLULAR ORGANIZATION

The Organization of Cells and other Organisms

By Laurence Picken. Pp. xxxvii + 629 + 34 plates. (Oxford : Clarendon Press ; London : Oxford University Press, 1960.) 84*s*. net.

The investigation of the biological cell has received in the past ten years a great impetus, primarily because of the insight that new techniques have given into the structure of its constituent macromolecules. This scholarly book is therefore most opportune, and its relation to present-day trends in cell biology needs careful consideration.

As the author indicates, this is an attempt to integrate the structural aspects of virology, bacteriology and immunology with cytology, and it is the great merit of the book that one author has been able to consider viruses, bacteria, the protozoa and the various structures inside and outside the cells of animals and plants from a single point of view. It must be unique to find an interesting discussion by the same author of, for example, bacteriophage genetics and the cuticle of isopods, and to find an attitude which invites the reader to study not only the observations but also the concepts which inform our attitude to the cell. In this breadth of approach the book compares with the great cytologies of the past and in its emphasis on structure and shape with D'Arcy Thompson's classic work.

There is, however, one major defect, which must be mentioned. This is the refusal, albeit deliberate, to examine, except in general terms, the chemical basis of the fine structures discussed. We thus have the study of macromolecules independently of the molecules which comprise them and with little mention of detailed aspects of their biosynthesis and replication. For example, while Gale's early work on protein synthesis and ribonucleic acid is mentioned, that published by Zamecnik, Hoagland and their colleagues since 1955 is not. A consideration of the latter would surely have modified the sections on cytoplasmic ribonucleic acid, and might perhaps have altered a balance in which three pages are devoted to the endoplasmic reticulum under the heading of "Other Cytoplasmic Membrane Systems", compared with the seventeen pages each devoted to the Golgi apparatus and the mitochondria.

It is also possible to criticize the rather naïve template hypothesis of protein synthesis discussed here, and the absence of any mention in this context of possible correlations between base sequence in deoxyribonucleic acid and the composition and structure of proteins. It would also have been most interesting to have had some discussion on the structure of myoglobin in relation to the other protein structures illustrated.

Inevitably, of course, in such a complex book as this, some at least of the interpretations will have been modified even before it reaches the printers. Even so, it is clear that these omissions and others like them arise from the basic philosophy which permeates it, and it is necessary to ask whether it is indeed possible to discuss the organization of cells without a more detailed consideration of their chemistry. Such a requirement might well make an already immense task prohibitive, but there is the alternative of treating a narrower range of biological structures in greater detail. One does not have to hold the extreme view that all biological problems can be solved with the aid of the enteric bacteria and their parasites, to wish that the author had given more time to a discussion of this choice.

This is really the crux of the matter. Imperfect scientists, faced with such a fascinating array of structures, may well be diverted from their immediate problems. May there not be sufficient paradoxes and exceptions in the present narrow fields to stimulate the most lethargic research worker ? Does not the emphasis on the final structure tend to hide an essential unity in ontogeny of everything the cell makes ? It is possible to conceive, and is even probable, that the nematocyst of a cœlenterate is synthesized in the same way as the pancreatic enzymes. It may well be that if we knew the contents of one 'black box', we could predict the properties of all the other cellular 'black boxes'.

Whatever our answers to these questions, they can only affect the emphasis that we would put on this or that aspect of structure, and not its general importance to our understanding of the cell. This careful and well-written account will provide an introduction to a whole range of problems, some of which are in danger of being neglected to-day—an introduction which will be helped by the presence of many plates and diagrams, including a welcome use of X-ray diffraction photographs to illustrate various facets of macromolecular structure. These latter would have been even more valuable, however, if the technique had been briefly described in order that the newcomer might have a better opportunity to appreciate the molecular basis of the identities and differences, which he is asked to see in the illustrations.

The volume with its excellent index and bibliography is, as might be expected, very well produced except for the descriptions which appear under the plates themselves. These are so short as to be misleading in certain cases (for example, Figs. 15·3 and 19·3), and the reader has always to refer to the longer descriptions, collected together at the beginning of the book.

In spite of its shortcomings this is a great personal achievement; in some ways more stimulating because it advances a view of the cell at present unfashionable; if there is one thing to be learnt from this book, it is that fashions change.

P. M. B. WALKER

AVIATION METEOROLOGY

Weather Forecasting for Aeronautics

By Joseph J. George. Pp. ix+673. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 15 dollars.

Handbook of Aviation Meteorology

(Air Ministry: Meteorological Office.) Pp. xvi+404+26 plates. (London: H.M. Stationery Office, 1960.) 25*s*. net.

THE first book is fascinating for the meteorologist whether or not he is concerned with the provision of forecasts for aviation. It is essentially a practical manual of techniques and rules for weather forecasting based on a wealth of experience and extensive study over a long period by a man who has for years been concerned with applying meteorology to airline operations.

The results largely apply to the North American continent and are thus not necessarily always directly applicable elsewhere in the world. Nevertheless, the author's techniques and presentation are sure to tempt many forecasters to try the methods out for themselves and will stimulate ideas on how comparable problems might be tackled elsewhere. This is where the book's value to the meteorologist outside North America lies.

It is unique in the field of meteorological literature to come across a book of such practical application that one cannot help but wonder whether meteorological research effort in general is too much devoted to theoretical studies. Perhaps the author himself had this in mind when he says, in reference to other works on the prediction of the movement and development of maritime cyclones, "the material is interesting . . . but it has the drawback of being mostly subjective and providing no numerical answer." This search for a numerical answer is the keynote of the book, with the result that no attempt is made to justify or explain statements and rules in terms of physical and dynamical meteorology. Some of these may cause a raising of eyebrows among the theorists. Mr. George need not make any apology on this score, however, since it is quite apparent that he is dealing throughout with the application of facts emanating from appropriate studies and their justification, and explanation is neither necessary nor appropriate in a book of this nature.

The book can be regarded as composed of three sections. The first (Chapters 2–11) deals with the movement and development of pressure systems and fronts, culminating with two chapters contributed by R. J. Shafer on the computation of pressure changes (referred to as "the Poor Man's Numerical Weather Prediction System") and an example of the construction of a prognostic chart by applying the rules developed in the preceding chapters. Altogether it constitutes nearly half the book and includes practically 100 pages on the movement, deepening and filling of cyclones.

The second covers the prediction of meteorological elements of particular significance to the operation of aircraft, including very low ceilings and fogs, severe weather conditions (thunderstorms, line squalls, turbulence, hail, icing), upper winds and temperatures. It is most comprehensive and includes many useful empirical formulæ. The section is rounded off by a chapter on the use of radar in forecasting.

The third section devotes some 120 pages to local forecast studies relating to 14 airports in the United States. These could well serve as models of the type of work that should be done at every airport in the interest of improving the accuracy and reliability of aerodrome forecasts within the limits of present-day observing practices.

Every forecaster engaged in work for aeronautics should have a copy of Mr. George's book. Although the production is such that it would make a handsome addition to the bookcase, it deserves more than occasional reference and could well justify a constant place on the forecaster's desk as an additional tool for his job. Perhaps it is not too much to hope that it will inspire others to produce similar practical manuals on forecasting for aeronautics in Europe and elsewhere.

Handbook of Aviation Meteorology is a successor to Dr. R. C. Sutcliffe's well known *Meteorology for Aviators* which was first produced in 1938. Dr. Sutcliffe's book has been regarded as the standard text-book, not only in the United Kingdom but also in many other countries, for the meteorological training of pilots and navigators, both civil and military, for their licencing examinations. With the general extension of aviation to higher altitudes and the advancement of meteorological knowledge during the past two decades, there has been an ever-increasing need for a revised version of Dr. Sutcliffe's book. This *Handbook of Aviation Meteorology* will, therefore, be welcomed, particularly by pilots and others concerned with the applications of meteorology to aviation, as fulfilling a long-felt need.

The book includes much new material. It is gratifying to find mention of so many modern operational factors, such as temperature accountability, engine icing, runway visual range, clear air turbulence, helicopter operations, meteorological aspects of aerodrome design, to name but a few, as well as the inclusion of new knowledge about old operational problems, such as thunderstorms and airframe icing.

The treatment of some of the more difficult concepts is particularly good. They are explained lucidly and in detail, with adequate diagrams and illustrations. For example, the 'Tephigram' (so long an imponderable mystery of doubtful purpose to many) will be much more readily understood by the reader of the *Handbook*, and its many uses and value will be better appreciated by the clear examples of its application. Altogether, the evident objective of tailoring the book to suit the reader for whom it is primarily designed is successfully achieved and, in particular, it was a wise decision to keep the mathematics of the derivation of formulæ in an appendix instead of interspersing it in the text.

The only major criticism of this book is that it is already out of date in certain aspects dealing with the procedures for providing meteorological service to pilots and operators. It is recognized that frequent changes occur of necessity in these procedures in order to keep pace with the rapid development of aircraft and airline operations. Nevertheless, for a book published in the jet age of 1960, it is indeed unfortunate that the chapter on "Meteorological Service for Aviation" should largely reflect the position as it was in the first half of the 1950's when so many changes have occurred and new trends emerged since then. It is considered that as this chapter is short (barely 6 pages) it could have been brought up to date immediately before going to press, or could have been written in more general terms to withstand better the weathering of these years of advancement. At the very least the suggestion that for further reading (Appendix 3) one should consult an International Civil Aviation Organization document published in 1951 (and which has been obsolete and out of print for the past five years) should have been corrected.

Fortunately, it is only a very tiny proportion of the whole book that can be criticized in this way. Otherwise it is an excellent production and very well illustrated. It can confidently be predicted that it will be widely used by pilots and other flight-crew members not only as a basic training manual but also as an interesting and readable book of very great value to their work. This book can also be strongly recommended to anyone who wishes to extend his knowledge of meteorology beyond the elementary stage, without scaling the heights of the more advanced text-books on the subject.

THE LITERARY PRESENTATION OF SCIENCE

The Craft of Technical Writing
By Daniel Marder. Pp. xiv+400. (New York and London: The Macmillan Company, New York, 1960.) 35*s*.

HERE we have one more addition to the seemingly endless ranks of books—a large proportion of them coming from America—on how to write scientific and technical, or more properly technological, papers, articles, reviews, reports and even books, including presumably books about how to write scientific and technical, or more properly technological, papers, articles. . . . Is there here not more than a suggestion of the infinite regress ?

About two years ago I expressed the opinion (*Nature*, 184, 1749; 1959) that the best of these books, in any event for British writers, was Godfrey and Parr's *The Technical Writer*; I see nothing in the one now before me to justify any revision of the earlier statement. At a rough estimate the earlier book, though 60 pages shorter, contains twice as much useful material, justification for its being 10*s*. dearer than the new one.

Plenty of other books of this class have appeared during the post-War years; one cannot help wondering not only just what they are aiming at but also whether we are to see a continuation of this proliferative growth until every university in the United States, and perhaps every scientific and medical department in the larger ones, will have its own and special manual of presentation, alongside its own text-books of biochemistry, physics, statistical methods, etc.

In the general field of text-books there is such an abundance that the would-be student could not escape complete confusion did not the helpful hand of his professor guide him gently to usage of the proper departmental 'Holy Writ'. No such help is available, however, to the British student faced with a multiplicity of these well-meaning aids to the writing of his own language; he will therefore have to rely on such unintentional warnings as that to be found in Dr. Marder's preface, where he is told that "effective writing comes about through the knowledge and application of rhetorical principles . . ." The mind boggles at the thought of some of our less literary-minded colleagues trying to coat the bitter pill of their writing with the jam of rhetoric.

Admonitions like this destroy the value of much good advice given by Dr. Marder. After all, most rules for writing simple (when simplicity is desirable), clear and unambiguous prose are recognized by him and are indeed the same on both sides of the Atlantic. Nevertheless there are to-day legitimate differences between the two major "English-speaking" countries; a witness to this is the highly significant, even though not generally appreciated, fact that Fowler's seminal *Modern English Usage* has now been replaced by Margaret Nicholson's *A Dictionary of American-English Usage*. This, be it noted, is published in New York by the Oxford University Press, though naturally obtainable in Britain. Fowler's book was published by the same Press, but from Oxford.

Among the many deficiencies of Dr. Marder's book is his complete failure to observe, or even to mention, the invaluable distinction drawn originally by Fowler, and still retained by Nicholson, between the relative pronouns 'which' and 'that'. Again, Dr. Mander must with regret be included in the long ranks of those incurring Prof. A. V. Hill's wrath because they will insist on using 'data' as a synonym for such terms as results, figures or values. Mercifully, though, Dr. Marder has not yet joined the all too rapidly increasing band who cannot recognize the word as a plural noun.

There does not appear to be in this book anything of particular appeal to the British scientific or technological writer. In general, what Dr. Marder advocates is in fact common practice for all those who use the English language with reasonable rectitude in their writing; it differs in no important essentials from the advice to be found in the best post-War books on the subject published (and written) in the United Kingdom. They began, I think, with Kapp's *The Preparation of Technical Information*, now nearly thirteen years old, and they might fittingly be allowed to end, in any event for the present, with the comprehensive volume by Godfrey and Parr, to which I have already referred. Apart from anything else, legitimate differences in the usage of language between ourselves and our American colleagues naturally receive the American treatment in Dr. Marder's book, which is sufficient to make its use as a guide to British writers a little hazardous, to put it mildly.

There is a felicity of writing that can hardly be taught, but that may perhaps be hardly, in the other sense, acquired, if by no simply definable process; but the ability to handle the English language as an effective tool in the communication of scientific and technical knowledge and information can surely be derived, if at all, from possession and study of Kapp, Gowers, Godfrey and Parr and, perhaps needless to add, Nicholson, since Fowler is no longer with us. I cannot see that Dr. Marder has anything to offer in addition.

A. L. BACHARACH

ION TRANSPORT: AN UNORTHODOX VIEW

Transport and Accumulation in Biological Systems

By Dr. E. J. Harris. Second edition. Pp. xi + 279. (London: Butterworths Scientific Publications, 1960.) 50*s*.

THE first edition of Dr. Harris's book appeared eleven years after the War, at the end of a decade in which the use of radioisotopes and flame-photometry had led to a very rapid advance in the knowledge of cell permeability. In the four years which have preceded the publication of a second edition progress has been slower, but a great deal of experimental work has been done, and a digested presentation of this new work is very welcome. The plan of the book remains the same: a few introductory chapters on the physico-chemical features of membrane penetration are followed by accounts of the transport of water, ions, and simple organic molecules by a wide variety of animal membranes; a final chapter gives a brief account of ion movements in plant cells, particularly in giant algal cells and in yeasts. The different animal tissues are described separately, and if this sometimes does less than justice to the resemblances between cells of different types, it discourages that too easy transference of results and hypotheses from one tissue to another, which is a constant temptation to anyone working in this field.

A controversial feature of the book is Dr. Harris's interpretation of equilibration curves. In a number of tissues, including muscle and red cells, the kinetics of ion-exchange between the cell phase and the exterior are not always first order. Dr. Harris explains this by supposing that diffusion in the cell interior is a rate-limiting factor. The more usual explanation is that the departure from first order kinetics comes about because one is dealing with a whole population of cells, differing in size, shape, and probably also in permeability, so that what is observed is the sum of a large number of first order processes. Dr. Harris points out that: "Analysis of kinetics assuming several first order processes is no more than the expression of the first two or more terms of the series describing the diffusion process". This is formally correct, but, though it is good for us to be reminded that the same kinetic behaviour may be predicted by more than one model, it remains true that the population of cells exists, that the cells do vary slightly, and that when the exchange of sodium or potassium in a *single* muscle fibre was examined by Hodgkin and Horowicz, first order kinetics were followed.

The question whether exchange is limited by the membrane resistance or by diffusion in the cell interior is important because it affects one's whole approach to the investigation of ion transport. Consider, for example, the distribution of sodium and potassium across muscle or red-cell membranes. In the conventional view, the chief problem to be solved is the elucidation of the way in which energy from cell metabolism is used to shift ions of a particular species across the cell membrane from a lower to a higher electrochemical potential. In Dr. Harris's view, "There is no reason to expect that metabolic energy is directly involved in the ordinary sodium and potassium turnover processes, for these resemble exchanges on an inert ion exchanger". The need for active metabolism, if the normal intracellular ionic composition is to be maintained, is attributed to the effect of metabolism on the affinity or selectivity of the adsorption sites. If Dr. Harris is right, views on ion transport will have to be completely re-oriented. But, whatever the difficulties of the conventional theory may be, it is not likely that many workers will be as ready as Dr. Harris to dismiss the membrane—at least until there is more evidence for the existence of enough specific adsorption sites within the cell.

LOUIS PASTEUR

Louis Pasteur

A Master of Scientific Enquiry. By Jacques Nicolle. Pp. 196+8 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1961.) 35*s*. net.

JACQUES NICOLLE is well qualified to write about Louis Pasteur. Through family and other connexions he has been able to learn much about the motives and methods of a truly great man whose contribution to science has been far greater than his epoch-making discoveries. This book describes how Pasteur approached and tackled the immediate problem, and, as a result, Nicolle can fairly claim to have produced a great deal more than 'just another biography'.

Louis Pasteur is concerned only with Pasteur the investigator. From his beginnings in stereochemistry to his final essay in human biology, the pertinacious Frenchman approached each investigation in the same way. He never moved until he was steeped in all that was already known; he insisted on examining agronomic and industrial material on the spot; he carried out his researches as near the source of difficulty as possible, even if it meant setting up a makeshift laboratory; he reduced his propositions and his apparatus to the simplest terms; and no tentative claims were made until his results had become self-evident.

In Pasteur's inquiries into the divergent types of tartaric acid, problems of wine- and beer-making, the causes of pébrine and flacherie in silkworms, the nature of anthrax and chicken cholera, the claims of distinguished colleagues to support the truth of abiogenesis (the possibility of which Pasteur never wholly renounced) and the origin of rabies, Nicolle shows how Pasteur's method of approach never varied and still stands as a model for men of science everywhere. It is indeed a tribute to a man whose father served with Napoleon that his methods are now being applied to the solution of industrial problems. Nicolle's book can take its place as a worthy successor to René Vallery-Radot's admirable *La Vie de Pasteur* and *Les Oeuvres de Pasteur*, which owed so much to its editor, Pasteur Vallery-Radot.

T. H. Hawkins

TERPENE PROPERTIES AND STRUCTURES

Die Terpene

Sammlung der Spektren und Physikalischen Konstanten. Von J. Pliva, M. Horák, V. Herout und F. Sorm. Teil 1 : Sesquiterpene. Pp. xxii + 1–228. (Deutsche Akademie der Wissenschaften zu Berlin: Kommission für Spektroskopie.) (Berlin: Akademie-Verlag, 1960.) n.p.

THIS work is not a compilation of analytical data from all available sources. It is designed not only as an aid to the identification of terpenes but also as material for the study of relations between the infra-red spectra and molecular structure. Advisedly limiting the former objective for the better attainment of the latter, the authors include only physical data determined on the identical sample used for the infra-red work. Largely, therefore, this is a report on a consistent plan of laboratory work, over about twelve years, by a single team at the Czechoslovakian Academy of Sciences.

The plan provides for the fractionation of essential oils, by a standardized technique of distillation followed by alumina-column chromatography, into constituents in which further treatment produces no change of physical characters, including infra-red absorption. These isolates are investigated and classified primarily on the basis of infra-red spectra. Most, though not all, are compounds previously known; but the Prague group has been prominent in the work which in recent years has led to the revision or final elucidation of the structures of such long-known compounds as caryophyllene and humulene (to which, respectively, 9- and 11-membered rings are now assigned), as well as the successful investigation of such new terpenes as the acoran series from calamus oil, embodying spiro-linked 5- and 6-membered rings.

The criterion for classification of a compound is the infra-red spectrum of the saturated hydrocarbon formed by its complete hydrogenation, using Adams's catalyst at room temperature. As a means of investigating structure, it is claimed that this technique, compared with Ruzicka's dehydrogenation procedure, has more general applicability, less risk of altering the carbon skeleton, and has higher yields, permitting of work on smaller quantities. From twenty to thirty carbon skeletons are thus recognized among the sesquiterpenes, and these are named by modification of familiar, or at least identifiable, trivial names, for example, caryophyllan from caryophyllene, zieran from zierone. Sub-groups such as vetivan, isovetivan and neovetivan provide for the *cis-trans* isomerism which may arise naturally or in the course of the hydrogenation.

217 natural or artificial sesquiterpenes are described, each on its own card (British Standard *A*4 size). A complete card gives molecular and graphic (though not steric) formulæ, density, refractive index and specific rotation, boiling-point (under low pressure) or melting-point, ultra-violet absorption characters if any, a brief indication of source and means of purification, literature references on isolation and constitution, and an infra-red transmittance curve from 650 to 1,500 or 2,000 cm.$^{-1}$, as appropriate, in a rock-salt prism instrument of resolving power 2–3 at 650 and 7–10 at 2,000 cm.$^{-1}$. Experimental data on film thickness, solvent, etc., are supplied.

Indexing, both by classes and by individuals, is adequate. The type correctly indexed as "eremophilan" appears in the structure-key as "eremophyllan".

Further publication on the monoterpenes and higher terpenes, and on the results of gas-chromatographic or other improved methods of separation, is contemplated.

E. G. Kellett

SERVOMECHANISMS

Control Engineering

(The Van Nostrand Series in Electronics and Communications.) By Prof. Gordon J. Murphy. Pp. xii + 385. (Princeton, N.J.: D. Van Nostrand Company, Inc; London: D. Van Nostrand Company, Ltd., 1959.) 56*s*.

THIS book presents in some detail the mathematical theory of linear servomechanisms, and, without treating any particular topic exhaustively, describes its application to several different types of system. Techniques for non-linear systems are confined to the two final chapters. So many books have now been published in this field it is probably appropriate to describe in some detail the contents of the present text. After a very general introductory chapter, the second deals with the Laplace transform, the transfer function and related stability considerations under the heading of "Time Response". There follows an excellent chapter on design in the *s*-plane which concludes with a description of the root-locus method. The use of this method is very much a matter of practical experience, but many readers would none the less welcome rather more discussion of its application than is actually included. These two chapters are complemented by the next on frequency response, which covers well-trodden ground in a clear style with several examples to illustrate theory. The three following chapters deal with specific types of system, namely the carrier-control, dead-time and sampled-data systems. A chapter on noise concludes the treatment of linear servomechanisms. The two chapters on the analysis of non-linear systems deal with the describing function and the phase-plane technique.

The text throughout proceeds from the general to the particular, an approach which tends in places somewhat to obscure, or postpone, full appreciation of the significance of a result or technique. The work is therefore not suitable as an introduction to the subject, but forms a useful and clearly written work at a more advanced level.

Problems are included at the end of each chapter, and a table of fifty-two Laplace transforms is included as an appendix.

PHYSICS DEPARTMENT LIBRARY

Classification and Multiplicity of Growth Layers in the Branches of Trees at the Extreme Lower Forest Border

By Waldo S. Glock, R. A. Studhalter and Sharlene R. Agerter. (Smithsonian Miscellaneous Collections, Vol. 140, No. 1. Publication 4421.) Pp. x+294+36 plates. (Washington, D.C.: Smithsonian Institution, 1960.) n.p.

THIS very detailed study of growth rings in the branches of a number of species of angiosperms and gymnosperms emphasizes the complexity of the problem of the formation of growth rings. The investigation, which was made in Texas, was concerned mainly with trees of the forest border or beyond, where conditions may be assumed to be less favourable for tree growth than within the forest itself. Some of the trees showed multiplicity of growth layers, any one of which might extend over the tree or be confined to a larger or smaller area. One branch, known to be four years old, showed eight growth rings and reference is made to trees subjected to intermittent irrigation which had 15 sharply bordered growth layers formed in four years.

The authors found these growth layers to be extremely varied and sometimes had difficulty in distinguishing between the limits of those formed during a growing season and that which terminated the season. In a distinct seasonal layer it is to be expected that the first-formed cells will be thin walled and perhaps larger than those formed at the end of the increment, where the ring may be well marked by the radial flattening of the last-formed cells or, at least, by a distinct difference between the last-formed cells of the ring and the adjacent first-formed cells of the succeeding ring. No criteria were found by which a false (intraseasonal) ring could be certainly distinguished from one terminating the period of annual growth.

Post-seasonal growth layers were found, that is, incomplete growth-layers produced after the termination of the main seasonal growth, but probably completed before the onset of winter.

Not surprisingly, the authors conclude that ring counts may not be a reliable method of absolute dating and find that frost rings, which could also be induced to form experimentally by the application of dry ice, serve as a more dependable guide.

F. W. Jane

International Review of Neurobiology

Vol. 2. Edited by Carl C. Pfeiffer and John R. Smythies. Pp. xii+410. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 11 dollars.

THE second volume of *The International Review of Neurobiology*, like the first, is a collection of nine unrelated articles, five of which may be classified as pharmacological. J. Mardones of Chile writes on the addiction of rodents to alcohol; F. W. Schueler of Tulane, on the hemicholiniums; E. J. Walaszek of Kansas, on the cortical pressor-response to epinephrine as affected by schizophrenic serum; E. Costa of Illinois, on serotonin; and A. Herz of Munich, on drugs which influence the conditioned avoidance-response of laboratory-animals. Two articles are mainly biochemical. L. E. and M. R. Hokin of Wisconsin discuss the significance of phosphatidic acid and phospho-inositide in the transport of sodium-ions across neuronal membranes; and E. Roberts and E. Eidelberg of California, the metabolic and neurophysiological roles of γ-amino-butyric acid. The remaining two contributions are both from the United Kingdom. R. M. Gaze of Edinburgh reviews work on the regeneration of the optic nerve in amphibians; and H. J. Eysenck of London describes methods of assessing the value of drugs in cases of psychological illness. All the articles contain much interesting material, but the pharmacological five are less impressive than the other four because of a tendency to build too large a superstructure of assumption on a necessarily slight base of fact. The volume is once again well produced, with full references to the literature and a good index.

Denis Brinton

The Observer's Book of Trees

Compiled by W. J. Stokoe. Revised edition. (The Observer's Pocket Series.) Pp. 228+12 plates. (London and New York: Frederick Warne and Co., Ltd., 1960.) 5*s*.

THE Observer's books must be familiar to many. Their size and uniformity make them handy pocket books, and their clarity and arrangement enable easy reference.

This book on trees is a revised edition of that published in 1937. It describes 106 species of the trees and larger shrubs found in the British Isles. Technical terms have been avoided so far as possible, as the aim has been to assist the observer in identification.

There are more than a hundred half-tone photographs, fifty line illustrations and twelve colour plates. These cover the general appearance, bole, foliage, fruit and flower of individual trees, giving excellent impressions at a glance.

One noticeable difference from the original edition is the inclusion of an illustrated guide to 'identification by twigs and buds', which is useful for months when there are no foliage distinctions. Another difference is the newly devised section of coloured plates. These plates, though less beautiful and fewer in number than in the earlier edition, cover far more ground and are of more practical value. Each plate is divided into four or five groups, showing leaf, flower and fruit of fifty-two different trees.

The book has an introduction and two indexes: one classified by families, genera and species; the other alphabetical.

This newly planned edition will be a worth-while purchase for those whose old copies are becoming worn through well-justified use. The price is amazingly low by present-day standards.

B. J. G. Maitland

Clays and Clay Minerals

Proceedings of the Seventh National Conference on Clays and Clay Minerals, Washington, D.C., October 20–23, 1958. Edited by Ada Swineford. (International Series of Monographs on Earth Sciences, Vol. 5.) Pp. ix + 369. (London and New York: Pergamon Press, 1960.) 60*s*. net.

THIS seventh volume continues the excellent tradition of previous volumes. Most of the papers are mineralogical in nature, and constitute useful advances in our knowledge of clay deposits. There is an excellent review article by W. Parrish on the X-ray diffractometer. An article by L. G. Schutz on quantitative X-ray determination of clay minerals emphasizes the numerous difficulties that still remain in this field. There is a very full study, almost amounting to a monograph, from the Agricultural and Mechanical College of Texas, on the differential settling tendencies of clay minerals in saline waters.

Apart from this article, there are few contributions on the colloidal side of clay mineral studies. However, Dr. R. K. Schofield collaborated in an article on the swelling pressures of sodium montmorillonite pastes, and this must be one of the last contributions he made before his death.

The transference of the publishing of these proceedings from the United States to Great Britain has resulted in a definite deterioration in the standard of binding. But then, few British firms seem able to achieve the quality of binding that is almost uniform in America. They ought to give some attention to the matter. In these times it ought not to require decades for a good technique, possessed by one country, to be transmitted to another.

This volume is edited, with her usual care, by Ada Swineford. I would like to plead with her, however, to have some mercy on bibliographers. These annual proceedings ought to have some short title, by which they can be referred to—I would suggest *Proc. 7th Clay Min. Conf.* The fact that this is Monograph No. 5 of the Earth Science Series seems to be just a blind, designed to make the bibliographical position even more confusing than it already is.

D. M. C. MacEwan

Lowie's Selected Papers in Anthropology

Edited by Dr. Cora du Bois. Pp. xii+509. (Berkeley and Los Angeles: University of California Press; London: Cambridge University Press, 1960.) 10 dollars; 80*s*.

LOWIE'S memory is well served in this selection of essays by his former pupil and friend Prof. du Bois.

Quite properly, no effort has been made to select material from his eighteen classical monographs on the Plains Indians, or from his ten major books, which ought to stand complete as they are.

Fortunately, Lowie himself had already selected a good deal of material which he regarded as reasonably original and acceptable contributions to anthropological thinking, and in an autobiographical note written in reply to questions from the National Academy of Sciences summarizes his contributions with humility and with the same critical attention that he devoted to all other work.

This selection has been amplified by the editor, who consulted, among others, Kroeber, Radin and Spier. Especially valuable are the six essays left unpublished at his death.

Lowie was completely bilingual in English and German, and fluent in other languages. Moreover, he was thoroughly conversant with the work of great philosophers and scientists, and had all the interests of a well-educated man. About a tenth of his large output was devoted to subjects outside anthropology.

When we read the section on "Theories and Theorists", and note the people whose work he esteemed and critically assessed, we get the measure of the man, and realize why the best anthropologists have come from those who entered the subject with a mind already well developed in other disciplines. In my own view, it is only such people who can give the subject the place it deserves in the universe of discourse among living and civilized minds.

T. K. Penniman

AGARD Aeronautical Multilingual Dictionary

Edited by G. H. Frénot and A. H. Holloway. Pp. xix+903. (London and New York: Pergamon Press, 1960. Published for and on behalf of Advisory Group for Aeronautical Research and Development, North Atlantic Treaty Organization.) 140*s*. net.

INTERDEPENDENCE between various peoples is particularly pronounced in the aeronautical sciences and well cared for in the Advisory Group for Aeronautical Research and Development under the chairmanship of Th. von Kármán. Thus the Documentation Committee of this Group considered it an important duty to prepare and issue a technical aeronautical dictionary in several languages: Dutch, English, French, German, Italian, Russian, Spanish and Turkish. The first issue is now available and it turns out to be rather more than a dictionary: In fact, it contains translations of the *Glossary of Aeronautical Terms and Definitions* issued by the British Standards Institution (B.S. 185). The translation has been a co-operative effort and has been carried out in each case in countries in which these languages are spoken, except for the translation into Russian, which has been attended to by the British Ministry of Aviation. The result is workmanlike and authoritative, and the *Dictionary* is easy to use. The vocabulary of a rapidly developing science develops with it and it is therefore intended to continue and to expand the dictionary so as to keep it up to date. For this purpose, it is printed on loose punched sheets and supplements can easily be obtained and inserted. In this way, revisions of the source glossary, which is now about ten years old, can also be accommodated. The *Dictionary* is a credit to the editors and their many helpers and it will serve a truly useful purpose all over the world.

D. Küchemann

Wild and Free

Stories of Canadian Animals. By H. Mortimer Batten. Pp. 192. (London and Glasgow: Blackie and Son, Ltd., 1961.) 10*s*. 6*d*. net.

THIS book is a collection of seven stories. Each is about animal adventures, covering such creatures as wolves, deer, beavers, bears, moose, and many others. The stories themselves are both interesting and thrilling, but the book offers something more than this: the reader can learn much about life in the wilds of Canada; and the stories will inculcate a deeper feeling for animals' reactions to environment and circumstance than mere facts can ever portray. It shows that zoology is not merely a text-book subject, but is vivid reality if seen with a sympathizer's eyes.

For example, there is the case of an orphan fawn that makes several attempts, before succeeding, to join a herd of deer when its mother is killed. None of the does will accept it, so from sheer need of companionship, it attaches itself to the buck. From him, by example, it learns how to cope with life at an early age, when the other fawns are still relying on their mothers. Thus it is the only fawn survivor when the herd is attacked by bears.

There are seven full-page illustrations to this, the fifth and last book by the late H. Mortimer Batten.

B. J. G. Maitland

RADIO ASTRONOMY AND COSMOLOGY*

By PROF. MARTIN RYLE, F.R.S.

ASTRONOMY differs from most sciences in that we cannot do experiments; the astronomer must build up from his existing observations a picture or 'model' of the universe, and then look for further effects which should be observable if his model were correct. Although in 700 B.C. the Babylonians were making excellent observations without attempting to interpret them, and although the Greeks proposed models without always looking too carefully into how well they fitted the facts, this approach has always been present, and in the seventeenth century led, through Kepler and Newton, to a good understanding of the solar system.

But what were the stars? Kepler had no conception of their great distance, and imagined them to be on the surface of a fixed sphere with a radius some 2,000 times that of the Earth's orbit. But it seems certain that Newton had a better idea when he wrote:

"But if the matter were evenly disposed throughout an infinite space, some of it would convene into one mass, and some into another, so as to make an infinite number of great masses scattered great distances from one another throughout all that infinite space. And thus might the Sun and fixed stars be formed, supposing the matter were of a lucid nature".

We can see here the first idea of an 'infinite' universe, in which the Sun has no more significance than any of the stars.

There now began the exploration of space on an ever-increasing scale. William Herschel, by constructing larger telescopes than had ever been built before, was able to show that the diffuse band of light of the Milky Way was in fact due to countless stars, and he thus confirmed Newton's suggestion of the insignificance of the Sun. To-day we know that our own Galaxy, the Milky Way system, is a flattened disk containing some 100,000 million stars each comparable in size and luminosity with the Sun.

But the observations of William Herschel and later his son John showed, besides the millions of star images, some thousands of diffuse sources of light or 'nebulæ'. Some of these are now known to be clouds of luminous gas in our Milky Way system, but even at that time the Herschels considered the possibility that these sources were themselves distant 'island universes' too far away for any of the stars to be resolved individually. It was not until methods of distance-measurement had been established in the present century that these suggestions could be confirmed, showing an apparently limitless universe containing, at great separations, compact islands of stars, or galaxies, of which the Milky Way is one.

Besides showing the insignificance of the Earth, these observations raised new problems. One of these, first propounded by the German astronomer Olbers, is based on an observation which any of us can make—that it gets dark at night.

If we look at the sky we see that between the stars it is dark; a larger telescope will see fainter stars here, but again it is dark between them. Now if we must suppose that the universe is infinite in extent, then in whatever direction we look we will eventually see the surface of a star. Although the intensity from each star individually will be very weak, since they must occur in every direction, the sky should have the same brightness as the surface of the Sun: but if this were the case the Earth would be heated to 6,000° and would immediately be vaporized. We cannot avoid the difficulty by supposing that the light from distant stars is absorbed; by the very fact of absorbing the light the obscuring matter will be heated until it has the same temperature as the stars—when it will radiate as much light as it absorbs.

It seems that we can only explain this paradox by supposing that the universe is not infinite. But if we ignore the local stars in our own Milky Way system, we find that the sky is uniformly dark in all directions and we should have to return to a pre-Copernican idea of a universe constructed with us at its centre, having, in the meantime, demonstrated our complete insignificance.

The discovery which eventually led to the solution of the problem was made by the American astronomer Slipher, in 1912. Slipher, who was studying the spectra of the stars in distant galaxies, found that, for a particular galaxy, the spectral lines were displaced slightly, and all occurred on a slightly longer wavelength than expected. This displacement of the lines towards the red end of the spectrum, the so-called 'red shift', is just what would be expected if the light were emitted from a moving source. His observations suggested that not only this galaxy but also a number of others were all moving away from us, and later work led, in 1928, to the conclusion that no matter in what direction one looked, the galaxies were travelling away from us; it was also found that the speed of recession was greatest for the most distant galaxies.

We can now see an explanation for the darkness of the night sky; the light we receive from a very distant galaxy will have suffered such a large red-shift that most of its energy now falls in the infra-red; any visible light received must be emitted in the ultra-violet, where the energy emitted is very small. As a result the light from galaxies beyond a certain distance will be very small, and we have in effect produced a limit to the size of the universe we can see.

Although we have found an explanation for the observations, we have had to introduce the idea of a universe changing with time, and if we relate the rates of recession of galaxies at different distances, we must conclude that all those which we now see must have been crowded close together about 10,000 million years ago. This 'age of the universe' is little more than twice the age of the Earth as indicated by the radioactivity in the oldest rocks. Although the observations cannot indicate whether this period of high density should be regarded as the 'creation' or simply a phase in a universe the density of which varies periodically, they do imply that the appearance of the surrounding universe is changing with time.

In 1948, however, Bondi, Gold and Hoyle proposed an entirely different model, based on the supposition that the universe as a whole is completely unchanging with time. In order to account for the expansion of the universe and the consequent loss to view of distant galaxies, they introduced the idea that new matter is continuously created everywhere throughout space; this matter will eventually condense to provide new galaxies to replace those lost to view through the expansion. Although many types of observation and experiment have suggested that matter and energy cannot be created or destroyed, it has never been verified with an accuracy sufficiently high to rule out the theory of 'continuous creation'.

---

* Substance of a Royal Institution Discourse delivered on February 24.

If we accept this Steady-State theory, we have a model which has the philosophical attraction that the universe presents the same appearance no matter from where, or at what time, it is observed. It is a universe unlimited in space or time, and the only unfamiliar feature which we have to accept is that the law of conservation of matter and energy is not quite true.

What we must now ask is whether any of the models proposed bears any resemblance to the actual universe? Here we need to look for subsidiary consequences of the different models and see whether any form the basis for observational test. While it is likely to be very difficult to distinguish between different forms of evolving cosmology, there is a good chance that there are detectable differences between any evolving model and the Steady-State model. In the evolving case we shall expect to find a progressive ageing of the galaxies, and the average distance between galaxies will steadily increase; on the Steady-State model new galaxies are being born to replace those lost by the expansion and we shall always find a mixture of old and young galaxies in any sample we choose.

If, therefore, we could compare a photograph of the surrounding galaxies taken a thousand million years ago with one taken to-day, we should be able to make this distinction. Although this particular experiment is impossible, we can do something very like it by observing galaxies at a distance of a thousand million light years. What we see is a picture of these galaxies as they were when the light left them, and since the light has been travelling for a thousand million years, we can see what changes have occurred in this time by comparing them with nearby galaxies, from which the light has taken a much shorter time to reach us. By extending our observations to greater and greater distances we can in this way explore back to earlier and earlier periods in the history of the universe. This is the reason why astronomers want to study the faintest galaxies, and why the great 200-in. telescope on Mount Palomar was built. Unfortunately, even with this telescope, it has so far proved impossible to reach any definite conclusion, owing to the difficulties of making sufficiently accurate observations of sufficiently distant galaxies.

There seemed little hope of overcoming a barrier apparently so serious; but in 1952 a most remarkable discovery was made—that the second most intense source of radio waves which had been detected in the new science of radio astronomy was a very distant galaxy, at a distance of 500 million light years. Its intensity showed that its radio emission was about a million times more powerful than that of our own or other nearby galaxies.

The fact that a source of such power could exist was surprising enough, but almost as remarkable was the evident rarity of such sources; there are about 100 million galaxies within a distance of 500 million light years, and yet only this one produces radio emission so intense.

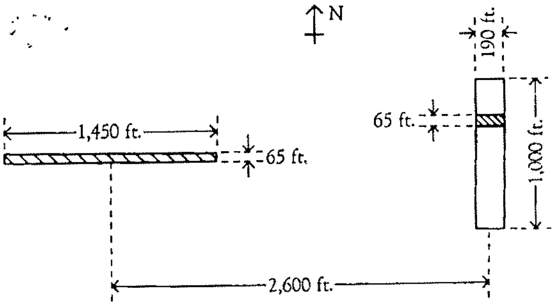

Fig. 1. Diagram of the Cambridge interferometer.

More detailed observations with the 200-in. telescope at Mount Palomar suggested that this source was a collision between two complete galaxies. This explained the rarity of such sources (for the chance of such an encounter is extremely small) and the additional energy needed to maintain the powerful emission of radio waves was supplied by the collision.

The existence of such a source suggested at once the possibility of exploring to greater distances, and thus to earlier stages in the history of the universe than would ever be possible in optical astronomy. But before we can use radio observations to test any particular cosmological theory, we must find some quantity which we can predict according to the theory, and which we can also measure. One such quantity, as we have seen, is the density of galaxies at different distances—or equally well, the density of radio galaxies. But in this case we have no way of measuring distance directly. If we knew the average power of the sources, we could use their intensities as a measure of distance.

The first problem is therefore to find the power of the sources, so that we can predict, according to a given cosmological theory, the relative number which we should expect to find in a given range of intensity. We can then compare these results with the actual numbers we find from our observations. We must endeavour to make this comparison for the weakest possible sources—for the further we can penetrate in distance, or the further back in the history of the universe we can reach, the greater will be the differences between the predictions of the different cosmological models.

It seemed impracticable to build an instrument of sufficient size by conventional means, but at Cambridge we have developed a new method of obtaining a very large resolving power, by moving a smaller aerial to different positions within a much larger effective aerial. Our new instrument consists of two elements, one of which is 1,450 ft. × 65 ft. and aligned east–west; the other is a smaller aerial 190 ft. × 65 ft. mounted on railway lines 1,000 ft. long running north–south (Fig. 1). The Earth's rotation scans the beam around a 4-deg. strip of sky each 24 hr., the strip being selected by the elevation of the two aerials.

In each set of observations, the moving aerial is driven to the north end of the rails and the observations are recorded (as holes in punched tape) for 24 hr.; we then move the aerial by about its own width and another set of observations is made. After 25 days we have all the information we need to produce a map of the whole 4-deg. strip.

In order to do this, we must make about a quarter of a million calculations, and these are made on *Edsac*, the computer at the Cambridge University Mathematical Laboratory. The output of the com-

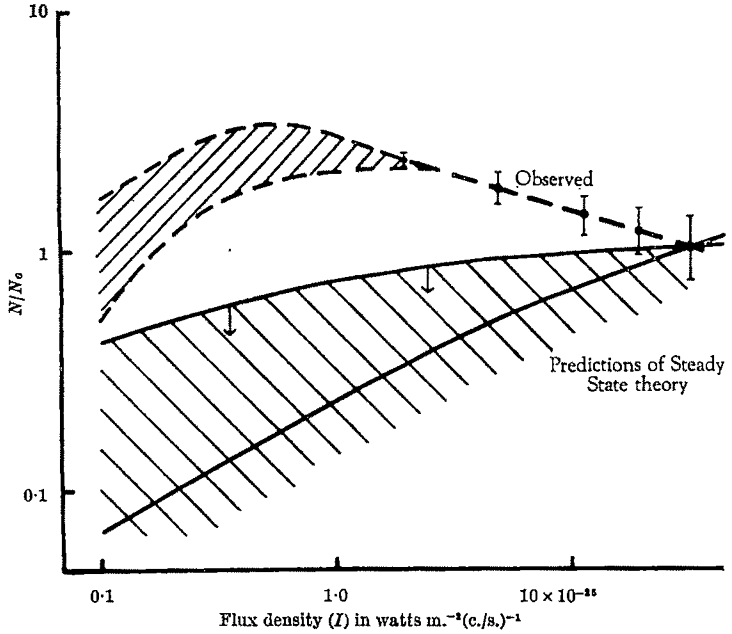

Fig. 2. Plot of relative number of sources observed (N/N_0) above given intensities I. The dotted lines represent the extension of the observations to weaker sources than can be observed individually; they are based on a statistical method which gives no information about the positions or intensities of individual sources, but allows limits to be set to the number of sources of different intensities. The full lines are the curves predicted by the Steady-State model for two values for the effective power of the sources

puter is printed on sheets which enable us to find the positions and intensities of the sources, and the detail obtained is the same as if we had built two aerials each 800 ft. × 500 ft.

We have been using this telescope continuously since it was completed in the summer of 1958, most of the time on problems relating to the cosmological question.

Our first problem was to establish the power of the sources—so that we could predict the relative number of sources we should expect to find at different intensities. At the same time we must make sure that the observations are not being diluted by large numbers of relatively weak sources at small distances —for we know that some of the sources are the remains of supernova explosions inside our own Galaxy—and others are nearby galaxies with relatively weak radio emission.

We have used three methods of finding the power of the sources, the first of which is based on radio methods alone, and involves no assumptions about the nature of the sources. This method showed that only a few per cent of the observed sources were within the Galaxy, and that most of them were external galaxies having a radio emission at least 1,000 times greater than that of our own Galaxy. If we suppose that most of the sources emit as much optical radiation as our own Galaxy, then the limiting optical brightness of the sources allows us to set an even greater limit to the radio emission. The third method was based on measurements of the angular diameters of the sources, and again indicated an average radio emission 10^4–10^5 times that of the Galaxy. From these results we can now compute the number of sources we should expect to find at different intensities; but before we can compare the results with what we observe, we must explore a number of possible difficulties which might affect the interpretation of the observations. One difficulty of this sort is the possibility that radio galaxies might occur in clusters—if they did so, then although we would be able to recognize the individual sources in a nearby cluster, a very distant cluster might be mistaken for a single nearby source. We therefore made a number of subsidiary investigations of this sort to see what corrections would be necessary.

The final, and most extensive problem was to determine the actual number of sources above given intensities, down to the smallest value we could reach. The results, plotted as the number of sources N compared with the number N_0 which would have been observed in the absence of effects of the red-shift, are shown in Fig. 2. The corresponding curves predicted by the Steady-State model on the basis of (*a*) the lowest permissible value of radio power, and (*b*) the value suggested by the optical data, are also shown in Fig. 2; the discrepancy seems too great to be explained by errors in the observations or their interpretation, and suggests that the Steady-State theory in its original form does not correspond to the actual universe.

This is only the beginning of the problem, and the simplest of the questions which one can ask. There are many versions of evolving cosmologies, and there may be special cases of the Steady-State model which fit the present results. More detailed observations may make it possible to eliminate some of these too.

CONTINENT AND OCEAN BASIN EVOLUTION BY SPREADING OF THE SEA FLOOR

By ROBERT S. DIETZ,
U.S. Navy Electronics Laboratory, San Diego 52, California

ANY concept of crustal evolution must be based on an Earth model involving assumptions not fully established regarding the nature of the Earth's outer shells and mantle processes. The concept proposed here, which can be termed the 'spreading sea-floor theory', is largely intuitive, having been derived through an attempt to interpret sea-floor bathymetry. Although no entirely new proposals need be postulated regarding crustal structure, the concept requires the acceptance of a specific crustal model, in some ways at variance with the present consensus of opinion. Since the model follows from the concept, no attempt is made to defend it. The assumed model is as follows:

(1) Large-scale thermal convection cells, fuelled by the decay of radioactive minerals, operate in the mantle. They must provide the primary diastrophic forces affecting the lithosphere.

(2) The sequence of crustal layers beneath the oceans is markedly different from that beneath the continents and is quite simple (Fig. 1). On an average 4·5 km. of water overlies 0·3 km. of unconsolidated sediments (layer 1). Underlying this is layer 2, consisting of about 2·0 km. of mixed volcanics and lithified sediments. Beneath this is the layer 3 (5 km. thick), commonly called the basalt layer and supposedly forming a world-encircling cap of effusive basic volcanics over the Earth's mantle from which it is separated by the Mohorovičić seismic discontinuity. Instead we must accept the growing opinion that the 'Moho' marks a change of phase rather than a chemical boundary, that is, layer 3 is chemically the same as the mantle rock but petrographically different with low-pressure phase minerals above the Moho and high-pressure minerals below. This change of phase may be either from eclogite to gabbro[1], or from peridotite to serpentine[2]; its exact nature is not vital to our concept, but we can tentatively accept the eclogite–gabbro transition as it has more adherents. Common usage requires that we reserve the term 'mantle' for the substance beneath the Moho, but in point of fact, the gabbro layer (as a change of phase) is also a part of the mantle—a sort of 'exo-mantle'. Except for a very thin veneer, then, the sea floor is the exposed mantle of the Earth in this larger sense.

(3) It is relevant to speak of the strength and rigidity of the Earth's outer shell. The term 'crust' has been effectively pre-empted from its classical meaning by seismological usage applying it to the layer above the Moho, that is, the sial in continental regions and the 'basaltic' layer under the oceans so that the continents have a thick crust and the ocean basins a thin crust. Used in this now accepted sense, any implications equating the crust with rigidity must be dismissed. For considerations of convective creep and tectonic yielding, we must refer to a lithosphere and an asthenosphere. Deviations from isostasy prove that approximately the outer 70 km. of the Earth (under the continents and ocean basins alike) is moderately strong and rigid even over time-spans of 100,000 years or more; this outer rind is the lithosphere. Beneath lies the asthenosphere separated from the lithosphere by the level of no strain or isopiestic level; it is a domain of rock plasticity and flowage where any stresses are quickly removed. No seismic discontinuity marks the isopiestic level and very likely it is actually a zone of uniform composition showing a gradual transition in strength as pressure and temperature rise; and in spite of the lithosphere's rigidity, to speak of it as a crust or shell greatly exaggerates its strength. Because of its grand dimensions, for model similitude we must think of it as weak[3]. If convection currents are operating 'subcrustally', as is commonly written, they would be expected to shear below the lithosphere and not beneath the 'crust' as this term is now used.

(4) As gravity data have shown, the continents are low-density tabular masses of sial—a 'basement complex' of granitic rocks about 35 km. thick with a thin sedimentary veneer. Since they are buoyant and float high hydrostatically in the sima, they are analogous to icebergs in the ocean. This analogy has additional merit in that convection of the sima cannot enter the sial. But the analogy gives the wrong impression of relative strength of sial and sima; the continental lithosphere is no stronger than the oceanic lithosphere, so it is mechanically impossible for the sial to 'sail through the sima' as Wegnerian continental drift proposes. The temperature and pressure are too high at the base of the sial to permit a gabbroic layer above the Moho; instead, there may be an abrupt transition from granite to eclogite.

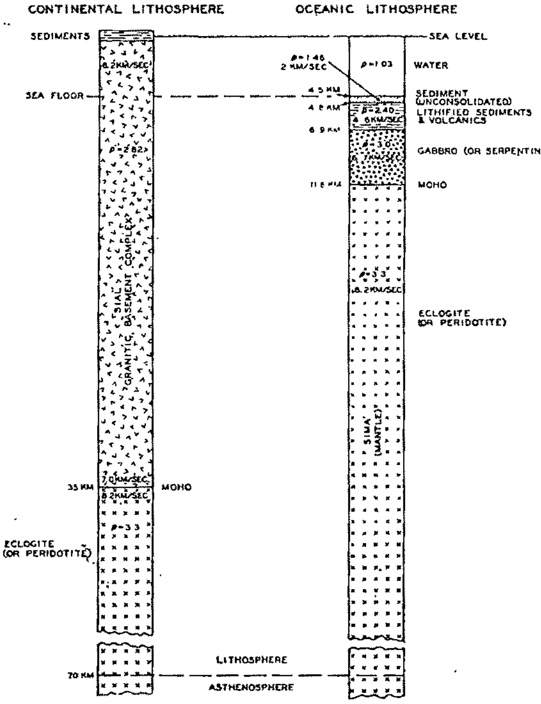

Fig. 1. Generalized crustal sections through the lithosphere beneath the continents and the ocean basins as presumed in this paper. Seismic velocities and densities are shown for the various layers

Spreading Sea Floor Theory

Owing to the small strength of the lithosphere and the gradual transition in rigidity between it and the asthenosphere, the lithosphere is not a boundary to convection circulation, and neither is the Moho beneath the oceans because this is not a density boundary but simply a change of phase. Thus the oceanic 'crust' (the gabbroic layer) is almost wholly coupled with the convective overturn of the mantle creeping at a rate of a few cm./yr. Since the sea floor is covered by only a thin veneer of sediments with some mixed-in effusives, it is essentially the outcropping mantle. So the sea floor marks the tops of the convection cells and slowly spreads from zones of divergence to those of convergence. These cells have dimensions of several thousands of kilometres; some cells are quite active now while others are dead or dormant. They have changed position with geological time causing new tectonic patterns.

The gross structures of the sea floor are direct expressions of this convection. The median rises[4,5] mark the up-welling sites or divergences; the trenches are associated with the convergences or down-welling sites; and the fracture zones[6] mark shears between regions of slow and fast creep. The high heat-flow under the rises[7] is indicative of the ascending convection currents as also are the groups of volcanic seamounts which dot the backs of these rises.

Much of the minor sea-floor topography may be even directly ascribable to spreading of the sea floor. Great expanses of rough topography skirt both sides of the Mid-Atlantic Rift; similarly there are extensive regions of abyssal hills in the Pacific. The roughness is suggestive of youth, so it has commonly been assumed to be simply volcanic topography because the larger seamounts are volcanic. But this interpretation is not at all convincing, and no one has given this view formality by publishing a definitive study. Actually, the topography resembles neither volcanic flows nor incipient volcanoes. Can it not be that these expanses of abyssal hills are a 'chaos topography' developed as strips of juvenile sea-floor (by a process which can be visualized only as mixed intrusion and extrusion) and then placed under rupturing stresses as the sea floor moves outward?

The median position of the rises cannot be a matter of chance, so it might be supposed that the continents in some manner control the convection pattern. But the reverse is considered true: conditions deep within the mantle control the convective pattern without regard for continent positions. By viscous drag, the continents initially are moved along with the sima until they attain a position of dynamic balance overlying a convergence. There the continents come to rest, but the sima continues to shear under and descend beneath them; so the continents generally cover the down-welling sites. If new upwells do happen to rise under a continental mass, it tends to be rifted. Thus, the entire North and South Atlantic Ocean marks an ancient rift which separated North and South America from Europe and Africa. Another such rift has opened up the Mediterranean. The axis of the East Pacific Rise now seems to be invading the North American continent, underlying the Gulf of California and California[8]. Similarly, the Indian Ocean Rise may extend into the African Rift Valleys, tending to fragment that continent.

The sialic continents, floating on the sima, provide a density barrier to convection circulation—unlike the Moho, which involves merely a change of phase. The convection circulation thus shears beneath the continents so that the sial is only partially coupled through drag forces. Since the continents are normally resting over convergences, so that convective spreading is moving toward them from opposite sides, the continents are placed consequently under compression. They tend to buckle, which accounts for alpine folding, thrust faulting, and similar compressional effects so characteristic of the continents. In contrast, the ocean basins are simultaneously domains of tension. If the continental block is drifted along with the sima, the margin is tectonically stable (Atlantic type). But if the sima is slipping under the sialic block, marginal mountains tend to form (Pacific type) owing to drag forces.

Implications of the Concept

Ad hoc hypotheses are likely to be wrong. On the other hand, one which is consonant with our broader understanding of the history of the Earth may have merit. While the thought of a highly mobile sea floor may seem alarming at first, it does little violence to geological history.

Volumetric changes of the Earth. Geologists have traditionally recognized that compression of the continents (and they assumed of the ocean floors as well) was the principal tectonic problem. It was supposed that the Earth was cooling and shrinking. But recently, geologists have been impressed by tensional structures, especially on the ocean floor. To account for sea floor rifting, Heezen[10], for example, has advocated an expanding Earth, a doubling of the diameter. Carey's[11] tectonic analysis has resulted in the need for a twenty-fold increase in volume of the Earth. Spreading of the sea floor offers the less-radical answer that the Earth's volume has remained constant. By creep from median upwellings, the ocean basins are mostly under tension, while the continents, normally balanced against sima creepage from opposite sides, are under compression.

The geological record is replete with transgressions and regressions of the sea, but these have been shallow and not catastrophic; fluctuations in sea-level as severe as those of the Pleistocene are abnormal. The spreading concept does no violence to this order of things, unlike dilation or contraction of the Earth. The volumetric capacity of the oceans is fully conserved.

Continental Drift. The spreading concept envisages limited continental drifting, with the sial blocks initially being rafted to down-welling sites and then being stablized in a balanced field of opposing drag forces. The sea floor is held to be more mobile and to migrate freely even after the continents come to rest. The sial moves largely *en bloc*, but the sea floor spreads more differentially.

Former scepticism about continental drift is rapidly vanishing, especially due to the palæomagnetic findings and new tectonic analyses. A principal objection to Wegener's continental drift hypothesis was that it was physically impossible for a continent to 'sail like a ship' through the sima; and nowhere is there any sea floor deformation ascribable to an on-coming continent. Sea floor spreading obviates this difficulty: continents never move through the sima—they either move along with it or stand still while the sima shears beneath them. The buoyancy of the continents, rather than their being stronger than the sima, accounts for this. Drag associated with the shearing could account for alpine folding and related compressional tectonic structures on the continents.

Persistent freeboard of the continents. A satisfactory theory of crustal evolution must explain why the continents have stood high throughout geological time in spite of constant erosional de-levelling. Many geologists believe that new buoyancy is added to continents through the gravitative differentiation from the mantle. Spreading of the sea floor provides a mechanism whereby the continents are placed over the down-wells where new sial would tend to collect, even though the convection is entirely a mantle process and the role of the continents is passive. It also follows that the clastic detritus swept into the deep sea from the continents is not permanently lost. Rather, it is carried slowly towards, and then beneath, the continents, where it is granitized and added anew to the sialic blocks.

Youth of the ocean floor. It follows paradoxically from the spreading concept that, although the ocean basins are old, the sea floor is young—much younger than the rocks of the continents. Marine sediments, seamounts, and other structures slowly impinge against the sialic blocks and are destroyed by underriding them. Pre-Cambrian and perhaps even most Palæozoic rocks should prove absent from the ocean floors; and Mohole drilling should not reveal the great missing sequence of the Lipalian interval

(Pre-Cambrian to Cambrian) as hoped for by some. All this may seem surprising, but marine geological evidence supports the concept.

On his discovery of the guyots of the Pacific, Hess[12] supposed these were Pre-Cambrian features protected from erosion by the cover of the sea. But Hamilton[13] proved the guyots of the Mid-Pacific Mountains were Cretaceous, and these seem to be among the oldest of the seamount groups. In an analysis of the various seamount groups of the western Pacific, I was forced to conclude that none of them was older than mid-Mesozoic. The young age of the seamounts has been puzzling; certainly they can neither erode away nor subside completely. Also, there seem to be too few volcanic seamounts, if the present population represents the entire number built over the past hundred million years or more. The puzzle dissolves if sea floor spreading has operated. Modern examples of impinging groups of seamounts may be the western end of the Caroline Islands, the Wake–Marcus Seamounts, and the Magellan Seamounts[14]. All may be moving into the western Pacific trenches. Seamount *GA*-1 south of Alaska may be moving into the Aleutian Trench[15].

The sedimentary layers under the sea also appear to be young. No fossiliferous rocks older than Cretaceous have yet been dredged from any ocean basin. Radioactive dating of a basalt from the Mid-Atlantic ridge gave a Tertiary age[16]. Kuenen[17] estimated that the ocean basins should contain on an average about 3·0 km. of sedimentary rocks assuming the basins are 200 million years old. But seismic reflexions indicate an average of only 0·3 km. of the unconsolidated sediments. Hamilton[18], however, believes that much of layer 2 may be lithified sediments. If *all* layer 2 is lithified sediments, Hamilton finds that the ocean basins may be Palæozoic or late Pre-Cambrian in age—but not Archæan. But very likely layer 2 includes much effusive material and sedimentary products of sea floor weathering. In summing up, the evidence from the sediments, although still fragmentary, suggests that the sea floors may be not older than Palæozoic or even Mesozoic.

Spreading and magnetic anomalies. Vacquier, V., *et al.* (in the press) recently have completed excellent sea-floor magnetic surveys off the west coast of North America. A striking north–south lineation shows up which seems to reveal a stress pattern (Mason, R. G., and Raff, A. D., in the press). Such interpretation would fit into spreading concept with the lineations being developed normal to the direction of convection creep. The lineation is interrupted by Menard's[6] three fracture-zones, and anomalies indicate shearing offsets of as much as 640 nautical miles in the case of the remarkable Mendocinco Escarpment[19]. Great mobility of the sea floor is thus suggested. The offsets have no significant expression after they strike the continental block; so apparently they may slip under the continent without any strong coupling. Another aspect is that the anomalies smooth out and virtually disappear under the continental shelf; so the sea floor may dive under the sial and lose magnetism by being heated above the Curie point.

By considering an Earth crustal model only slightly at variance with that commonly accepted, a novel concept of the evolution of continents and ocean basins has been suggested which seems to fit the 'facts' of marine geology. If this concept were correct, it would be most useful to apply the term 'crust', which now has a confusion of meanings, only to any layer which overlies and caps the convective circulation of the mantle. The sialic continental blocks do this, so they form the true crust. The ocean floor seemingly does not, so the ocean basin is 'crustless'.

I wish to express my appreciation to E. L. Hamilton, F. P. Shepard, H. W. Menard, V. Vacquier, R. Von Herzen and A. D. Raff for critical discussions.

MOUSE CHIMÆRAS DEVELOPED FROM FUSED EGGS

By Dr. ANDRZEJ K. TARKOWSKI

Department of Zoology, University College of North Wales, Bangor, Caernarvonshire*

THE regulative capacities of an egg can be defined by following the development of either its separated parts (or blastomeres) or of united whole ones. The mammalian egg as an object of experimental embryology has been studied more extensively along the first line of approach[1–6]. It has been shown that the isolated blastomeres of 2-cell and even 4-cell eggs can effect regulation. Normal offspring from 'half' blastomeres were reported in the mouse[2,3] and the rabbit[4,6]. 'Quarter' blastomeres of the mouse egg can develop at least into blastocysts[2,3] and in the rabbit can give rise at least to 9½-day-old embryos[5,6].

The only attempt, so far, to fuse mammalian eggs was reported by Nicholas and Hall[1]. These authors transferred pairs of naked, slightly adhering 1-cell rat eggs. A single embryo developed until term, but as the effectiveness of the union achieved had not been checked, the result was not quite conclusive.

In undertaking the work to be described here, it was decided that the *conditio sine qua non* of experiments

---

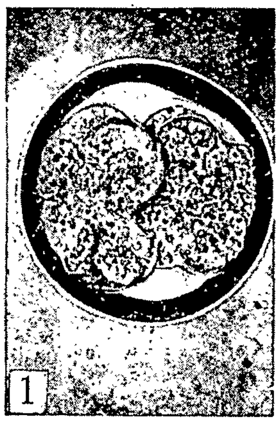
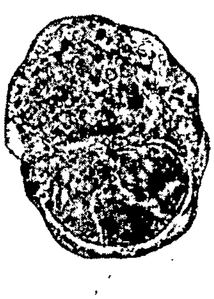
PHYSICS DEPARTMENTAL LIBRARY





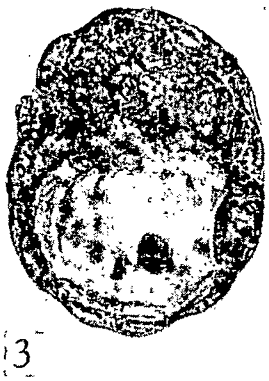


Fig. 1. Two 8-cell eggs compressed in a small drop of medium suspended in liquid paraffin. (× 300)

Fig. 2. Single naked blastocyst developed from 8-cell egg cultured for 24 hr. (× 400)

Fig. 3. Double blastocyst developed from two fused 8-cell eggs after 24 hr. in culture. (× 400)

of this kind was to keep the fused eggs *in vitro* up to the formation of the blastocyst. Moreover, the conditions of culture must be such as to allow the eggs to be observed during development, thus ensuring that all the blastomeres had been incorporated into the one blastocyst.

Work of this type may contribute, as does the other line of approach, to the understanding of the mechanism of normal early development. It should offer, in addition, some new opportunities for research into genetics, developmental genetics and the factors controlling sexual differentiation. Unless eggs from an inbred strain are used, the united components are not genetically identical. In addition, in 50 per cent of cases, sex chimæras would be expected.

The eggs used throughout these experiments were in late phase of the 8-cell stage. The donors were from A_2G albino and $C57$ black inbred strains and from a *LAB* Grey random-breed colony. The eggs of the first two strains were from spontaneous ovulations and the animals were killed in the afternoon of the third day (day when vaginal plug is found is denoted as first day of pregnancy or pseudopregnancy). All the eggs of *LAB* Grey origin were from hormonally induced ovulation in mature animals[7]. Intraperitoneal injection of 3–4 I.U. of pregnant mare serum ('Gestyl') were given, followed after 37–42 hr. by 3–4 I.U. human chorionic gonadotropin ('Pregnyl', Organon Laboratories), and the animals were paired with either *LAB* Grey or A_2G males. Autopsy was performed 78–83 hr. after the second injection. Combinations of eggs united were as follows: (1) $(C57)^2 + (A_2G)^2$, (2) $(LAB\ \mathrm{Grey})^2 + (LAB\ \mathrm{Grey})^2$, (3) $(LAB\ \mathrm{Grey} \times A_2G) + (LAB\ \mathrm{Grey} \times A_2G)$, (4) $(LAB\ \mathrm{Grey})^2 + (LAB\ \mathrm{Grey} \times A_2G)$. It must be added that the offpsring from *LAB* Grey × A_2G cross is dark agouti with black eyes, and so in combination (3), both components had the factor for dark pigmentation and in the combination (4) only one of them. As recipients, *LAB* Grey females mated with vasectomized males were used.

The technical procedure comprised: (*a*) removing the zona pellucida, (*b*) joining the eggs, (*c*) culturing, (*d*) transplanting.

(*a*) It was previously reported[3] that the zona pellucida can be removed by mechanical means. The technique was improved for this purpose. A micropipette, with an internal diameter of 65μ, attached by rubber tubing to a compressible rubber bulb was used. The egg was rapidly sucked into the pipette, causing rupture of the zona and allowing the naked egg to escape. The size of the pipette and the suction pressure applied are critical for the success of this operation. All manipulations were carried out under a dissecting microscope. The eggs were under constant observation, and only those with all blastomeres undamaged were used for further work.

(*b*) Two naked eggs were sucked into a pipette and placed with a small drop of medium in liquid paraffin. With another pipette (internal diameter not more than 40μ) attached to a compressed rubber bulb, most of the medium was withdrawn from this drop, thus squeezing the eggs together (Fig. 1). Such pressure was applied for a period of 5–30 min. Several such drops were placed on the bottom of a shallow glass dish treated previously with silicone fluid ('Repelcote', Hopkin and Williams). Up to this moment all manipulations had been carried out in Tyrode's solution with 0·1 per cent bovine plasma albumin, fraction V (Armour).

(*c*) The culture medium was based on that of Whitten (refs. 8, 9 and personal communication). The medium finally adopted consisted of Krebs–Ringer bicarbonate containing per 130 ml. of solution, 2·6 mgm. of phenol red, 4·0 mgm. of both penicillin salt and streptomycin, 400 mgm. of bovine plasma albumin fraction V, and 130 mgm. of glucose. The medium was sterilized by filtration through 'Sterimat' filters (T. B. Fords, Ltd.), in Hemmings bottles, then covered with liquid paraffin and stored at − 20° C. With a sterile pipette, medium was taken through a layer of liquid paraffin and a drop of about 2–4 mm.^{3} (though the amount of medium is not critical) placed over each of the small drops containing eggs. The small drop was immediately incorporated into the big one and thus each pair of eggs was cultured separately. More liquid paraffin was added to fill up the dish, which was then covered with a piece of glass. The eggs were cultured at 38° C. Liquid paraffin was gassed before use with 5 per cent carbon dioxide in air, and the *p*H of the medium in the drops immediately adjusted itself to 7·4.

(*d*) The eggs were cultured for 24 or 36–40 hr. and transplanted only after reaching the blastocyst stage. The eggs from the first group (24 hr.) were transferred either to the oviduct on the first day (using the method previously described[10]) or to the uterus on the third day according to the method of McLaren and Michie[11], slightly modified. The eggs kept in culture for 36–40 hr. were transplanted to the uterus only on the third or fourth day of pseudopregnancy. It has been shown previously by McLaren and Biggers[12] that normal 8-cell mouse eggs kept *in vitro* for two days and transferred as blastocysts, develop normally to term, the rate of survival being the same as with untreated controls.

After a few hours in culture, the boundary between the eggs was less clearly defined and in 12–16 hr. each pair had completely rounded up into a single morula, leaving no trace of dual origin. In some of these eggs a small blastocœl had appeared by this time and after 24 hr. nearly all had developed into early blastocysts. In general, the rate of development was not very uniform and depended on the phase of 8-cell stage used and on the time spent by the eggs at room temperature during the manipulations. After 36–40 hr. the blastocysts were swollen and very large. No strict measurements of the size of 'double' blastocysts nor of single control ones have been made, because of their quick shrinkage at room temperature. The difference in volume of double and single blastocyst was, however, unmistakable, the difference in the size of the inner masses being very conspicuous (Figs. 2 and 3). The lack of the zona pellucida does not affect the size of the naked, single blastocysts, which compare well with their littermates cultured with the zona pellucida intact.

Usually, only a single blastocœlic cavity was formed from the very beginning. Sometimes, however, two distinct cavities appeared, separated either by trophoblastic cells or by the whole bulk of the fused inner masses. With advancing development the two cavities invariably joined together and a perfectly normal blastocyst was formed. In some cases the fusion was not complete, some 1/8 blastomeres or their derivatives being left outside. It was decided, therefore, not to use for transplantation those blastocysts in which more than one 1/8 blastomere (or its equivalent in 1/16 or 1/32 blastomeres) were not completely incorporated.

The general results of the development after transplantation are presented in Table 1. The results concern only those experiments in which eggs of *LAB* Grey origin were used, as no embryo has developed after transferring 19 fused $(C57)^2 + (A_2G)^2$ eggs. Among four different combinations of time and type of transfer, only one (line 3) proved to be completely unsuitable. The lack of success was certainly due to the unprepared state of the uterus, which does not allow retention of the eggs.

The first autopsies were performed on the tenth day of pregnancy. At this time, all 6 embryos available were already within the range of normal size variation. A pair of identical twins was also found, the embryos being of different size and retarded approximately 24 and 12 hr. Recipients killed on the twelfth and the fourteenth day yielded 4 (+ pair of identical twins) and 5 embryos respectively. Apart from the twins, all the others fall within the range of normal variation in size.

Of the females left until term, 4 were allowed to litter naturally, the other 4 were killed in the evening on the nineteenth day, the young were removed by Cæsarean section and placed with foster mothers which had littered on the same day, or one or two days before. Although the young seen just after birth and all those seen at the time of Cæsarean section appeared morphologically completely normal and alive, the subsequent mortality-rate was very high. Out of 10 young littered naturally, none survived. Some of them were partially eaten by their mothers immediately after birth, the others were found dead, though intact, during the first 24 hr. Among 8 young delivered by Cæsarean section, 3 died immediately, 1 survived for 20 hr., 2 for 3 days, and 2 are still alive at the time of writing, being 2 and 5 weeks old respectively. The factors causing this high post-natal mortality are obscure at the moment.

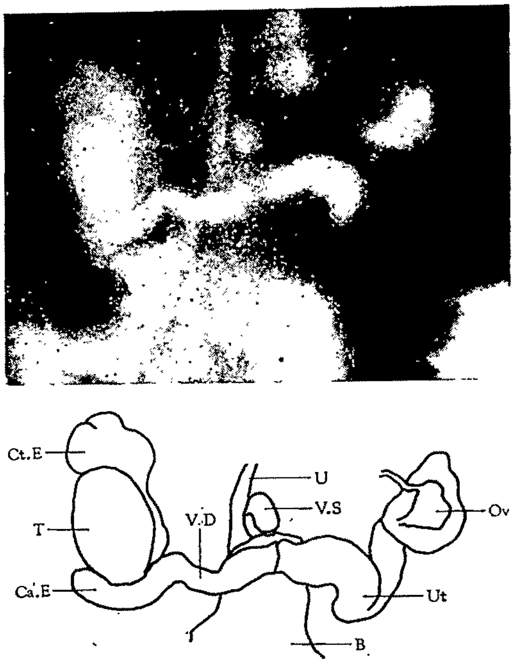

Fig. 4. Photograph (× about 16) of genital apparatus with what appears to be male organs on the left side and female on the right side. The interpretation is given in the key diagram. *B*, bladder; *Ca.E*, cauda epidydymis; *Ct.E*, caput epidydymis; *Ov*, ovary; *T*, testis; *U*, ureter; *Ut*, uterus; V.D., vas deferens; V.S., vesicula seminalis

Theoretically, 50 per cent of experimental embryos should be female/male genetical chimæras, 25 per cent males and 25 per cent females. 14 young were available for examination, but only macroscopical details have, so far, been studied. The results of dissection are as follows: 2 females, 9 males and 3 animals with genital apparatus of a clearly mixed type, with a varying degree of intersexuality (Fig. 4). Although the genital apparatus of some other animals classified as males seems to exhibit some deviation from the normal type, nothing more can be said until histological analysis is made. The ratio—2 females, 3 female/male and 9 males—suggests that some of the 'males' are in fact also sex chimæras in which the male component dominates. In the mouse (as in other mammals) the male gonads begin to differentiate earlier than the female gonads[13]. It is possible to

Table 1. DEVELOPMENT OF DOUBLE BLASTOCYSTS AFTER TRANSPLANTATION

Duration of culturing	Time and type of transplantation	No. of recipients	Total No. of transplanted blastocysts	Implantations	Embryos or young	Successful transplantations
24 hr.	Evening 1st day oviduct	13	63	22	16	8
	Evening 3rd day uterus	7	32	18	13	6
36–40 hr.	Morning 3rd day uterus	7	21	1	1	1
	Morning 4th day uterus	12	37	10	6*	6
	Total	39	153	51 (33 per cent)	36 (38*) (21 per cent)	21 (54 per cent)

* 2 pairs of identical twins.

assume that in the sex chimæras the hormones from the male part of the gonads suppress, to some extent, the development of female characters. On the other hand, the 3 clear cases of intersexes, mentioned above, exclude the possibility of complete dominance being an absolute rule. However, nothing is known at present about the distribution in the embryo of the cells derived from the two-component eggs. It seems more likely that the contribution from these two sources to different regions of the body, or even of the organs, is not uniform and varies from individual to individual. The genital apparatus can provide a clear indication of irregularities of this kind. The inconstant genetical constitution of the tissues contributing to this apparatus, when influenced by secondary stimuli, could produce a variety of abnormalities.

The striking ability of mouse eggs to unite and develop into one blastocyst, at so late a stage as the 8-cell, can be accounted for on the basis that the position of the cells is not yet determined. It is during the succeeding mitotic cycle that the trophoblastic cells (or strictly speaking enveloping cells) move and overgrow the cells of the inner mass[14,15]. The movements of enveloping cells must be caused by differing surface activities of the two kinds of cells. In the case of fused eggs, these movements are influenced by the presence of two groups of cells of the inner mass. Consequently, the enveloping cells tend to overgrow the two inner masses together, leaving free from the beginning, or retreating afterwards from, the surface between them. The observations made just after joining and during the first few hours of culturing support this hypothesis. The mechanical squeezing is applied for a short time and results only in approximation of the eggs. Though sticking together, the eggs represent at this time two distinct entities. It is during culturing, when no mechanical squeezing is applied, that the boundary gradually vanishes and real union takes place. The 8-cell stage is the latest convenient stage for this purpose. Eggs joined at the 12-cell stage do adhere together, but later almost invariably separate completely to form two blastocysts.

The perfect morphology of 'double' blastocysts would seem to preclude the possibility that the descendant cells of only one egg contribute to the developing embryo. It will be possible, perhaps, to obtain in future additional proof on purely genetical grounds. In the present work one combination of fused eggs—$(LAB\ \mathrm{Grey})^2 + (LAB\ \mathrm{Grey} \times A_2G)$—offers a possibility of tracing the existence of one component due to its factor for pigmentation. It can be assumed that if the pigment were revealed in some form in all or at least in the majority of cases, this could be considered as indirect evidence that the non-pigmented component is also present. As all but one of the young died before the time when skin pigmentation appears, the only criterion available was the eye colour. Among 15 embryos and young, 14 had black eyes, including both embryos in one pair of identical twins. The one additional animal which has survived has black eyes and a uniform coat of the type of the hybrid component.

Briefly, the evidence for real chimærism in the experiments described is three-fold: (1) complete union of two eggs into one blastocyst as seen in culture *in vitro*; (2) the presence of intersexes; (3) the presence of black pigment in the majority of embryos developed from pigmented + non-pigmented fused eggs.

Experiments are still in progress and a detailed account will be published elsewhere.

This work was done during the tenure of a Rockefeller Foundation fellowship. I wish to thank Prof. F. W. Rogers Brambell for allowing me to use the facilities of this laboratory and for his interest and encouragement.

OBITUARIES

Maurice, Duc de Broglie, For.Mem.R.S.

MAURICE DE BROGLIE, who died on July 14, 1960, was one of that small band of scientists who pursue their researches privately with their own means. In some respects he was unique. Not only did he establish a laboratory for his own research in his Paris home, but he also collected around him a group of younger men who worked under his guidance. His brother, Louis de Broglie, joined him shortly before the First World War, and much of the initial inspiration of Louis's work came from Maurice's influence. Louis Leprince-Ringuet, Jean Trillat, Jean Thibaud, Alexandre Dauvillier, Bruno Rossi, were among those in his research school. It was his achievement to establish a private research centre of world-wide reputation in his mansion in the rue Chateaubriand.

Maurice de Broglie was born on April 27, 1875, in Paris. He entered the Ecole Navale in 1893 and served for ten years in the Navy. When he left it, in 1902, he established a small laboratory in his house. He was, at that time, interested in the electrical charges on fine particles suspended in an ionized gas, and studied these movements in an electric field, the method afterwards used by Millikan to measure the electronic charge. In 1913 he was one of the first to study X-ray spectra and X-ray absorption. He developed a spectrometer in which he registered, on a photographic plate, the reflected rays from a lattice plane of a slowly rotating crystal. I remember that time well, because Maurice de Broglie and my father corresponded so regularly and compared their results.

During the First World War, he had a commission in the French Navy and made a considerable contribution to the underwater detection of submarines and the development of radio.

After the War, de Broglie continued his researches on X-ray absorption discontinuities, and published, with his brother Louis, *La Physique des Rayons X*, which was a well-known standard work at that time. The laboratory was greatly enlarged and the number of research workers increased. De Broglie's interests turned towards nuclear physics, and some of the devices for observations of high-energy particles which have now become classical were first developed by de Broglie's team. He was elected to the Académie Française in 1934. For ten years he was president of the Conseil Scientifique de l'Energie Atomique.

De Broglie won the warm affection of his students and his many friends all over the world, who will retain pleasant memories of their visits to his home and laboratory, where he was the kindest and most genial of hosts.

W. L. BRAGG

Prof. E. Henriot

WITH the death on February 1 of Emile Henriot, Belgian science lost one of its foremost representatives. Although of French origin (he was born in Besançon in 1885), he spent practically his entire scientific life in Belgium as professor of physics in the Université Libre de Bruxelles and was made emeritus professor in 1956. He suffered in the last few years from ill-health, which fortunately did not diminish in any manner his lucidity or his mental powers.

Among his many contributions to physics, two stand out by which his name will be remembered. The first was the subject of his doctor's thesis. By a masterly series of investigations, he was the first to show definitely that potassium and rubidium are naturally radioactive. This work, done before the First World War, was an investigation in the best tradition of the great French school of radioactivity measurements.

In more mature years came his justly famous investigations of extremely high angular velocities. He found that suitably placed air-jets can be used to spin tops at very high speeds, and he developed this technique to the point where it could be used for certain physical measurements. Although he originally wanted to use it for a precision determination of the speed of light, in the hands of Beams these air-driven tops became the mechanism of the then most successful ultracentrifuges.

Henriot was attracted time and again to questions of optics, where he was able to use his great theoretical skill. Problems of birefringence and molecular vibrations have been treated very successfully in several of his papers.

His contributions to physics went considerably beyond his own research. He was an outstanding teacher, and several of his former pupils are now professors of physics in different places. To the physics community at large, he was known as the organizer of the physics conferences of the Solvay Institute. For more than thirty years, he was a member of its administrative committee and for about twenty years he was its secretary. To the physicists going to these conferences he was a familiar figure, and he succeeded in maintaining these conferences at a very high level.

Physics was not his only love. Everything human attracted him, and his friends could, and did, learn much from him about art or archæology. He had a fine collection of Greek marbles and a beautiful library adorned by many valuable books. Moreover, he was an extremely warm human being, and those who had the good fortune of being his friends deplore his death.

The many distinctions which came to him were never mentioned by him. He was a very modest person, modest almost to shyness. He married one of his former students, who became his collaborator for very many years. During the Second World War, Henriot was professor at the University of Algiers, when evacuated from Belgium and France. By coincidence, his daughter still lives there. In the opinion of some of his colleagues, the good physics tradition in Algiers really started with his teaching there.

All his friends and the world of physics will miss him.

L. MARTON

Mr. G. W. G. Briggs

GUY BRIGGS, assistant director of the National Institute of Agricultural Botany, died in hospital at Cambridge on March 7. His death at fifty-seven brings a deep sense of loss to his colleagues in many countries who shared his interest in problems relating to grassland and to seeds.

His early interest in agriculture developed as he lived during school vacations on his grandfather's farm at Melbourne in Derbyshire. From King's College, Wimbledon, he went to Wye College, where he gained distinction in botany and in agriculture in the diploma examinations.

Entering the Colonial Agriculture Service in 1926, he was in close touch with the experimental farms and with advisory work among the growers. Those who knew him at that time remember the keen personal interest he took in all who sought his assistance, both Africans and Europeans. He played a leading part in the development of the rice crop and he had the satisfaction of seeing Nigeria become self-supporting in this cereal.

Retiring on medical advice from the Colonial Service in 1945, he was appointed as a technical officer at the National Institute of Agricultural Botany, becoming head of the Seed Production Branch in 1948 and assistant director of the Institute during January 1960.

Briggs's great organizing ability was admirably combined with a deep appreciation of technical problems on seed production. The researches of Stapledon and his colleagues at Aberystwyth had shown the value of leafiness and persistence in grasses and clovers, and had led to the development of a series of varieties which possessed these qualities. Briggs played an important part in bringing these to the notice of growers and in helping to develop methods of seed production which enabled the new varieties to be grown commercially on a large scale without losing their distinctive features.

The agricultural industry was beginning to appreciate the value of seed produced under technical supervision, and it was Briggs who was mainly responsible for organizing, on behalf of the National Institute of Agricultural Botany, the national certifying authority for herbage seeds. In this he had the strong support of the Welsh Plant Breeding Station, the seed trade and the National Farmers' Union.

Briggs took an active interest in developments in seed production abroad, and when, in 1958, the Organization for European Economic Co-operation adopted throughout the eighteen member countries an international scheme for herbage seed certification, experience gained in working the British scheme proved most valuable.

The comprehensive survey Briggs gave in his paper to the International Grassland Congress at Reading in 1960 has led to a better appreciation of the part seeds of high quality can play in the improvement of crop production.

At Cambridge, Guy Briggs was particularly valued for the soundness of his advice, which was always given in the most kindly way. He was able to make friends of those with whom he worked and he has made a big contribution to the good relations which exist between research workers, seedsmen and farmers.

His influence will continue to be felt, both through the work he did and through the help and training he gave to so many others.

Guy Briggs leaves a widow and a son of his first wife, who died in 1945. F. R. HORNE

NEWS and VIEWS

New Scientific Attachés : Dr. C. R. S. Manders and Mr. W. F. G. Drury

DR. CHARLES MANDERS has been appointed to the new post of scientific attaché to the British Embassy, Tokyo. He will hold the rank of senior principal scientific officer and joins the Department of Scientific and Industrial Research from the Ministry of Defence. Dr. Manders was educated at King's College, University of London, where he obtained a double first (general and physics). He served in the army during 1941–47, including a two-year spell as a lecturer at the Military College of Science. In 1947 he joined the Scientific Civil Service and for the past ten years has been with the Ministry of Defence on scientific duties. He is interested in education and has a translation of a collection of Soviet technological curricula, and also a translation of a French book on thermodynamics, in the course of publication.

Mr. W. F. G. Drury, scientific assistant to Sir John Carroll, deputy controller (research and development), Royal Naval Scientific Service, has been appointed scientific attaché to the British Embassy in Stockholm, in succession to Mr. G. H. Greenhalgh. He was educated at University College School, Hampstead, and on leaving school at 18, joined the Electrical Research Association as a technical assistant. He entered the Civil Service two years later, and during 1938–53 he was at the Admiralty Signal School, working mainly on radar and radio research and development projects. In 1953 he was appointed to the British Joint Service Mission in Washington. He returned to the Admiralty Signal Research Establishment in 1955 and was appointed to his present post in 1956.

Pharmaceutical Chemistry in London: Prof. W. H. Linnell

PROF. W. H. LINNELL, who is retiring from the chair of pharmaceutical chemistry in the School of Pharmacy, University of London, was appointed to the staff as reader in 1926 and to the chair of pharmaceutical chemistry in 1949. He had previously studied at the University of Durham, 1919–23, and, following the award of the Earl Grey Memorial Fellowship, at Lincoln College, Oxford. He afterwards had experience as a member of the research staff of H.M. Fuel Research Station. In 1956, while retaining the chair of pharmaceutical chemistry, he was appointed dean of the School of Pharmacy in succession to Prof. H. Berry. He is a member of the British Pharmacopœia Commission and the Revision Committee of the British Pharmaceutical Codex. In 1960 he was chairman of the British Pharmaceutical Conference at Newcastle upon Tyne. Prof. Linnell has been responsible for the development of the new subject of pharmaceutical chemistry in the School, and his own research work has been mainly in the field of chemotherapy.

Prof. W. B. Whalley

DR. W. B. WHALLEY has been appointed to the chair of chemistry created on Prof. Linnell's retirement from the chair of pharmaceutical chemistry at the School of Pharmacy, University of London. Throughout his academic career, Dr. Whalley has been associated with the University of Liverpool. After taking the Ph.D. degree in 1940 he worked in the Research Department of the General Chemicals Division of Imperial Chemical Industries, Ltd., at Widnes. A few years later he returned to Liverpool and began a long and productive collaboration with Prof. Alexander Robertson. Together they investigated successfully the structures of many natural products, especially complex heterocyclic compounds of oxygen. However, the most notable development was the study of fungal metabolites with varied structures, many of which were elucidated. Citrinin, rosenonolactone, and the novel class of pigments typified by sclerotiorin are good examples. Since Prof. Robertson's retirement in 1957, Dr. Whalley has continued energetic work with fungal metabolites, partly in collaboration with Dr. J. S. E. Holker, and he has turned his attention to their biosynthesis. Dr. Whalley's research interests have extended to other fields, and his numerous publications include several valuable review articles. In 1952 he spent six months at Smith, Kline and French Laboratories, Philadelphia. At Liverpool, where he has been reader since 1957, Dr. Whalley's work has not been confined to the Organic Chemistry Department. He is at present senior tutor of the Faculty of Science, and for some years he has been prominent in educational circles in Merseyside as a school governor, extra-mural lecturer, etc. Dr. Whalley's new post will give scope to his talents as an administrator, research worker and teacher, and his numerous friends look forward to his success in it.

The Royal Aeronautical Society : Elections and Awards.

AIR MARSHAL SIR OWEN JONES has been elected president of the Society. He has served on the Council since 1955 and was a vice-president of the Society during 1957–60. *Honorary Fellowship* of the Society has been conferred on Sir Sydney Camm, director and chief engineer, Hawker Aircraft, Ltd., and J. D. North, chairman and managing director, Boulton Paul Aircraft, Ltd. *Honorary Companionship* of the Society has been awarded to J. N. Toothill, director, Ferranti, Ltd., Hollingwood, Lancashire, and general manager, Ferranti, Ltd., Edinburgh.

At the annual general meeting of the Society held on May 4 the following awards were announced: *Simms Gold Medal*, to Prof. D. B. Spalding for his paper, "Heat and Mass Transfer in Aeronautical Engineering"; *George Taylor (Australia) Gold Medal*, to A. J. Troughton for his paper, "Relationship between Theory and Practice in Aircraft Structural Problems"; *Edward Busk Memorial Prize*, to C. Bourque and Prof. B. G. Newman for their paper, "Reattachment of a Two-dimensional, Incompressible Jet to an Adjacent Flat Plate"; *Orville Wright Prize*, to Prof. W. H. Wittrick for his paper, "Analysis of Stress Concentrations at Reinforced Holes in Infinite Sheets"; *Herbert Akroyd Stuart Memorial Prize*, to J. S. Alford, for his paper, "Power Plants for Supersonic Transports"; *Branch Prize*, to Lieut. Commdr. D. J. Whitehead for his paper, "The Low Speed Approach and Catapult Launch Problems in High Performance Naval Aircraft"; *Usborne Memorial Prize*, to T. W. F. Moore for his paper, "Some Experiments on the Reattachment of a Laminar Boundary Layer separating from a Rearward Facing Step on a Flat Plate Aerofoil".

The Society has also announced the following awards: *Silver Medal*, to R. Hafner, technical director (research), Westland Aircraft, Ltd., for outstanding work in the design and development of rotary-wing aircraft; *Bronze Medal*, to L. Haworth, assistant chief engineer, Propeller Turbines, Rolls-Royce, Ltd., for his work leading to advances in aircraft gas-turbine design; *British Gold Medal for Aeronautics*, to Dr. S. G. Hooker, technical director (Aero), Bristol Siddeley Engines, Ltd., for outstanding achievement in aero-engine design and development; *R. P. Alston Medal*, to R. P. Dickinson, superintendent, Aeroplane and Armament Experimental Establishment, Boscombe Down, for his achievement in the execution and direction of flight test observation work; *Wakefield Gold Medal*, to Dr. E. Eastwood, director of research, Marconi's Wireless Telegraph Co., Ltd., for his contributions to the development of air traffic control and navigational aids; *British Silver Medal for Aeronautics*, to Pierre Satre, technical director, Sud-Aviation, Paris, for his work on aircraft design, with special reference to his development of the rear-engined configuration. *N. E. Rowe Medals*, for younger members of the Society, and awarded for the best lecture given to any Branch of the Society by a member of a Branch: 21–26 years age-group, to J. Wilding, of the Chester Branch, for his paper "Bird Flight and the Aeroplane"; under-21 years age-group, to W. Bishop, of the Brough Branch, for his paper "The Development of Tailless Aircraft and Flying Wings".

The Queen Elizabeth II Canadian Medical Fund

DR. M. W. PARTINGTON has been appointed the first "Queen Elizabeth II Scientist" by the Queen Elizabeth II Canadian Fund to Aid in Research on the Diseases of Children; the Fund was established by the Federal Government of Canada to mark the occasion of Her Majesty's visit to Canada in 1959. Dr. Partington, a Research Fellow in neurology at the Research Institute of the Hospital for Sick Children, Toronto, will take up his new post on July 1 in the Department of Pædiatrics at Queen's University, Kingston, where a permanent research unit will be set up to initiate, foster and carry out research on pædiatric problems, such as mental deficiency and epilepsy in children. Three "Queen Elizabeth II Fellowships", totalling 13,500 dollars, were also awarded to: Dr. John Alexander Lowden, to continue studies towards a Ph.D. degree in biochemistry at McGill University, under Drs. K. A. C. Elliott and L. S. Wolfe; Dr. George Greenough Hinton, research fellow in neurology at the National Hospital for Nervous Diseases and Hospital for Sick Children, London (England), to work at the War Memorial Children's Hospital and the Psychiatric Research Centre, London (Ontario), under Drs. J. C. Rathbun and D. Zarfas; Dr. Hugh Taylor, chief resident of the Children's Hospital, Winnipeg, to work in the Department of Pediatrics, New York University, under Drs. J. Dancis and S. Krugman.

Science in Society

THE impact of scientific and technological progress on society is being examined in more than 200 research projects in the colleges, universities, and other institutions in the United States. These studies are described in a newly released issue of the National Science Foundation publication, *Current Projects on the Economic and Social Implications of Scientific Research and Development*, 1960 (Pp. v+124. Washington, D.C.: Government Printing Office, 1961. 40 cents). The effects of science and technological progress are examined in relation to such subjects as agriculture, impact on selected industries, administration and management, and labour. Other factors being studied are patents, scientific man-power and creativity, and science policy. Each project is summarized and listed with the names of the investigators, address of institution, and the anticipated form of publication of results. The first issue of this publication covered the year 1959. During 1959-60 the number of projects reported to the Foundation more than doubled.

Bibliography of Influenza

THE American Institute of Biological Sciences has issued the first of a new quarterly publication containing a bibliographical record of articles published on influenza and related subjects in the United States and elsewhere (*An Annotated Bibliography of Influenza*, Vol. 1, No. 1; September 1960. Pp. 20. Published quarterly. Washington, D.C.: American Institute of Biological Sciences, 2000 P Street, N.W., 1960). Approximately 2,600 journals are being examined for information. Each issue of this bibliography is divided into the following major categories: general and review; epidemiology; clinical; pathology; prophylaxis; immunology; virology; and animal studies.

The Smithsonian Institution

BULLETIN No. 220 of the United States National Museum is a list of type specimens of reptiles and amphibians in the Museum (*Type Specimens of Reptiles and Amphibians in the U.S. National Museum*. By Doris M. Cochran. Pp. xv+291. Washington, D.C.: Government Printing Office, 1961. 1.25 dollars). It has been compiled by Miss Doris M. Cochran, curator, and contains 1,742 names. An interesting introduction reviews the history of the collections and is followed by the list giving the original genetic, specific and sub-specific names. The name of the author is added and also the name of the publication where the name and description first appeared. Afterwards, if the original name of the genus or species is no longer accepted, the present synonym is added in italics. A comprehensive index completes the monograph.

Eye Examinations of Asian School Children

THE eyes of 359 children attending the Indian public primary school in Mwanza have been examined by members of the Biochemistry Nutrition Division of the East African Institute for Medical Research (Report, 1959–60. Pp. ii+36. Mwanza: East African Institute for Medical Research, 1960. Sh. 3). Apart from refractive errors there was almost no eye disease. Heights and weights were also obtained and all the data have been prepared so that comparison can be made with a similar study made by Pendse (1954) in Poona. This is the first time that refractive errors and growth data have been compared for two closely related communities in different parts of the world. In both height and weight the Gujerat children of Mwanza are superior to the Maratas of Poona. It is postulated that the greater growth of the Mwanza children is due to the improved conditions under which they now live in East Africa. The Mwanza refraction data showed a marked excess of emmetropic and near-emmetropic refractions compared with the normal distribution and also a myopic excess and a prolongation of the myopic tail. When a comparison is made of the percentage distribution of refraction in the Mwanza and the Poona children, close similarity is seen. Mixed astigmatism and anisometropia were present in 6·6 per cent and 8·6 per cent respectively of these children. These figures occupy a position intermediate between those of the Mwanza African children and those for Mvuni African children. About 1 per cent of the children had squint and less than 1 per cent were wearing glasses at the time of the examination. These Asian children were also examined for the presence and degree of water cleft opacities in the periphery of the lens. Comparison of the details shows that the incidence was slightly lower than in the Mwanza African children.

Journal of the Association for Computing Machinery

THE January 1961 issue of the *Journal of the Association for Computing Machinery* contains six major papers, at least three of which will be of general interest. The first of these, by Herbert Keller, is an analysis of finite automata with special reference to pattern recognition. The main theme is a description of various 'perceptrons', a mysterious term which for some time has puzzled British users of computers, being claimed by some to hide a concept of deep significance, and by others to be a triviality. Keller takes as his definition something which is usually regarded in Britain as a variety of synthetic neurone, and his analysis of the potentialities of this class of device will, no doubt, stimulate discussion. Ivan Flores contributes a paper which analyses the use of computers as sorting machines. This particular class of operation is one which does not show the machines at their best so that analyses which estimate efficiencies are always useful. Probably the most generally interesting contribution is that by Leiner and Youden on generating pronounceable names on a computer. Their particular names have four letters and an amusing touch is their lament: " . . . some of the computer-generated words, although highly efficient phonetically, were semantically unsuited for permanent inclusion in the records". It seems that some humans had to draw up a proscribed list before the records were fit for publication.

The Pontide Paradox

ACCORDING to a number of prominent geologists, the region occupied by the present Black Sea ('Pontus Euxinus' of the ancients), even as late as the second half of the Tertiary era, was occupied by a land mass called Pontide. Furthermore, according to this hypothesis the present Crimean mountains represent the northern fringe of this land mass untouched by a widespread subsidence affecting the greater part of this continent. On the other hand, some geologists query the idea of the existence of Pontide in the late Tertiary era, and their views are supported by M. V. Muratov (*Priroda*, 6, 57; 1960), who, in a series of palæogeographical maps, illustrates the evolution of the future Black Sea from its initial stages to the northern geosyncline of the Tethys. Such a hypothesis also finds its support in the observed peculiarities of the present-day flora and fauna of the Crimea. These biogeographical data, on the other hand, provide N. I. Rubtzov (*Priroda*, 8, 83; 1960) with an additional argument in the support of the hypothesis of the existence of Pontide.

Cultural Sequences in Hokkaido, Japan

QUITE a lot is known about the prehistory of China. Pekin man and the stone-age industry found in the cave with his remains have at least given a start for the study of the earliest cultures of that vast region. Again, not a few of the museums in Britain display painted pots of Neolithic date—the earliest of a long line of painted pottery from China. Much less is known about the earliest history of Japan. The article by Lieut.-Col. H. A. MacCord in a recent paper (*Proc. U.S. Nat. Mus.* (No. 3443, Vol. 112): Pp. 481–503 + 14 plates. Washington, D.C.: Government Printing Office, 1960) does not profess to fill this gap, but does describe some research work undertaken during 1953–54 in the island of Hokkaido, in the region of the Ishikari Plain. Pottery, most of it decorated, and stone tools were found, and many of these are illustrated in 14 full pages of half-tones. The stone tools include polished 'celts', knives and arrow heads, some of obsidian. Some day we shall hope to see a volume on Japanese prehistory; the results published here will certainly merit inclusion in all libraries of archæology and ethnology.

The Advisory Group for Aeronautical Research and Development

THE Advisory Group for Aeronautical Research and Development announces the following schedule of meetings: June 5–9, Documentation Committee on "Exchange of Information in the Nato Countries" (Paris); July 12–19, Seminar on Astronautics, jointly sponsored by the University of Southampton and AGARD (Southampton); July 18–21, Fluid Dynamics Panel on "The Use of Rocket Vehicles in Flight Research" (The Hague); July 24–26, Avionics Panel Technical Meeting on "Microminiaturization" (Oslo); Structures and Materials Panel Specialists' Meeting of the Material Group (Oslo); July 27–28, 11th AGARD General Assembly, "Scientific Goals of Space Exploration and Research" (Oslo); July 31–August 2, Avionics Panel Technical Meeting on "Low-noise Electronics" (Oslo).

Field Studies Council: Summer and Autumn Courses

THE Field Studies Council has announced the programmes of special courses to be held during

1961 at its various Field Centres. *Malham Tarn Field Centre* (near Settle, Yorkshire): grasses, sedges and rushes (July 5–12); mosses and liverworts (August 23–30); identification and ecology of lichens (August 30–September 6); ecology of freshwater animals (August 30–September 6); meteorology, organized in conjunction with the Royal Meteorological Society (September 6–13); fungi (September 6–13); Pennine fossils (September 13–20); rivers and streams (September 20–27); karstic land-forms (September 20–27); spider ecology (September 20–27). *Flatford Mill Field Centre* (East Berghold, near Colchester, Essex): art of botanical illustration (July 19–26); landscape painting courses (August 9–23); animal life in the soil (August 9–16); insect ecology (August 16–23); field archæology (August 23–September 6); small mammals (September 16–23); autumn art week (October 4–11). *Slapton Ley Field Centre* (Slapton, Kingsbridge, Devonshire): outdoor painting course (August 9–16); natural history fortnight (August 9–23); introduction to the study of lichens (August 16–23); introduction to the study of seaweeds (August 16–23); natural history of south-western woodland (August 30–September 6); geology and scenery for beginners (August 30–September 6); introduction to the study of lower plants (September 20–27). *Dale Fort Field Centre* (Haverfordwest, Pembs.): weather and bird movements, organized under the auspices of the Royal Meteorological Society and the British Trust for Ornithology (September 6–13). Further information on each of the courses can be obtained from the Warden of the Field Centre concerned.

Keele Foundation Year Course

The Nuffield Foundation has made a grant of £5,000 to the University College of North Staffordshire to pay for an investigation into the effects of the Keele Foundation Year course. This course, unique to Keele, is taken by all students in the first year of the four-year degree course and is designed to introduce the student to some of the methods and information necessary to an estimate of the inheritance, the problems and the achievements of modern western European man. The grant will pay the salary of a Research Fellow and an assistant who will attempt to establish any relationship there may be between performance in the Foundation Year course and such factors as previous educational record, subsequent performance in the degree course, career after graduation, etc. It is hoped that the information obtained may give valuable indications of ways in which the Foundation Year course can be further developed or modified and that this may be the first stage of a continuing inquiry.

Announcements

The Meldola Medal for 1960 has been awarded to Dr. J. N. Bradley, for his work in the field of physical chemistry, with special reference to the kinetics of reactions involving free radicals and reaction in shock waves studied by mass spectrometry. The award is made by the Royal Institute of Chemistry with the concurrence of the Society of Maccabaeans.

Dr. R. Conrad, assistant director of the Medical Research Council's Applied Psychology Research Unit at Cambridge, will act as consultant in applied psychology to the General Post Office for an initial period of two years.

At a meeting held on May 11, the Council of the Association of British Chemical Manufacturers appointed Mr. H. W. Vallender as deputy director of the Association.

The following appointments at the U.N. Food and Agriculture Organization have been announced: Dr. Hans Dietrich Cremer, to be chief of the Applied Nutrition Branch; Dr. Arthur H. Dolff, to be assistant chief of the Research Branch of the Radiological Health Division.

The sixteenth annual electronics, instruments and components exhibition and convention of the Institution of Electronics will be held at the College of Science and Technology, Manchester 1, during the periods July 6–8 and 10–12 inclusive. This programme will incorporate a scientific and industrial research section, a manufacturers' section and a number of lectures and films. Further information can be obtained from the general secretary, W. Birtwistle, Institution of Electronics, 78 Shaw Road, Rochdale, Lancs.

The Department of Mathematics of the Hatfield College of Technology is organizing a summer school on "Mathematics of Automatic Control" during June 26–30, the object being to enable mathematicians and engineers working on problems of automatic control to study some of the relevant mathematical techniques developed in recent years in Britain, America and the U.S.S.R. Further details can be obtained from the Academic Registrar, Hatfield College of Technology, Hatfield, Herts.

The annual meeting of the American Society of Pharmacognosy will be held at the University of Houston during June 19–21. Among the subjects to be considered are: opportunities for Ph.D. pharmacognosists; specific techniques of thin-film chromatography; uridine nucleotides in glycoside biosynthesis; chemo-taxonomy of selected groups within the Coniferae; research on south-western drug plants; the pharmacognosy of the anti-cancer plants, the periwinkles. Further information can be obtained from Melvin R. Gibson, School of Pharmacy, Washington State University, Pullman, Washington.

Elliott Brothers (London), Ltd., a member of the Elliott-Automation Group, is organizing a private symposium and exhibition on "Analytical Instrumentation of Industrial Process Control" at the Connaught Rooms, London, during June 13–14. Included will be papers on: the application of analysis instruments in the United States; the continuous measurement of moisture; analysis instruments from the point of view of the user; experience with plant stream analysers at Imperial Chemical Industries, Ltd., Billingham; trends in continuous process analysis. The exhibition will include a selection of 'Quality Control' instruments supplied by the Analytical Instruments Division of Elliott Brothers (London), Ltd., Further information can be obtained from John Geddes, Elliott-Automation, Ltd., 34 Portland Place, London, W.1.

Errata. The following corrections are necessary in the communication entitled "Minimum Range to Artificial Earth Satellites" in *Nature* of April 22, p. 333. In the first line of the paragraph containing equation (5), for "$\rho_s = \rho_s = \infty$" read "$\rho_s = \rho_p = \infty$". Further, the numerator on the left-hand side of equation (5) should read "$\lambda(\dot{f}')_{f'=f}$"; in some copies the differentiation sign has not registered.

ELECTRICAL CONTACTS

A SYMPOSIUM on "Electrical Contacts", organized by the Institute of Physics and the Physical Society, in collaboration with the Institution of Electrical Engineers, was held during April 5–7, at Brunel College of Technology. The membership was limited to some 260 by the accommodation only, and interest in the subject was such that acceptances were closed some weeks before the date of the symposium, which, although not meant to be international in character, was, nevertheless, attended by representatives from a dozen different countries. The subject under consideration, being of fundamental scientific interest as well as of obvious practical significance, proved itself to be of concern to physicists, engineers, metallurgists and chemists from both industrial and Government research establishments as well as universities. The symposium was so arranged that the main aspects of electrical contact phenomena could be discussed in some detail in separate sessions.

The opening session consisted of an address by Prof. F. Llewellyn Jones (University College of Swansea) on "The Physics of Electrical Contact Phenomena", in which the main aspects of contact operation were surveyed, and the important problems of fundamental significance indicated, as well as the methods by which they are now being attacked in the various laboratories. The sessions which followed each consisted of between four and six short papers grouped under the headings: principles, fundamental investigations and techniques, contact surfaces, methods and design, non-metallic contacts, and miscellaneous subjects. Each session included a discussion. In this brief communication it is not possible to give an account of all twenty-five papers in detail; a fuller report is being published in the *British Journal of Applied Physics*. This notice will be confined to comments on the scope of the discussion and the general conclusions reached.

The opening survey address considered the whole contact operation from the initial approach to the final separation of the electrodes, in the order in which the events usually take place. The aspects concerning fundamental physics and some of the problems still unsolved were pointed out. For example, the behaviour of a contact just before the electrodes actually touch ($\sim 10^{-4}$ cm. apart) involves interesting problems of surface physics relating to the electrical activity of surfaces due to the presence of thin films. Attention was also directed to the interesting and varied phenomena associated with molten, and possibly boiling, metal in the microscopic region of contact. In this connexion, contact physics can make a contribution to our knowledge of the properties of metals at high temperatures in the molten state. A ciné-film was exhibited, showing the quasi-static molten metal bridge passing through a series of mathematically predictable shapes before sudden breaking. The establishment of a micro-arc immediately on the breaking of the bridge was then considered, and the possibility of ionic transfer in the high-temperature plasma pointed out. Finally, the importance of surface films was referred to in the operation of very light-duty contacts with negligible currents—the electro-static contacts.

In the second session dealing with principles, the theme of the properties of metals at high temperatures was further developed by Dr. M. R. Hopkins (University College of Swansea). Thermal instability in a contact was discussed by Dr. J. B. P. Williamson (Cavendish Laboratory and Tube Investments, Ltd., Cambridge). Because of the importance of the nature and behaviour of surface films on contact electrodes (continually emphasized during this conference), the mechanism of formation of oxide films on metals was considered by Dr. O. Kubaschewski (National Physical Laboratory). Interest in non-metals was illustrated by a paper on the friction and wear of graphitic and non-graphitic carbon in which the important rule of adsorbed layers was stressed by Dr. J. W. Midgley (English Electric, Ltd., Leicester).

In the third session, the different techniques of investigations of the various aspects of contact operation were described. P. E. Watts (Associated Electrical Industries, Aldermaston) showed how the effect of temperature asymmetry on matter transfer was being investigated, while Dr. C. H. Jones (Royal Marsden Hospital) described the work done at the Department of Physics, University College of Swansea, using radioactive tracer techniques for the measurement of metal transfer. This sensitive method enables the transfer in an opening contact to be measured with very low series inductances, and it was concluded that transfer in platinum, palladium and silver was not independent of the micro-arc discharge. Dr. A. Fairweather (Post Office Research Station) illustrated the properties of the mechanical deformation of contact electrodes at closure by means of models in two-colour laminated 'Plasticene'. He showed that different forces produce geometrically similar indentations, and that the flow-patterns depend on frictional constraints.

Most of the remainder of the session was devoted to the properties of contact surfaces. The practical aspects of very light-duty electrical contacts were assessed in a review paper by Dr. J. C. Chaston (Johnson Matthey, Ltd., London). From the practical point of view of design and manufacture important factors were electrode shape and material, surface finish, contact-loading force, and in particular the separating force and freedom from bounce.

The cleanliness of precious metal surfaces was discussed by H. C. Angus, while Dr. W. Betteridge (both of International Nickel Co. (Mond), London) considered the operation of extremely light-duty contacts at high temperatures. For example, at temperatures of 500° C. contact, operation can become difficult because of oxidation, welding and thermoelectric effects. So far as noble metals are concerned, investigations show that gold and platinum are film-free, but that ruthenium has a highly conducting oxide. Electro-deposition of metals was described in some detail by F. H. Reed (International Nickel Co. (Mond), London), and other papers provoked much further discussion on this topic. Quantitative assessment of electrode activity due to surface films was described by E. B. Pattinson (Department of Physics, University College of Swansea) and the influence of dust on contacts was considered by Dr. J. A. Greenwood (Tube Investments, Ltd., Cambridge). Dr. Fairweather discussed the effects of plastic lubricants and the behaviour of granular materials. With these materials, energy losses depend not only on the properties of the material but also on granule dimensions and the structure of the granular boundaries. A description of recent contact research in Japan was given by Prof. G. Matsumoto (Tohoku University). The properties of electrodes of silver–nickel and silver–metallic oxides, produced by powder metallurgy, were described, as well as work on arc suppression by electro-chemical treatment of the electrode surfaces. The selection of electrical contact materials for light-duty applications was surveyed by Dr. V. G. Morradian (Engelhard Industries Inc., New Jersey). The proceedings closed with a summary by Dr. M. R. Hopkins.

The last conference on electrical contacts in Britain was held in 1952 (see *Nature*, 169, 960; 1952), and it is interesting to consider the developments which have occurred since then. Despite hopes that recent developments in electronics, particularly in the field of semi-conductors, might avoid difficulties associated with conventional metal-to-metal contacts, it is clear that basic problems in electrical contacts are still with us. Some practical problems have been solved, or circumvented, but others have appeared in new forms. However, considerable advances have been made in our knowledge of the physics of the molten metal bridge, its formation, growth and final destruction, and of the micro-arc to which it appears to give rise in certain conditions. At the same time, work in this field is enlarging our knowledge of the properties of metals at very high temperatures.

Another important conclusion can be drawn from this most interesting and worth-while symposium. In the conference of 1952 it was not clear that the engineer concerned with the operation of contacts, and the physicist concerned with fundamental processes, were attacking the problem together; at the present conference there appeared to be far closer liaison between the physicist and engineer, and, further, it was apparent that the designer now fully appreciates methods of approach depending on investigation in controlled conditions of, for example, ambient atmosphere and surface state.

Dr. J. Topping, principal of the Brunel College of Technology, who welcomed and opened the conference, is to be congratulated on the excellent arrangements.

GAS CHROMATOGRAPHY

THE Gas Chromatography Discussion Group held its third annual general meeting on April 21 at the University of Birmingham. Membership had risen by 75 during the preceding year to 346, including 94 from 18 countries other than Great Britain.

Highlights for the year had been the publication of the first two volumes of *Gas Chromatography Abstracts*, and the very successful third international symposium at Edinburgh the previous June which had attracted more than five hundred delegates from twenty countries. The *Proceedings* had been published in a 466-page volume before the end of the year.

The group is planning another informal symposium in the autumn, and arrangements for the fourth international symposium, this time in Hamburg during June 13–16, 1962, are already well advanced.

The Retention Data Sub-Committee reported that very little data had been submitted to them, and after considerable discussion agreed to consider the usefulness of relative retention data, which require less rigorous control of conditions and would probably be more readily available than the absolute data they had been seeking.

The scientific section of the meeting opened with a welcome by Prof. R. C. Robb.

The first paper was presented by Mr. M. B. Evans on the relation between the retention volumes of unsymmetrical compounds and cognate symmetrical ones. The work has since been published in the *Journal of Chromatography*[1].

Mr. C. E. Roland Jones discussed technical details in the examination of pyrolysis products, describing a micro-apparatus for use with the Pye argon chromatograph. He illustrated its use in the identification of plastics, especially those which were not amenable to identification by infra-red spectroscopy.

Dr. R. P. W. Scott discussed the effect of temperature on resolution both theoretically and in the light of experimental results. He showed that for any required separation there was an optimum temperature for a given film thickness and this was more marked with thick films of stationary phase than with thin ones; conversely there was an optimum thickness for a given temperature and an optimum combination of both for minimum analysis time.

Dr. I. Halasz read a paper entitled "Quantitative Analysis of Hydrocarbons with Capillary Columns and Flame Ionization Detectors". He had investigated thoroughly a large number of factors affecting quantitative accuracy, and designed a stream splitter which apparently eliminated the uncertainties of previous models since the scores of tabulated results which he produced showed a consistent accuracy of about 1 per cent.

In the discussion which followed, Dr. Kovats produced some quantitative results from 2 μl. of rose oil on an unusually wide capillary column used in conjunction with a tungsten filament katharometer. Efficiencies of 40,000–100,000 theoretical plates had been obtained from such columns.

The final paper by J. G. A. Hölscher of the University of Eindhoven was presented by Dr. M. Van Swaay. He was able to show that ionization in argon detectors could be caused by photons from a pulse discharge. Such a discharge caused a current to flow between two electrodes in a mixture of argon and a hydrocarbon, with a time lag characteristic of the velocity of photons rather than metastables, ions from the discharge being screened off by a series of grids.

S. J. HAWKES

TELEVISION AND FILM TECHNIQUES

A CONVENTION on television and film techniques, sponsored jointly by the British Kinematograph Society and the Television Society, was held at the Institution of Electrical Engineers during April 20–21.

Sir Harold Bishop, director of engineering of the British Broadcasting Corporation and president of the Television Society, opened the Convention with an address on the topical problems of television in the United Kingdom. He said that the B.B.C. supported the report of the Television Advisory Committee and that it was convinced of the long-term advantages which would result from the use of 625-line standards in the ultra-high-frequency bands IV and V (470 Mc./s.–960 Mc./s.). In particular, line visibility was notably less than with our present 405-line standards and the introduction of larger screens would aggravate the 'lininess' of the present images. Programme interchange with European countries, all of which except France had adopted the 625-line standard, would also be facilitated. Sir Harold also spoke of the B.B.C.'s wish to start a limited service of colour television compatible with the present 405-line service in band I.

Mr. J. Roizen gave a lecture on "The Use of Videotape for Colour Television Recording". He described the various methods that the Ampex Co. in California had investigated with the object of achieving satisfactory magnetic-tape recording of colour television signals. The composite colour video signal contains a subcarrier which is, in the American National Television System Committee system, amplitude-modulated with chrominance signals in phase quadrature. The frequency of this subcarrier is 3·59 Mc./s. and 1 cycle, or 360° of it, occupies a time duration of 0·28 μsec. The phase of the vector representing the chrominance signal carries the information from which the colour being transmitted is obtained and it has been found by experiment that errors of the order of 5° can be detected by a skilled viewer. A 5° error phase can therefore arise from a time variation or error of 4 nanosec. (10^{-9} sec.). In the recording of television signals on film (telerecording), the complete television image is exposed to the film, but in magnetic-tape recording the signal wave-form is recorded as a function of time or distance across, and along, the tape, the synchronizing pulses also being included. It is apparent that any non-uniformity of relative velocity between tape and 'head wheel', in the periphery of which four recording heads are embedded, will give rise to a timing error which will result in a change of the resulting colour. One line of investigation consisted, therefore, of an attempt to stabilize the relative velocity between tape and 'head wheel' to a much greater precision than had been required for the recording of monochrome (black-and-white) television. The servo-mechanism normally used employs a 240 c./s. electric signal derived optically from black-and-white patches on the 'head wheel', but a more accurate feedback signal was needed so the frequency was raised to more than a hundred kilocycles per sec. Even this was scarcely adequate, and another line of investigation led to the correction of signal-timing errors by means of a delay line having a controlled variation of delay. The difference in phase between the synchronizing signal derived from the video wave-form of the outgoing 'playback' television signal and a source of stable synchronizing signals is used to control the capacitance of a silicon diode forming part of the capacitance of the delay line. The outgoing video signal is passed through the delay line, and the delay is varied in such a manner as to compensate for the timing errors in the signal. The compensation is such that quite satisfactory results are now obtained: the timing error accumulated during the interval between successive colour synchronizing signals (a line-scan period) presumably being not greater than a few nanosec. The scheme described is known as 'Super-Amtec'.

Mr. B. J. Davies described a rapid-processing machine for 16-mm. film. The increasing use of magnetic-tape recording for television, or 'videotaping' as it is now termed, has caused the technical side of the film industry to consider means of accelerating the developing of film to the point at which it offers an attractive alternative method of making permanent records of television programmes, despite the fact that the advent of 'videotape' has resulted in an increase in the use of film in the television industry. The Kodak Co. has developed this machine around a very rapid processing cycle, the duration being about 60 sec. and the film velocity 38 ft./min. The method is called viscous-layer processing and is a departure from the liquid-bath methods previously used. The developer and fixer are applied to the photographic emulsion by means of special rollers over which the film is passed.

Messrs. Polonsky, Cassagne and Sauvanet described "Recent Progress in the SECAM Frequency Modulation Colour Television System". This system of colour television, the idea of M. Henri de France, has been developed by the Compagnie Française de Télévision, and has been improved over the years by the authors and M. Chaste who, with M. Cassagne, delivered a paper on the subject before the Institution of Electrical Engineers in April 1960. As in the American National Television System Committee's method, the colour information is transmitted by means of a modulated subcarrier but, instead of amplitude modulation being used, the subcarrier is frequency-modulated. Furthermore, unlike the Committee system wherein both the amplitude and the phase of the amplitude-modulated subcarrier are used simultaneously, the one representing saturation and the other hue, in the SECAM system the frequency-modulated subcarrier represents only one quantity at a time (television line by television line). This subcarrier is thus frequency-modulated alternately, line by line, by one of two colour-difference signals (for example, red intensity minus luminance and, afterwards, blue intensity minus luminance). This method of transmitted colour information renders the transmitted signal more 'rugged' and resistant to the various electrical and propagation hazards likely to be encountered. It is claimed that colour receivers based on this system are simpler to align in the factory, easier to service and more stable, as well as being more suitable for an unskilled viewer to operate. The receiver requires an expensive delay line in order to compensate for the non-simultaneous transmission of colour signals, and there is a theoretical loss of vertical colour resolution of two to one as compared with National Television System Committee, but the authors state that the Committee's system contains several times more vertical colour resolution than is required, and it must be said that the excellent demonstration given by the authors, with assistance from the Hirst Research Centre of the General Electric Co., the General Post Office and the B.B.C., showed no apparent lack of vertical resolution. It was suggested that, from the technical and picture quality point of view, there was little to choose between the SECAM and the National Television System Committee systems.

Dr. W. E. Glenn described a thermoplastic recorder for television and similar signals. The device, developed in the General Electric Research Laboratories in Schenectady, bears a fundamental resemblance to the Eidophor, which will be mentioned later. Brighter pictures than those from a cathode-ray tube could be obtained if the image were stored for display and then illuminated by a separate source of light, such as an arc. Photographic recording (telerecording) is a good example since, in reproduction, a film projector may be used, although many applications require re-televising of the storage medium. In Dr. Glenn's apparatus, which consists of an evacuated enclosure, an electron beam, appropriately modulated with a television signal and deflected in the usual manner of scanning impinges on a thin film of low-melting-point thermoplastic on which a charge image is thus placed. Beneath the top film is another of a transparent conducting material and beneath this is a transparent high-melting-point tape. The conducting layer acts as one plate of a condenser, the other being the charge image itself. By melting and then freezing the top layer, the charge image is replaced by the same image impressed into the thermoplastic by electrostatic force in the form of hill-and-dale deformations. The film or tape now has a permanent record on it and may be stored for subsequent play-back. For this purpose a modified schlieren optical system and a light source are required, although, for editing purposes, the actual image can be made visible on the film. The entire process of melting and freezing the thermoplastic takes a few milliseconds, and the ultimate resolution is limited by the wave-length of the light used for projecting (200 television lines per mm. is a practical figure). For colour images, a phase-diffraction-grating method may be used and a special optical system is required for projection. The author projected some thermoplastic film through a suitably modified projector.

Prof. E. Baumann described "Recent Developments on the Eidophor Large Screen Projector". The idea, conceived by Prof. Fischer in 1939 and afterwards developed with Dr. Thiemann, Prof. Baumann and others at the Zurich Technische Hochschule and, later, by Eidophor, Ltd., relies on the light-valve principle described earlier. In an evacuated enclosure, an electron beam, suitably modulated with a television signal and scanned in the usual manner, 'writes' a charge image on a thin film of oil on the conducting surface of a concave mirror. The viscosity of the oil is sufficiently low to allow the electrostatic forces between the charge image and the mirror surface to deform the oil into hill-and-dale irregularities. The mirror is in the light path of a schlieren optical system, and the deformations of the oil, acting as the reflecting surface, are revealed as optical images on a large projection screen. Prof. Baumann demonstrated the Eidophor by receiving, from a B.B.C. studio, a 405-line film transmission which, after passage through the Eidophor, was seen on the large screen in the lecture theatre. Although the film was not particularly bright, the possibilities of the system were quite apparent.

Mr. Grimshaw of the Kodak Co. read a paper by Messrs. Veal and Richey of Eastman Kodak Research Laboratories, Rochester, U.S.A. The paper, "Technical Requirements of Systems and Film for Colour Television", dealt with the difficulties of reproducing colour film on colour television. In particular, the contrast-range normally encountered in colour film is too high for colour television, resulting in loss of luminance and colour information in dark parts of the viewed image. Whereas a contrast-range of 100 : 1 is not rare in film, colour television is at its best within a range of about 20 : 1. This is due to many cases, but it is not difficult to see that, since the optical projection of film in the cinema (or home) relies on the light-valve principle, in which a source of light illuminates a screen after multiplication of the light intensity by the transmission factor of the film, the contrast-range of projected film may be limited only by flare and diffusion in the projector and on the screen, provided that the ambient illumination of the screen is zero. The fact that the reproduction of colour by photographic film is a negative-colour process, whereas its reproduction by television is a positive-colour process, also makes the colour televising of colour film rather more difficult. The paper presented graphs which revealed that greater horizontal resolution could be obtained from a three-Vidicon film scanner than from a flying-spot film scanner employing three photomultiplier cells. This came as a surprise to some members of the audience, who wondered whether American experience with flying-spot scanners had, perhaps, been less extensive than European.

Messrs. A. R. Stanley and J. Treays read a paper entitled "Colour Television Engineering: Studio Problems and Techniques". They gave a short historical account of the experimental colour transmissions radiated by the B.B.C. and went on to discuss a number of matters connected with studio programmes in colour. Experience showed that it is preferable for each picture-originating source to have its own coder so that the primary-colour signals are not sent round the studios. They found that the composite signal, that is, the luminance signal added to the modulated subcarrier, was more 'rugged' and suitable for the various processes which occur in a television studio, such as cutting, mixing and fading. It was interesting to note that during a slow mix from one composite colour signal to another, during which the two signals are added, the resulting colours were quite satisfactory and gave the impression of two colour pictures being superimposed. Presumably because a colour picture contains more information, it was found that individual shots could last longer than in the case of a monochrome programme, although the compatible black-and-white programme viewer must not be forgotten. The performers' make-up presented some novel problems: it seems that the chemical composition of perspiration varies from individual to individual and the colour of make-up can vary throughout a day's rehearsals and performance. Coloured performers require less make-up and are, therefore, easier to deal with than white people. In order to align and set up the cameras, these were presented with a set of Munsell colour chips illuminated by the normal studio lighting and the images on the picture monitors in the control room were compared with a similar set of Munsell chips illuminated with illuminant *C*, which has the chromaticity of the 'white' standard for the National Television System Committee colour television. When a programme involves film inserts, great care has to be taken to ensure a colour match between similar scenes which may be viewed in succession from a colour-television camera and from a colour-film scanner, or telecine machine. Although the necessarily low contrast required for the colour transmission seemed to be quite satisfactory for the compatible monochrome viewer there was, at times, a subtle change of mood in that the dark colours which were required for the colour viewer made the compatible black-and-white picture rather sombre. During the lecture, some very fine colour slides were projected, showing studio scenes for colour programmes.

Messrs. A. R. Stanley and S. N. Watson introduced "Colour Television Engineering: Equipment Problems and Techniques". The authors discussed five characteristics of colour television which gave least satisfaction to viewers during the B.B.C. colour field-trials mentioned in the historical survey of the previous paper. It had been clearly demonstrated that the colour cameras were the weakest link in the chain. The paper dealt with a number of matters which affect the correct reproduction of colour scenes. For example, no effort is made to ensure negative lobes in the spectral response characteristics of the colour analysis filters in the cameras, although it is possible to achieve an approximation to negative-lobed characteristics despite the impossibility of using 'negative light'. The 'taking gamma' of the cameras is important, as are the errors due to shading (or spurious) signals in the image orthicon tubes used in the cameras. The latter may cause errors of hue, particularly in low-luminance patches of the scene. Since the phase of the modulated colour subcarrier determines the reproduced hue, any departure from linearity of the phase/frequency characteristic of any part of a transmission network in the region close to the frequency of the subcarrier (2·66 Mc./s. in the case of the National Television System Committee system adapted to 405-line standards) causes errors of hue. In particular, if the transmission system suffers from a non-linear effect which causes a change of phase to occur in sympathy with a change of signal-level (in the composite video signal the luminance signal and the chrominance or modulated subcarrier signal are added) a change of hue and brightness will result. The possible existence of this phenomenon places a rather stringent requirement on the linearity of television equipment such as studio broadcast apparatus, and radio links. An excellent demonstration followed the lecture. Colour film and slides originating in a B.B.C. studio were transmitted by Post Office equipment to the lecture theatre of the Institution of Electrical Engineers and the received images were projected on to the large screen by a Marconi's Wireless Telegraph Co.'s three-tube Schmidt projector. The registration of the three primary-colour images was very good indeed. The effect on hue of a 10° change of subcarrier phase was shown and also the deterioration in picture quality to be expected from the use of two transmission links in series. Both deteriorations were slight. The technique of using a low-pass filter to attenuate all Fourier components (and noise) of the luminance signal, which would otherwise occupy the frequency band set aside for the chrominance signal (which shares an upper part of the full luminance channel) and the subsequent employment of a non-linear device ('crispener') to reconstitute artificially an impression of sharpness was also successfully demonstrated. An electronic masking unit showed how an improvement can be made to the properties of colour film for colour-television purposes.

R. D. A. MAURICE

STUDY OF DEFECTS IN PORPHYRIN METABOLISM BY MEANS OF ISOTOPES

THE Biology Division of the French Atomic Energy Commission held, during September 1960, a colloquium at Saclay on the use of tracers in the study of diseases of porphyrin metabolism. Participants from Europe and the United States enjoyed three days of intense discussion as guests of the Atomic Energy Commission and the Ministry of National Education. The topics debated ranged over a wide field; full proceedings of the conference will be published in due course.

In the opening address, Prof. A. Bénard reviewed our present knowledge of porphyrin biosynthesis and of the disturbances giving rise to the different clinical forms of porphyria. It was his view that such diseases were variants of a single fundamental abnormality. Symptoms were due not to the porphyrins themselves but to associated metabolic disturbances such as interference with the synthesis of purines. He concluded an impressive survey by reference to recent therapeutic measures which have shown some promise in the treatment of acute porphyria, namely, administration of 2 : 3-dimercapto-propanol, ethylenediaminetetraacetic acid or adenosine monophosphate.

The genetic aspect of the porphyrias was then dealt with. It was pointed out that the several hundred South African cases of 'porphyria variegata', all being descended from a single pair of Dutch settlers, necessarily represent manifestations of the same genetic abnormality or group of abnormalities found in the progenitors and might well, therefore, display a characteristic pattern. A fascinating account of the recently discovered 'Turkish porphyria' was given by Dr. R. Schmid. It is an acquired porphyria due to consumption of wheat containing hexachlorobenzene. Several thousand human cases have occurred and the disease has also been reproduced experimentally in animals. Topics further discussed during the first day's sessions were the symptomatology of acute intermittent porphyria and its causation, and also the difficulties attending the interpretation of investigations made with isotopic tracers on such patients.

While it is generally felt that the excessive excretion of porphobilinogen and δ-aminolævulic acid in acute hepatic porphyria is due to over-production of these materials, the exact biochemical mechanism leading to such over-stimulation of the porphyrin pathway is still in doubt. Experiments designed to test the possibility of restricted conversion of glycine into serine were inconclusive. A hint as to the means by which δ-aminolævulic acid production is normally regulated may be forthcoming from the experiments described by Shemin who showed, in one system studied, that δ-aminolævulic acid is itself an inhibitor of the enzyme producing it. This points to the possibility of a negative feed-back control operating in the normal cell. The combination of administration of porphyrinogenic drugs with pantothenate deficiency promises to throw further light on the development of the nervous symptoms in acute porphyria. It has been generally assumed, since the self-experiment of Meyer-Betz, that photosensitization in the cutaneous porphyrias is actually caused by the porphyrins themselves. Direct evidence was lacking, however, until quantitative measurements were made by Magnus and collaborators on patients with the use of a powerful monochromator. This technique and the results it afforded were described and exemplified by the case of a man with sun-burn type photosensitivity who, nevertheless, showed highest cutaneous sensitivity in the Soret band region of the spectrum. Further investigation showed that his red cells and fæces did, in fact, contain abnormally large quantities of porphyrins.

The increase in urinary excretion of porphyrin which accompanies lead intoxication has aroused the interest of biochemists for many years, but is as yet little understood. New light may be thrown on this problem by the finding of Gajdos and his collaborators that lead ions interfere with the passage of iron through the membrane of the developing red cell, the stroma, under these conditions, retaining iron rather firmly.

The biochemical mechanism of incorporation of iron into protoporphyrin and the part played by 'bound' forms of these reactants, the biosynthesis of porphyrins by human leucocytes and the metabolism of hæmoglobin within the red cell were next considered. It would appear from the work of Schapira and his co-workers that the hæmoglobin molecule within the erythrocyte is not metabolically inert, but that progressive structural alterations occur with the course of time. The effects of radiation on the synthesis of hæmoglobin in the bone marrow, and the results of a great deal of work on the relation of porphyrin structure to X-ray sensitivity, were also reported.

At the close of the meeting, Prof. C. Rimington endeavoured to lay before participants an appraisal of the most significant conclusions and to point to the fields from which the next major advances towards an understanding of normal and pathological porphyrin metabolism might be expected to come. He took the opportunity of thanking the organizers and the two bodies sponsoring the colloquium for their excellent work on behalf of porphyrin biochemistry and for their generous hospitality. This meeting will be long remembered with gratitude and pleasure by those who were gathered together in the stimulating atmosphere of Saclay.

C. Rimington

CONSERVATION OF BRITISH NATIONAL PARKS

In its recent eleventh annual report the National Parks Commission referred briefly to the question of afforestation in the National Parks, especially on Dartmoor and Exmoor, and also to its disappointment at the delay in amending the Act, particularly with regard to financial resources. Both these aspects have since been the subject of short adjournment debates in the House of Commons. In the first of these, on March 29, Mr. E. du Cann raised the question of afforestation, particularly in the Dartmoor and Exmoor National Parks. While supporting the voluntary agreement recently reached between the Timber Growers' Organization, the Country Landowners' Association, the Forestry Commission and the National Parks Commission regarding afforestation in the National Parks, Mr. du Cann questioned whether a voluntary agreement would be sufficiently effective, as it did not include all those concerned with afforestation in such areas.

In his reply, the Parliamentary Secretary to the Ministry of Housing and Local Government, Sir Keith Joseph, agreed that it was important to give the new scheme a fair trial. He thought that there was no reason to fear that landowners in the areas concerned, who were not members of the Association, would not, as individuals, comply with such agreements and, in reply to a specific question about trees on High House Moor, Dartmoor, said that discussions were still proceeding between the proposed developers and the authorities. On this specific issue it should be noted that considerable uneasiness still exists that the National Parks Commission will not be supported. The parties to the agreement were not despondent as to the prospects that the agreement would succeed, and Sir Keith Joseph appeared to have substantial grounds for his confidence that the spirit of co-operation already demonstrated by the production of this voluntary agreement, and the way it had been received and implemented indicated that, with common sense, it should be possible to reconcile the claims of forestry and the National Parks and the rights of landowners.

Nevertheless, Sir Keith recognized that failure of the scheme would create a new situation and this would have to be faced. Meanwhile, he said, the Minister wished to give the scheme a fair trial and he made it clear that he also wished that all concerned, whether members of the particular organizations or not, should participate in this voluntary consultation at all times. The Minister and the National Parks Commission would keep progress under careful review.

On the wider issue raised in the debate on March 30, progress also may be regarded as largely a matter of co-operation and common sense, but on the part of the Government common sense implies providing the financial means to the end enacted. The root of the difficulties encountered in the development of the National Parks lies in the failure of the Government to provide, under the National Parks and Access to the Countryside Act of 1947, the finance required to make the provisions of the Act effective. Under that Act the responsibility for the National Parks was placed within the planning system set up by the Town and Country Planning Act of 1947 instead of the national system envisaged by the Hobhouse Committee. The counties provide two-thirds of the Committee members and almost all the funds, although some of these counties are among the poorest in the country.

Nevertheless, the system has worked surprisingly well, though it is obviously unfair to expect local authorities to take a national point of view, and invariably set the national interest before local interests, particularly at heavy cost to the ratepayers who elect them. The advantages of close association with local interests are such, however, that in view of this experience, it seems highly probable that, given quite moderate Government support, sufficient, for example, to ensure the provision of adequate planning staff and a reasonable contribution to the capital costs of positive projects of development, the existing system could well be continued with success. Much could be done if the National Parks Commission had an annual sum of even as little as £100,000, in place of the present £20,000 (with some £5,000 in Exchequer grants to the National Parks), which it could use at its discretion, either in helping the weaker authorities to strengthen their planning staffs, or in assisting projects which, at present, the park planning authorities hesitate to undertake because of their fear to place excessive burdens on local ratepayers for the benefit of outsiders.

Such a system admittedly is pragmatic rather than the ideal national system, in which national purposes and projects are financed directly from national funds, as Mr. F. H. Hayman advocated on March 30. Admittedly, the development and preservation of the National Parks is often too dependent on the finance committee of the county councils concerned, as Mr. Hayman pointed out ; but to transfer the whole cost of the National Parks to national funds is not the only way of overcoming the difficulty, and if such a transfer lost local interest in, and support for, the National Parks the price might well lead to local misunderstanding and opposition. Mr. Hayman did not, however, appear to advocate quite such a drastic step though he made it clear enough that local resources and prejudices should not determine the objectives and purposes of a national undertaking.

In replying on this debate, Sir Keith Joseph asked for specific examples of projects which were now being frustrated by lack of funds, but claimed that direct Parliamentary grant, and not discretionary payment, was the appropriate way to finance public schemes. He confirmed that the Minister would look at all proposals made to him for amending the Act and said that he was at present seeking more information from the National Parks and the National Parks Commission to assist in this review. Sir Keith was emphatic that there was much more which could be done by the individual Park Committees which would receive Exchequer aid up to 75 per cent, but he thought the time might well have come to extend the legislative framework in some ways. Nevertheless, he did not think that finance was the only answer. Vigilance, effective administration and an imaginative approach must also play an important part, and probably the main value of both debates lies in the extent to which they demonstrate the need for public co-operation and understanding, and for such unceasing vigilance if the purposes of other Parks or Nature Reserves are to be served.

The whole subject was further discussed in the House of Lords on April 19 on a motion of Lord Silkin, who again stressed the importance of adequate financial provision. Lord Feversham also pointed out that existing provisions were completely inadequate, either to prevent or to control fires on heaths and moors, and Lord Dalton, who agreed as to the need for adequate financial provision, also pressed the claims of the long-distance footpaths. Lord Chorley specifically suggested that the National Parks Commission should have an annual sum of £150,000 at its disposition, and like most other speakers was critical both of the Electricity Authorities and of afforestation, though tribute was freely paid to the sympathetic attitude of the Forestry Commission and its present chairman. Earl Jellicoe, who replied on the debate for the Government, added little to what had been said in the Commons by Sir Keith Joseph, but referred particularly to Lord Feversham's suggestion of a direct Treasury grant to the National Parks Commission.

THE RESEARCH COUNCIL OF ALBERTA

THE forty-first annual report of the Research Council of Alberta covers the year 1960*, and includes a list of publications for 1956–60, and lists of members of Advisory and Technical Advisory Committees and of the staff of the Research Council. The Petroleum Division of the Fuels Branch has largely completed its work on the movement of oil in the presence of water in a pipe-line, and studies on capsule pipe-line transportation indicate that the presence of capsules in a flowing stream does not significantly alter pressure gradients, nor does the moving core appreciably distort the flow in the annulus. The capsule velocity appears to depend directly on capsule length and inversely on capsule diameter. The Division has also completed the first major phase in developing a generalized mechanism for the control of composition and accumulation of crude oils and natural gases in sedimentary basins, and the light paraffinic oils, which are usually found in positions corresponding to the areas of maximum depth of sedimentary basins, appear to owe their paraffinic constitution to the extensive action of oxidation and microbiological attack, both of which tend to destroy the less-resistant components of the developing crude oil. With the Coal Division the Petroleum Division is studying the transport of mixtures of pulverized coal and oil, while the Coal Division has also studied the combustion of pulverized fuel, the crystal structure and magnetic properties of coal chars, the plastic properties of Alberta coking coals and coal blends. Work on the mechanisms of coal pyrolysis and carbon formation is expected to bear directly on carbon production from low- and medium-rank coals, and physico-chemical investigations on humic acids from coal have shown that simple coupling reactions can convert humic acids into water-soluble materials without otherwise altering their chemical properties, and that humic acids can be made to yield five-membered cyclic anhydrides.

---

* Research Council of Alberta. Forty-first Annual Report, 1960. Pp. v+55. (Report No. 80.) (Edmonton: Research Council of Alberta, 1961).

The Natural Gas Division has been engaged largely in the separation of gases by selective adsorption on porous solids and with catalytic reactions in the adsorbed state, particularly the catalytic conversion of *cyclo*propane to propylene on crystalline alumino-silicates. The Groundwater Division has provided information which assisted in meeting several serious water-shortages, while the programme of the Geology Division included a study of the fossil content, distribution and physical make-up of Cretaceous rocks, the study of iron deposits and examination of a gypsum deposit at Mount Heed. The reconnaissance soil survey of the Hines Creek map sheet was completed, as well as an exploratory soil-survey by helicopter of some 10 million acres in the north-western part of the Province, while the Soils Division has also co-operated in work on the classification of forest sites and the irrigation of Solonetzic soils. The basic cloud-physics programme, with special reference to hail, included establishment of an enlarged meso-barograph network covering 10,000 sq. miles, upper wind observations stations at Penhold, Rimbey and Rocky Mountain House, and an expanded hailstone collection network. Synoptic investigations on hail now permit some differentiation of storms as related to certain areas to low-level convergence and moving cold-front activity.

ERADICATION OF MALARIA

ALTHOUGH progress towards world-wide malaria eradication has, in general, been satisfactory, there are some malaria eradication programmes that have failed to develop as speedily as they could. A report of the World Health Organization's Expert Committee on Malaria is mainly concerned with the reasons for these failures, and with methods of increasing the efficiency of eradication programmes*.

The technical, operational and administrative causes of failure are analysed in detail, and it is emphasized that success depends not only on careful planning and meticulous execution of the programme but also on the full support of the national authorities at every stage. This must be ensured at the outset by a signed undertaking from the Government.

The criteria given in the Committee's seventh report for discontinuing spraying operations and starting the consolidation phase are amplified and a fresh criterion added, namely, that surveillance should be fully established and adequate. The measures undertaken should include the passive as well as the active detection of cases, this being the only way to ensure that all areas are reached and that observations are continuous. With the view of reducing the costs of the consolidation phase without sacrificing efficiency, the report recommends that the World Health Organization should study the costs by heads of expenditure in as many countries as possible, and should encourage the detailed analysis of costs both by activity and by heads of expenditure in selected representative countries.

The report reaffirms that eradication may be considered to have been achieved "when an adequate surveillance mechanism has not discovered any evidence of transmission or residual endemicity, despite careful search, during three consecutive years". The criteria of eradication given in the sixth report of the Expert Committee on Malaria are re-examined; while the basic principles remain unchanged, the criteria are re-defined and expanded in order to cover the needs of special situations that have been met in practice. With the aim of establishing an official register of areas where eradication has been achieved, recommendations are given on the methodology of inspection and certification.

In countries where the administrative structure and the health services are still in the developmental stage, a "pre-eradication programme" may be necessary to create suitable conditions for the success of malaria eradication. An outline of such a programme is given, and it is suggested that an international team should be provided to advise the Government and, if necessary, to carry out the initial stages of the programme.

Health education forms an essential part of a malaria eradication programme; it must reach all levels of the population from the outset of the campaign and be continued throughout the consolidation and maintenance phases, in order to ensure continued co-operation of the public at a time when interest in malaria will have begun to wane. The report advocates that provision should be made for a special staff to run health education programmes under the malaria eradication programme.

The establishment of a standard terminology for use in evaluation and surveillance was considered by the Committee to be highly desirable, and it was recommended that the World Health Organization set up a drafting Committee to undertake this task.

The report directs attention to the value of chemotherapy in the attack phase of eradication programmes as well as in the later stages. The 4-aminoquinolines remain the most effective drugs and no significant changes are recommended in the regimen for radical cure. The use of salt medicated with chloroquine shows promise. Research is needed on the improved use of available drugs and to discover compounds with an improved action against malaria parasites.

It is believed that, in some countries, a reduction in the standard dosage of DDT (1 gm./sq. m.) used in spraying might be possible, but no such reduction should be made until appropriate field trials have provided unequivocal evidence that this would not jeopardize the success of the eradication programme.

Finally, the report considers the relation of simian to human malaria, particularly the recent experimental transmission of malaria from the lower monkeys to man. It is concluded that the practical importance of a simian reservoir of malaria is likely to be small.

A READING MACHINE FOR THE BLIND

By M. P. BEDDOES, E. BELYEA and PROF. W. C. GIBSON

Department of Electrical Engineering, Department of Psychology, Kinsmen Laboratory of Neurological Research, University of British Columbia, Vancouver

WE have investigated possible methods by which a machine can help blind persons to read from the printed page. This article describes work done on the problems of recognizing the alphabet letters, coding the output, and placing a hand-held pick-up probe accurately on the page.

The first notable reading machine was called the optophone by its inventor Dr. E. E. Fournier d'Albe[1,2], and in the early 'twenties a speed of 25 words a minute was claimed.

A devoted but small band of people have laboured with it since then with results, quoted recently in the Press[3], of up to 60 words a minute. This is not impressive considering the vast amount of experience which has been gained over the years, and it indicates two defects of the optophone principle: one is that the code sounds are difficult to learn; the other is that the fastest rate is well below that of normal reading speeds.

An American version[4] of the optophone which employs up-to-date engineering techniques has been disappointing also. Tests in progress since 1957 have established reading rates, when tape-recordings of the code-sounds are presented to subjects, of about 30 words a minute; but when a hand-held pick-up probe is used, 8 words a minute seems to be the fastest rate for experienced operators. The differences in the rates of the two versions (60 down to 8 words a minute) lie chiefly in the fact that the English machine uses a mechanical device scanning along the line to be read whereas the American one uses a manually held pick-up probe. The latter has advantages as regards cost, reliability and convenience to the user which are, at present, outweighed by its poor performance.

The optophone converts material from the page, a letter at a time, almost directly into electrical signals. For this reason it has been called[5] a 'direct translation' machine. Our work is with a 'letter-recognition' machine, so called because it first identifies (or 'recognizes') a letter and then triggers the appropriate code sound. With this type of machine there is a wide choice of audible codes making possible psychological advantages in learning and increased speed. Many workers in recent years have favoured the 'letter recognition' approach[7-11] because it permits the problems of identifying letters and of designing a suitable output code to be dealt with independently of one another.

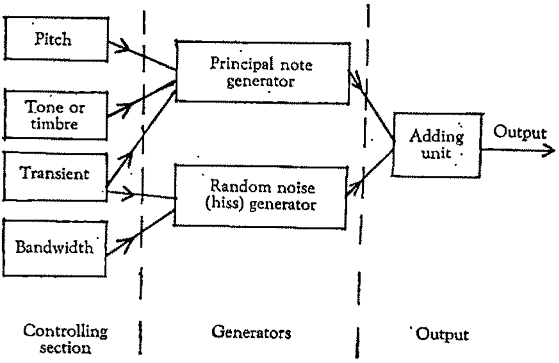

Fig. 2. Block diagram illustrating the generation of the sounds for the blind readers' code

The problem of recognizing standard typewritten print was investigated. Transparencies were made from impressions on ordinary bond paper of upper-case and lower-case alphabet letters from a portable typewriter. These slides were scanned by a flying-spot cathode-ray tube (Fig. 1). Sawtooth scanning was employed: vertical rate = 3,300 c.p.s.; horizontal rate = 80 c.p.s. Output from a photo-multiplier was processed by an R–C integrator with a time-constant of 11 m.sec. The scanning rates are not critical provided that this time constant is short compared with the period of the horizontal scanning (= 125 m.sec.) and long compared with that of the vertical scanning (= 0·3 m.sec.).

The operation of the apparatus is as follows. The output voltage, V_0, was large when scanning a long vertical line of appreciable width; such a line, for example, is the principal part of the letter I and is known as a 'riser'. Risers in letters b, d, f, h, etc., were easily spotted from the wave-form of V_0. A single horizontal line in letters such as n and u, etc., gave rise to a small value of V_0.

In identifying a letter, the apparatus of Fig. 1 may be used. The following sequence of tests on the wave-form V_0 was found necessary: (*a*) measurement of the height of the first maximum (results in Table 1: accuracy of ± 0·05 in 3 or ± 1·7 per cent is necessary); (*b*) measurement of the minimum following the above maximum; (*c*) a count of the number of maxima (used with letters such as m, w, M and W), with the scanning raster rotated through right angles; (*d*) measurement of the maximum; (*e*) measurement of the minimum between any adjacent maxima. Analogue and digital techniques are both used, and all letters can be decoded. The number of tests required to identify a letter varies, but the greatest number is four.

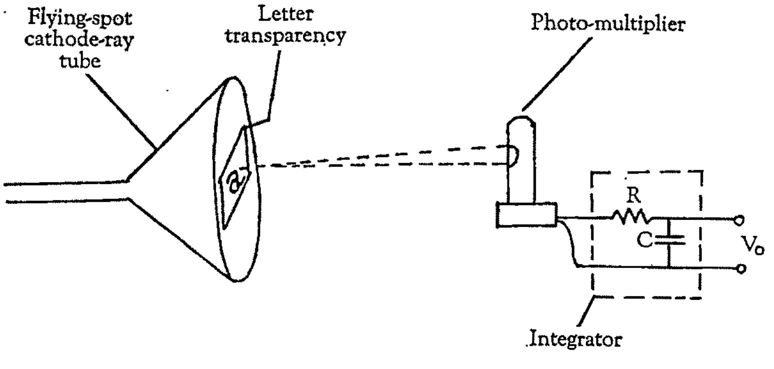

Fig. 1. Apparatus for investigating properties of letter recognition

Table 1. Classification of Letters according to Height of First Maximum of V_0

Height	1·0	1·1	1·2	1·3	1·4	1·5	1·6	1·7	1·8	1·9	2·0	2·1	2·2	2·3	2·4	2·5	2·6	2·7	2·8	2·9	3·0
Letter			dj			xy	cs	oa	euw	gmz	v	n	k	f	rbth	i	p			q	
Letter									CGO	SX	V	UZ	AMN		RY	HJTW	BDK	FQ	E	LP	I

In order to arrive at the best coding for the alphabet letter detected by the above procedure, we conducted experiments with various proposed audible codes of a semi-musical nature. Each alphabet letter is represented by a single sound (as opposed to the many in Morse). Such a sound is the result of combining the components listed below.

(*a*) 'Pitch'—four frequencies (corresponding to doh, ray, fah and sol of the sol-fah notation). (*b*) 'Timbre'—two wave-forms (sine-wave or rectangular wave). The above are produced in the 'principal note generator' (Fig. 2). (*c*) 'Hiss'—broadband noise from a separate generator is filtered through one of three bands in the audio spectrum. (*d*) 'Transient'—with or without a click at the commencement of the sound. Sixty-three distinct sounds can be made. The above list represents the best compromise obtained so far as judged by the following experiments.

Experiments were made to determine whether or not the components could be perceived either singly or in the presence of others. A pair of sounds each 0·1 sec. long and separated by 0·1 sec. silence was conveyed by a loudspeaker to a subject who was asked to judge if the pair was made up of the same sounds or different ones. About two hundred such tests, each separated by 3 sec., were presented to up to seventy-six subjects at a time. Errors with the final code (above) were less than 10 per cent.

The choice of components was made so that clear patterns were perceptible when the sounds were presented rapidly. The following word experiments indicate that such is the case.

Eleven three-letter words were chosen. Each was coded to occupy 0·7 sec., and they were presented in six random sequences to seven blind persons. Ages varied from 15 to 52 years; average age was 33. The code version of the word was followed by a 10-sec. silence; this was followed by the spoken word, and, finally, by the code-version again. Words were always presented in this order. In the first sequence, words were heard for the first time, but nothing was required from the subjects. In the second sequence and those following, the subjects were asked to write in Braille the appropriate word in the 10-sec. pause. Their 'guess' was confirmed or corrected by the subsequent voice-code cycle. Results are given in Table 2: no difficulty was found in decoding meaningful sentences made of strings of these words.

Further word experiments using the same material with some additions were made with thirty-seven sighted university undergraduates in psychology. Results are not as good as those for the blind group (cf. Table 2 with Table 3), but are still considered to be acceptable. Poor motivation probably accounts for the slower learning-rate.

Table 2

Sequence	2	3	4	5	6	7
Correct (per cent)	65	60	82	82	80	80

Table 3

Sequence	2	3	4	5	6	7	8	9	10	11	12
Correct (per cent)	17	23	33	42	44	48	53	54	59	62	63

A machine has been constructed with a hand-held probe for reading a very special type of print—printed Braille. This machine is being used to investigate the problem of placing the probe accurately on the page. A feature is its simplicity. Six miniature photocells are used to read from the Braille character; three cells are used to identify position; eighteen transistors and nine relays are required for reading purposes; only six transistors are required to provide the coded output. If printed Braille could be made popular, such a machine would provide a very economical link between the blind and the printers' art.

Acknowledgment is made to the National Research Council of Canada (Ottawa) for financial support of part of the work.

THERMAL SHOCK AND ITS EFFECT ON THERMISTOR DRIFT

By J. H. SWARTZ and R. RASPET

U.S. Geological Survey, Washington, D.C.

IN 1948, one of us (J. H. S.) undertook an investigation of sub-surface temperatures in drill-holes in Navy Petroleum Reserve No. 4 as a part of a study of permafrost problems in arctic Alaska. Early measurements were made with copper-coil resistance thermometers. Beginning in 1949, however, thermistors were used as the temperature-sensing element because of their high thermal sensitivity. These were mounted in a multiconductor cable employing a circuit designed to permit the use of a minimum number of conductors for a given number of thermistors and to allow a correction for temperature distribution along the wires[1]. In construction the cable jacket was slit to permit the insertion of the thermistors in the appropriate conductors. Originally the slits were closed by wrappings of pressure-sealing vinylite tape. Later the cable slits were sealed by special vulcanizing techniques.

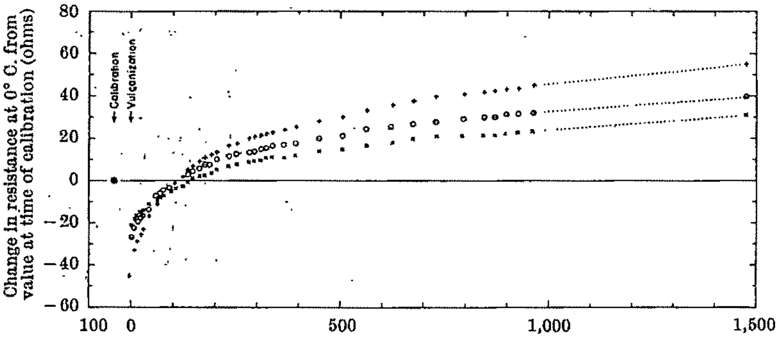

Fig. 1. Change in resistance at 0° C. with time after vulcanization (at 120°–130° C.) for 56 thermistors vulcanized in cables 199 and 200. ⊙, Mean of all 56 thermistors, cables 199 and 200; ×, thermistor 3786 (minimum change); +, thermistor 3834 (maximum change)

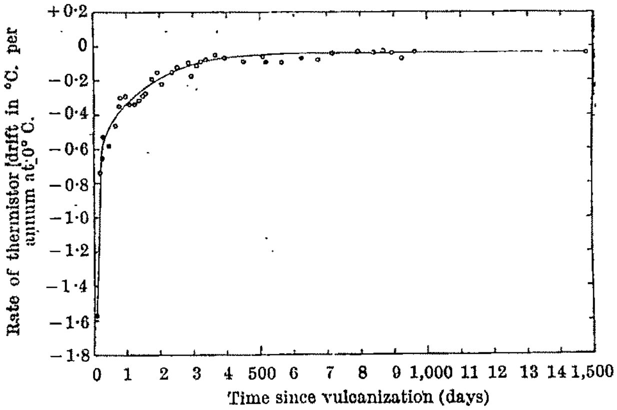

Fig. 2. Change in the rate of temperature drift with time for the mean of the 56 thermistors in cables 199 and 200

It was soon found that thermistor calibrations were disturbed by the vulcanization process. It was thought that this might be due to either of two factors: (1) chemical effects caused by free sulphur during vulcanization; (2) thermal shock caused by the heat of vulcanization. Experiments with litharge rubber, furnished through the kindness of the Rubber Section of the National Bureau of Standards, to eliminate most of the free sulphur during vulcanization, showed no apparent reduction of the effect. Nor was the effect either eliminated or reduced when a plastic-insulated cable was employed. This supported the idea that the effect was due largely, if not entirely, to thermal shock.

To test this hypothesis 12 thermistors were placed in a clean mould and raised to vulcanizing temperatures (120–130° C.) for 1 hr. All twelve showed the same typical calibration disturbance as those vulcanized in a cable.

Since that time some 80 thermistors have been investigated for the effects of thermal shock, and their subsequent calibration drift has been studied by recalibrations at approximately regular intervals in either a high-precision temperature-controlled bath or in an ice-bath. In particular, the resistances of 56 thermistors in two vulcanized cables have been rechecked in carefully prepared ice-baths, first at weekly, later at two-, three- and four-weekly intervals over a period of 961 days (2·6 years) with a later follow-up check at 1,475 days (4·04 years). This work has indicated certain generalizations to hold for the thermistors investigated (mostly type 17*A*, material No. 1 composition, disk-shaped). These were mostly a commercially available type composed of manganese and nickel oxides, disk-shaped, approximately 0·2 in. in diameter and 0·04 in. thick, with axial leads attached by silver-eutectic solder to a ceramic silver button attached to the face of the disk; at room temperatures its resistance is approximately 1,000 ohms and its rate of change of resistance with temperature approximately 4·4 per cent per deg. C.

(1) Of 70 thermistors heated to vulcanization temperatures the calibrations of all but one were offset in the heating direction, that is, after vulcanization their resistance at a given temperature was found to be lower than before vulcanization so that they registered too high an apparent temperature. For 55 of the 56 thermistors in the two vulcanized cables, for example, there was a decrease in resistance after vulcanization of 18–45 ohms, resulting in an increase in the apparent temperature of the ice-bath of 0·11–0·28° C. with an average of 0·20° C. as measured by the two cables. The one aberrant thermistor, No. 3,800, showed an increase in resistance after vulcanization of 1·9 ohms corresponding to a decrease of − 0·01° C. in the apparent temperature of the ice-bath.

Following the initial offset, all the heated thermistors began to increase in resistance (Fig. 1), returning exponentially towards their pre-vulcanization resistance. However, instead of approaching this value asymptotically, as had been expected, they reached this value after approximately 120 days, crossed over it, and continued to increase in resistance, but at a gradually diminishing rate. After four years they are still continuing to change, but at a slow and apparently nearly uniform mean rate of approximately 6 ohms per annum, equivalent to a decrease in the apparent temperature of the ice-bath of approximately 0·036° C. per annum (Fig. 2). The aberrant thermistor, No. 3,800, after the initial abnormal offset has shown a normally increasing resistance (decreasing apparent temperature) and has in fact closely paralleled the drift of the normal thermistors, as seen in Fig. 3.

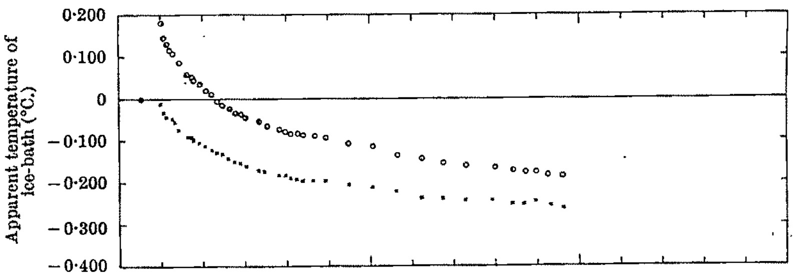

Fig. 3. Change of the apparent temperature of the ice-bath with time after vulcanization (at 120°–130° C.) as measured by the mean of 56 thermistors in cables 199 and 200 (⊙), and by thermistor No. 3800 (×)

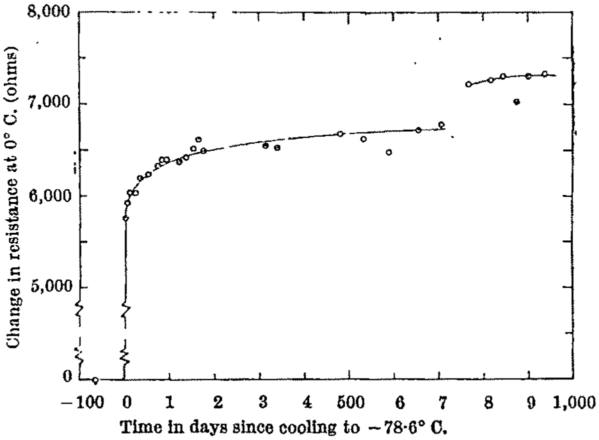

Fig. 4. Change with time in the mean resistance at 0° C. of 12 thermistors which were cooled to −78·6° C. at t = 0 days. The offset at 766 days was caused by a measurement at −30° C. made at t = 715 days following a long period at temperatures not lower than 0° C. Note that the vertical scale in this figure is 25 times that of Fig. 1

(2) Because heat shock offset the calibration in the 'hot' direction it was thought that cold-shock might produce an offset in the 'cold' direction, that is in the direction of increased resistance. Accordingly 12 thermistors were wrapped in paper and placed next to a block of dry ice (− 78·6° C.) for 15 min., then unwrapped and placed in contact with the dry ice for 1 hr. They were then allowed to return slowly to the temperature of the room and recalibrated. As was anticipated, all were found to have been offset to a higher resistance when rechecked in the ice-bath. The effect was, however, much more severe than in the case of the heated thermistors, the mean resistance of the 12 cooled thermistors at 0° C. having increased 5,754 ohms (Fig. 4). Of the 12 thermistors tested two were not greatly affected. The remaining 10, however, were seriously disturbed, one thermistor, No. 3,538, having its resistance increased nearly 500 per cent. The corresponding offsets in the apparent temperature of the ice-bath ranged from − 0·10° to − 29·73° C., with a mean offset for all 12 thermistors of − 18·91° C. This may be compared with a mean offset of only + 0·20° C. both for the 12 heated thermistors and for the 56 thermistors vulcanized in cables 199 and 200.

Following this initial 'cold-shock' offset the resistances of the 'frozen' thermistors did not, however, return towards their pre-shock values. Instead they too continued to increase exponentially at a gradually diminishing rate which, however, exceeded that of either the normal or the heat-shocked thermistors, as seen in Fig. 4. It may also be noted that the 'frozen' thermistors tended to become somewhat erratic, so that it was difficult at times to obtain a satisfactory bridge balance.

Because of the greatly increased resistance, as well as the erratic character, of some of the readings it was thought possible that the rather rapid chilling might have caused actual physical damage to the 'frozen' thermistors. A careful examination of all 12 thermistors was made under a microscope at magnifications up to × 100. Three of the twelve showed very fine, hair-line cracks in the side of the disk extending for short distances more or less parallel to the faces of the disk. These three were the most seriously disturbed of the 12, and thermistor No. 3,858, the most seriously disturbed of the three, was also the one with the most pronounced crack. The remaining 9 thermistors showed no evidence of any physical damage. This does not, of course, preclude the possibility of internal strains or lattice dislocations not externally visible.

(3) The thermistor drift after the initial thermal-shock offset, in all 80 thermistors investigated, was always an increase in resistance with time, although at a gradually diminishing rate of change, whether the thermal shock was due to heat or cold, and whether the initial shock-offset was plus or minus.

(4) Evidence from arctic measurements had indicated that thermistors permanently installed at points of constant temperature had a much smaller calibration drift than those exposed to variable temperatures. Accordingly a thermistor, No. 3,538, which had been subjected to more thermal shocks than usual, was placed in an ice-bath and kept continuously at 0° for 2·6 years. During the 269 days prior to this it had been vulcanized at 125° C., calibrated three times in a hypsometer at 100° C., and used for temperature measurements in a drill hole at 95° C. It would therefore have been expected to be more disturbed than the usual thermistor and subject to a faster rate of drift. Despite these facts, as seen (Fig. 5), its drift at a constant temperature of 0° C. was only 0·4 that of the normal vulcanized thermistor exposed to a variable temperature.

That this was not due to a naturally low drift-rate is shown by the two ice-bath determinations at − 47 and − 5 days in Fig. 5. The last previous heat shock was at − 242 days. Despite recovery periods, therefore, of 195 and 237 days respectively, these readings show a rate of change slightly greater than the mean after that recovery time for the 56 thermistors in cables 199 and 200.

(5) Because of the characteristic drift of the thermistors investigated it was found possible to use the drift curve to make corrections to an accuracy of the order of one or two hundredths of a degree Celsius over a 2·6-year period within which the calibration changed as much as 0·6° C.

In the light of these facts, it is evident that thermistors should be protected from large and sudden changes in temperature, whether hot or cold. Serious cold-shock is especially to be avoided. Room-temperature vulcanization is possible with special rubber compounds and accelerators, as well as with certain plastics. Pressure-sealing tapes may be used where they give adequate protection against leakage or the entry of water into the cable.

Calibrations should be made at the approximate temperature to be measured and should be restricted

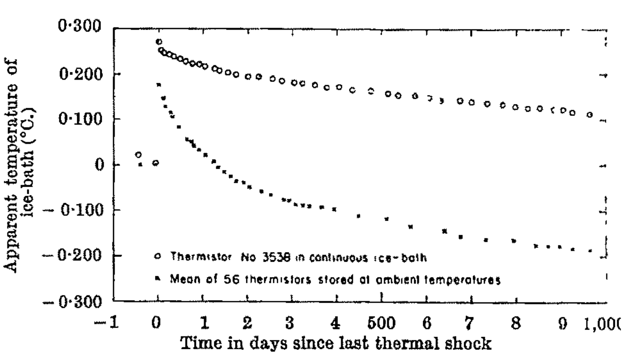

Fig. 5. Changes in the apparent temperature of the ice-bath with time (after hypsometer test at 100° C.) as measured by thermistor No. 3538 kept continuously at 0° C., compared with those measured by 56 thermistors vulcanized in cables 199 and 200 and stored at ambient temperatures between ice-point measurements

to as narrow a range on either side of that value as is feasible.

Thermistors which have been subjected to thermal shock should be allowed a sufficient subsequent rest period to allow their return to a normal drift-rate. They should be recalibrated just prior to, or just after, subsequent measurements, or both, depending on the precision desired and the length of the measurement period involved. If possible the thermistors used should be kept continuously at the temperature being measured for the entire measurement period, especially during a long-continued measurement series, in order to reduce thermistor drift to a minimum. With these precautions drift can be reduced to very small values. These values may often be still further reduced by properly applied corrections.

Publication of this investigation is authorized by the Director of the U.S. Geological Survey.

TWILIGHT AND THE 'CREP' UNIT

By Dr. ERIK TETENS NIELSEN

Entomological Research Center, Florida State Board of Health, Vero Beach, Florida, and Zoophysiological Laboratory of the University of Copenhagen

FOR a very long time many kinds of animals have been known to be most active around sunset. A relationship between the changing light intensity and activity is now usually presumed, and it has been shown[1] that the duration of the swarming of mosquitoes depends on the duration of twilight.

Civil twilight is the period from sunset to the time when darkness compels man to suspend labour in the open air. Similarly, the beginning of dawn in the morning is the moment when the light becomes sufficient for the resumption of normal human activity. In this article the discussion will be confined to conditions at sunset with the tacit understanding that corresponding conditions prevail at sunrise.

Even if the end of civil twilight is rather loosely defined it has long been known[2] that several natural phenomena occur at the very end of man's day: (1) stars and planets of the first magnitude are just becoming visible; (2) the purple light above the sunset disappears; (3) the anticrepuscular arch passes zenith (this is the borderline between the reddish tinged and the ashy or deep blue part of the sky); (4) the centre of the Sun is about 6° below the horizon. The last point permits an unequivocal definition of the end of twilight: it is the moment when the Sun's altitude is − 6° 00′.

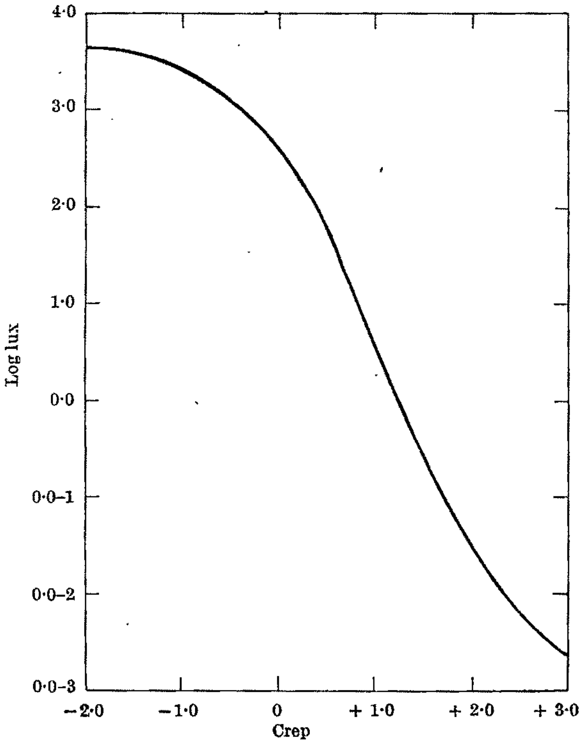

Fig. 1

The definition of the beginning of twilight depends on the various definitions of sunset. In most of the tables now in use[3–5] sunset is defined as the moment when the uppermost part of the Sun appears to coincide with the horizon. Due to the refraction of the atmosphere the Sun will at that moment be about 34′ below the horizon, and as the half diameter of the disk of the Sun is about 16′, the Sun's altitude at the moment of sunset is actually about − 50′. The refraction changes with the atmospheric conditions, and the sunset may be observed to occur one or even a couple of minutes in variance with the moment to be expected from astronomical tables. The duration of civil twilight given in such tables is the number of minutes required for the position of the Sun to change from − 50′ to − 6° 00′. The duration varies according to geographical latitude and season from 21 min. to several hours.

The effect of twilight on the habits of animals is caused by the change in illumination. The unit of illumination is the lux. It is convenient, and, according to Weber–Fechner's law, also the most correct, to operate with the logarithms of lux. The illumination is best measured as the diffuse light from the sky incidental to a horizontal plane. If the sky is clear the illumination depends almost exclusively on the altitude of the Sun. At sunset it is thus 2·60 log lux (400 lux), and at the end of twilight it is 0·55 log lux (3·5 lux). Biological phenomena depending on the illumination should therefore be related to the Sun's altitude rather than to the hour angle. Instead of using hours and minutes to describe the time-sequence of such habits of animals it is more convenient and logical to use a time unit based on the duration of twilight, especially when observations made at different latitudes and in different seasons have to be compared. In work now in progress on the comparative ethology of swarming of mosquitoes it has been found very useful to transform all time indications into such twilight values, called 'crep' (from *crepusculum*). One crep is defined as the number of minutes which, under the given conditions, correspond to the duration of twilight. Hours and minutes are changed to crep values by means of the expression:

$$\frac{\text{time of day} - \text{time of sunset}}{\text{duration of twilight}}$$

and correspondingly:

$$\frac{\text{time of sunrise} - \text{time of day}}{\text{duration of twilight}}$$

If sunset is at 18 h. 00′, and the twilight lasts 30 min., the hour 19 h. 00′ will be + 2·00 crep, and 17 h. 15′ will be − 1·50 crep. The values of crep are positive when they refer to the period during which the Sun is below the horizon, negative for periods after sunrise to before sunset. Sunrise and sunset have the crep value 0, while the end of twilight in the evening and the beginning of dawn have the values + 1·00 crep.

When the sky is clear a certain illumination corresponds to any given value of crep. Using the data of Kimball[2], Provost[6] and my own measurements from Florida, Iraq and Denmark, a table of corresponding values has been prepared; it will be published later[7], and is represented here as Fig. 1.

White clouds reflecting sunlight may give higher illuminations than those of the table, and lower values may be found when the sky is covered by dark clouds. Especially after sunset the differences are usually small compared with the rapid change of illumination. During a recent field investigation in Denmark the sunset illumination (2·60 log lux) occurred at the calculated minute on 21 out of 49 evenings; on 22 evenings this illumination occurred at an average of 0·1 crep (3½–6 min.) before sunset. On 6 evenings it became dark so quickly that the illumination was reduced to 2·60 log lux at 0·20–0·84 crep before sunset.

Fig. 1 shows that at least the middle part of the curve approximates a symmetrical S-shape with the turning point at + 1·00 crep. We have thus one more characteristic of the end of twilight: it is the moment when the illumination changes from an accelerating rate of change to a decelerating rate.

At places where animals are resting the illumination is often lower than in the open; however, there is usually a simple relationship between the illumination at such places and that measured in the open.

The calibration of light-meters often meets with difficulty because the lux is not defined purely as a physical unit. It is based on the curve of photonic relative luminous efficiency[8], which is an expression for the relative sensitivity of the human eye to light of different wave-lengths. A light-meter calibrated by means of a standard light source can only be used in the field by means of special filters. It is easier to calibrate the instrument by measuring the illumination in arbitrary units on a few clear evenings, and by means of the crep/(log lux) function to find the relationship between the arbitrary units and the illumination.

FOOD SELECTION BY SILKWORM LARVÆ, *BOMBYX MORI*

Citral, Linalyl Acetate, Linalol, and Terpinyl Acetate as Attractants of Larvæ

ONE of us (Y. H.)[1] has reported on the mechanism of food selection of silkworm larvæ, and has pointed out with regard to a principle of food selection that silkworms are attracted by three stimulants in mulberry leaves, namely, attractant, biting factor and swallowing factor. The attractant only induces the larvæ to the food and the biting factor raises the action of biting and the third, swallowing factor, helps the larvæ to swallow the food continuously. Agar jelly containing these three stimulants is eaten by the larvæ as from the mulberry itself.

This communication is concerned with the attractiveness of some terpenes for silkworms and the existence of citral, linalyl acetate, linalol, and terpinyl acetate in mulberry leaves.

As already described[1], the ether-soluble fraction of methanol-soluble matter from fresh mulberry leaves attracts silkworms. When a small amount of active carbon is added to this ether fraction the yellowish ether solution is obtained as a result of the absorption of green substances. This yellowish solution powerfully attracts the larvæ (Table 1). The neutral fraction of the ether solution, which is fractionated by washing with a 1 per cent solution of sulphuric acid and a 2 per cent solution of sodium carbonate in this order, and the steam distillate of this neutral fraction are also powerful attractants (Tables 2 and 3). The yield of an active fraction in this distillate is about 0·2 gm. per 4 kgm. fresh leaves. The ultra-violet absorption curve of this distillate resembles that of terpene alcohols, and the infra-red absorption spectra also closely resembles that of terpinyl acetate, and further detection by gas chromatography suggests the existence of citral, linalyl acetate, linalol and terpinyl acetate in this fraction. The attractive force was tested on the pure chemicals, citral, terpinyl acetate and some terpene alcohols (Table 3).

Six small circles along the circumference of a round filter paper are drawn in equal intervals and the paper is set in a shale (diameter: 8·5 cm.). Samples absorbed on cellulose powders are prepared as follows. A certain amount of the solution of the samples is absorbed on 0·25 gm. cellulose powder, and solvent is evaporated in the air, and then water is sprayed on it: on the other hand, the same amount of cellulose powders containing a small amount of water is prepared as control. These cellulose powders are divided into three portions respectively and put on six circles reciprocally. When the test on the difference of activities between *A* and *B* is taken in a set, the powders are put on in the order *A*, *B*, control, *A*, *B*, and control. Thirty hatched larvæ are placed on the centre of the filter paper. After leaving the set at 24° C. for a certain time, the number of larvæ gathered on each powder and wandering on the intermediate

Concentration 1 means that 1 c.c. of 10 mgm. per cent ethereal solution of substances was absorbed by 0·25 gm. cellulose powder and the powder was divided into three portions as described above, 1/2 means 1/2 c.c. of the solution and so on. *S*, *C* and *I* mean sample, control and intermediate space, respectively. Numbers of the larvæ are counted after 1 hr. at 24° C. Substances marked with an asterisk are those presumed to exist in mulberry leaves by gas-chromatographic techniques ; others do not exist in the leaves.

space are counted. The results of the test are given in Tables 1–4.

Thus, from these experiments, citral, linalyl acetate, and linalol, which are seen to exist in mulberry leaves, are very attractive to silkworm larvæ, and terpinyl acetate and hexenol[2] are less attractive. Other terpenes shown in Table 4 which have not been detected in mulberry leaves do not attract. These terpenes attract silkworm larvæ but do not stimulate biting.

We wish to thank Dr. Teruhiko Hosoi for his advice and Dr. H. Okamura of the Eikodo Co., and Dr. M. Ono of the Institute of Chemistry, Kyoto University, for the chemically pure perfumes and β-γ-hexenol, respectively.

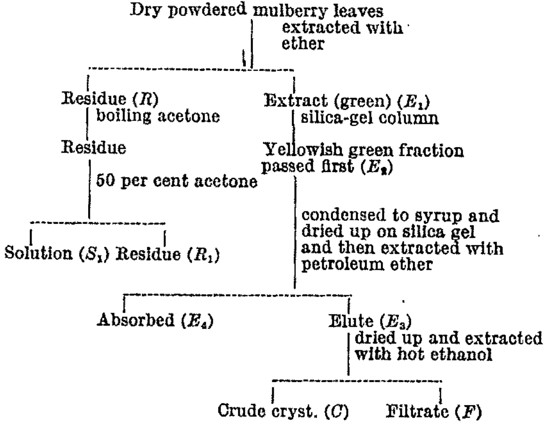
β-Sitosterol as one of the Biting Factors

DRY powdered mulberry leaves were extracted with ether and the extract was fractionated as in Scheme 1.

E_1 markedly attracts and stimulates the biting action of silkworm larvæ as described[1]; E_2 and E_3 are also positive in both respects. Crude crystal (*C*) from E_3 strongly stimulates biting but is not an attractant. On the contrary, filtrate (*F*) scarcely stimulates biting but is a strong attractant (Table 1). Therefore, it is possible to distinguish the biting factor from the attractant in the mechanism of food selection by silkworms.

Scheme 1



The crude crystal (*C*) from E_3 shows a strong Liebermann's sterol reaction. Thus the active principle to stimulate the biting action seems to be a sterol-like substance. Two of us (Y. H. and K. N.)[2] isolated β-sitosterol in a chemically pure state from mulberry leaves. As Table 2 shows, β-sitosterol showed strong activity on the biting test on agar thread which was softened with a small amount of water and sprayed with an ethereal solution of β-sitosterol. Other sterols, cholesterol and ergosterol, gave little activities on this test (Table 2).

Hobson reported[3] that a fat-soluble accessory growth factor required by all insects is cholesterol ; Fraenkel and Blewett have stated that sitosterol is utilized in place of cholesterol by phytophagous insects. But we have found that β-sitosterol is required as a biting factor in the mechanism of their food selection, since β-sitosterol, not only on agar thread but also on glass, stimulates biting, and although cholesterol and ergosterol probably have higher nutrition value than β-sitosterol, they give lower activities on the tests of both biting and swallowing actions as shown in Tables 2 and 3.

In Table 3, a set of test dishes requires a much larger amount of β-sitosterol (20 mgm.) in comparison with the sterol content in mulberry leaves (about 0·2 per

Table 1

	Test of attraction No. of larvæ gathered on. Total larvæ, 30				Test of biting action

B.d. + ergosterol (20 mgm.)	44

cent). Doubts may be expressed concerning the relation between the concentration and the activity unless it is supposed that there is an accumulation of β-sitosterol on the surface of mulberry leaves. It has been proved that when the leaves are wiped with an absorbent cotton containing a small amount of ether, the cotton strongly stimulates biting, and as a matter of course indicates a positive reaction for Liebermann's sterol test.

The swallowing test by newly hatched larvæ was made using pure β-sitosterol in place of the crude one (E_1 or E_2) by the modified method already described[1]. One basal diet consists of the following: 3 c.c. 2 per cent agar solution containing 1 per cent sucrose, 0·2 gm. cellulose powder and 0·3 gm. of R_1 which seems to have a swallowing factor (diameter of a Petri dish: 4·5 cm.). Ten newly hatched larvæ were put on an agar diet for 18 hr. at 24° C. and the fæces were counted (Table 3).

From Table 2 it is concluded that β-sitosterol is the biting factor and some sterols may be an accessory in mulberry leaves. From Table 3 it is clear that the larvæ require an unknown swallowing factor together with the biting factor, β-sitosterol, for their complete food taking, and the amount of food eaten is controlled by the concentration of β-sitosterol.

Further experiments suggested the existence of another water-soluble biting factor in the S_1 fraction.

We wish to express our thanks to Dr. T. Hosoi for his advice. This work was supported by a grant from the Ministry of Education.

CYCLICAL FEEDING-ACTIVITY IN COLONIZED MOSQUITOES

By DR. J. D. GILLETT
East African Virus Research Institute, Entebbe, Uganda

EXTENSIVE field-studies on African mosquitoes made over the past 18 years by Haddow and others[1] have demonstrated the cyclical nature of biting activity. These investigations show that a species usually exhibits a characteristic biting pattern, although this is not always constant throughout its range; they do not, however, show to what extent such patterns are a direct response to environmental stimuli, or to what extent they represent an expression of inborn rhythms. Such work has been based on the catching, and removal from the population, of female mosquitoes that alight on the bait, the mosquitoes so removed in unit time being sorted and counted at leisure. Clearly such a method depends on the presence of what, for practical purposes, can be regarded as an infinite population of mosquitoes, and this automatically precludes its use if biting activity is to be studied under controlled laboratory conditions. Yet it is precisely this approach that is now urgently needed[2]. The problem can, however, be studied in the laboratory if, instead of counting the number of mosquitoes that alight on the bait, we measure the amount of food they remove from it. The present article describes an experiment to test this method, using sugar solution as a source of food.

An apparatus has been devised which provides a continuous supply of food from a graduated tube. The apparatus was developed independently from, and it differs in principle from, the feeding apparatus described by Rodhain *et al.*[3], which allowed tsetse flies, *Glossina*, to suck blood through a mouse- or rat-skin membrane. They used an open graduated pipette in order to record the hydrostatic pressure of the blood, but mentioned that this would also allow measurement of the amount of blood ingested by each fly. The principle of the present apparatus is to record the amount of fluid removed from the bait in a given period of time as a measure of feeding activity. To do this it was essential that the apparatus be capable of feeding a large number of insects over a continuous period of several days. Changes in attractiveness were reduced by the use of perforated polyethylene or of fine-mesh metal gauze in place of animal skin. The alternative choice of metal gauze as a feeding surface was partly influenced by the description of an ingenious feeding device given by Dr. P. A. Woke at the eleventh International Congress of Entomology held in Vienna during August 1960.

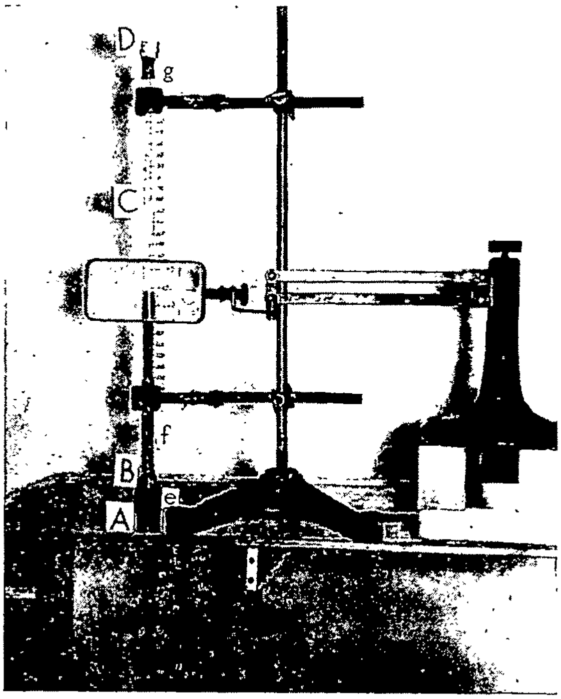

Fig. 1. Apparatus for recording the amount of fluid removed from the bait as a measure of cyclical activity in fluid-feeding insects

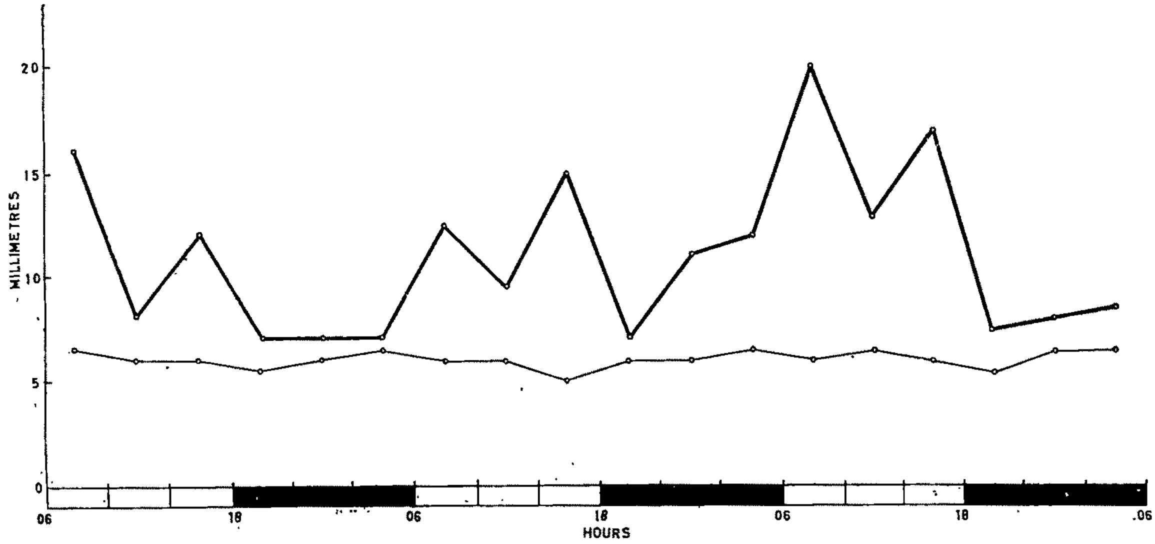

Fig. 2. Sugar feeding-cycle in the mosquito *A. aegypti*. Thick line: loss of fluid each 4 hr. through feeding plus evaporation (test series); thin line: loss of fluid each 4 hr. through evaporation only (control series). Light switched on 06–18 hr. (East African Standard Time) each day

The apparatus (Fig. 1) as used here consists of a wide feeding-tube, *A*, closed at the lower end by a 0·5-mm. mesh, non-corrosive, non-absorbent perforated cap, and connected above by a tapering middle-piece, *B*, to a narrow, transparent measuring-tube, *C*, graduated in mm. (7·0-mm. internal diameter and 300 mm. in length). These three parts are joined together by two pieces of flexible tubing (*e* and *f*), the latter being long enough (about 60 mm.) to allow flexure through 90° without occlusion. The open upper end of the measuring tube is attached to a short piece of flexible tubing, *g*, which can be closed by means of a screw-clip, *D*.

To prepare the apparatus for use, screw-clip *D* is left open, and the whole apparatus is bent at *f* to form a U-tube. Feeding-fluid is introduced, until the whole apparatus is nearly full. The two limbs of the U-tube are then adjusted until the fluid reaches the perforated end of the feeding-tube in one limb, and nearly to the top of the measuring-tube in the other. Screw-clip *D* is then closed and the apparatus is straightened out to a vertical position, with the feeding-tube at the lower end. It is placed on the gauze top of a cage containing the mosquitoes, the perforated end of the feeding-tube being in direct contact with the gauze top of the cage.

Fluid will be lost from the apparatus by two means: evaporation and mosquito-feeding. Allowance for the amount of fluid lost through evaporation can be made by using a duplicate apparatus over an empty cage as a control; the difference in loss of feeding-fluid in the two tubes can then be taken as a measure of feeding activity in a given time. With the dimensions given above, a drop of 0·5 mm. on the scale records a volume of $19 \cdot 24 \times 10^{-6}$ litre (19·24 µl.). For practical purposes this can be taken as roughly equivalent to five female-mosquito meals[4]. The estimate would, of course, vary according to species and strain used and will probably be different if both sexes were feeding on the fluid.

Two series of observations were run concurrently: a control series using the apparatus with 10 per cent w/v sugar solution (5 per cent glucose, 5 per cent sucrose) over an empty cage, and a test series using a similar arrangement over a cage of mosquitoes. These were *Aedes* (*Stegomyia*) *aegypti* (L.) from Ilobi, Nigeria, and had been colonized in Entebbe for two years. Until the day before the experiment was started, the mosquitoes had had access to raisins (continuously) and to blood (infant mice for 1 hr. a day). Throughout the experiment an egg-laying funnel was present[5]. The experiment was carried out under controlled conditions of temperature (28° C.) and humidity (70 per cent relative humidity) with an artificial light regimen of 12 hr. light each 24 hr. Observations were made every 4 hr. for 3 consecutive days and nights.

Table 1. Feeding-cycle in the Mosquito *A. aegypti* under Conditions of 12 hr. Light each 24 hr., expressed as the Amount of Fluid removed from the Bait each 4 hr.

The results are shown in Table 1 and in Fig. 2. The difference between the two series is very marked: whereas in the control the rate of loss of fluid is almost steady at 6 mm. each 4 hr., in the test series the rate fluctuates, showing two peaks in each light-'stretch', one in the first 4 hr. light-'period', another in the last (the terms 'stretch' and 'period' have been defined previously for use in this sort of work[6], and are used in the same sense here).

During the final 12 hr. light-stretch, observations were made hourly, in order to obtain a preliminary analysis of the two peaks. The results for this single 12-hr. stretch indicate that the two peaks are different in form—that in the first 4-hr. light-period being confined to the single hour following onset of light, that in the last 4-hr. light period being less concentrated.

It is not claimed that the feeding-cycle obtained in the present experiment represents the definitive cycle for the species, or even for the strain used. This particular cage of mosquitoes had previously been supplied with a blood-meal at a set time each day, and an acquired blood-feeding rhythm may have influenced the sugar-feeding rhythm. Moreover, it is not known whether both sexes contributed equally to the two diurnal peaks of feeding activity. The results do, however, indicate that, with this apparatus as a tool, or with other similar apparatus employing the same principle, the way is now open for a detailed study of feeding-cycles along the lines already used in the study of mosquito oviposition-cycles[2,5,6]. It is planned to use the apparatus first with sugar solution or fruit juice, using male and female mosquitoes both separately and together, and later with vertebrate blood. Initially, observations will be made on an hourly basis, but when the cycles have been 'established', a study of the mechanisms involved may then be made on a 4-hr. basis. Improvements and modifications can doubtless be made on the prototype described here; the apparatus is, for example, particularly suitable for use with photographic recording.

Certain inherent difficulties have to be overcome before this method can be adapted for the study of blood-feeding cycles. While clotting can easily be prevented by one of the standard methods, sedimentation of the cells, or denaturing and precipitation of the blood proteins, presents a more difficult problem. Sedimentation can be retarded considerably by agitation, and in preliminary trials this has been achieved by convection set up by a heat exchanger coil wrapped around the feeding-tube. If laked blood is employed, it is necessary to use perforated polyethylene or to coat the metal gauze of the feeding-tube with a fine film of paraffin wax. The most promising results so far have come from the use of laked blood with a heat-exchanger coil. Details about dilutions and preservation will be given in a later communication.

LEAKAGE CURRENT RECTIFICATION IN THE SQUID GIANT AXON

By Dr. WILLIAM J. ADELMAN and Dr. ROBERT E. TAYLOR

National Institutes of Health, Bethesda, Maryland, and Marine Biological Laboratory, Woods Hole, Massachusetts

THE total current which flows across the membrane of the giant axon of the squid in response to stepwise changes in membrane potential in a voltage-clamp arrangement was shown[1] to consist mainly of sodium and potassium ions plus a small unidentified component, termed 'leakage'. This component was approximated by an equivalent conductance and apparent equilibrium potential, both constant with time and membrane potential.

We intended, in this work, to test these approximations and to determine, if possible, what ions might be involved in the leakage.

We used the standard, point-control voltage-clamp arrangement[2] and attempted to eliminate the currents due to sodium and potassium by means of the following procedure: (1) the membrane potential was controlled at a value close to the resting potential, during periods of measurement; (2) at intervals of about 1 sec. a 55 mV. hyperpolarizing pre-pulse of 7 msec. duration was followed immediately by the test pulse, either to a further hyperpolarized value or to the sodium equilibrium potential; (3) the membrane current at 0·4 msec. following the application of the test pulse was measured and taken to be the leakage current; (4) the sodium equilibrium potential was varied by substitution of choline ions for sodium ions in the external medium; (5) temperature was maintained at 10 ± 1° C.

For hyperpolarizing pulses sodium and potassium contributions to the leakage current are expected to be negligible, because the total current does not depend on the external sodium or potassium concentration (ref. 1 and this article). At the sodium equilibrium potential there is no net sodium current. If the depolarizing steps follow a hyperpolarizing pre-pulse, the onset of the potassium current is delayed[3] to such an extent that a negligible potassium current is expected during the first half millisecond.

We must distinguish between components of the total current, which are carried by sodium and potassium ions and are subject to the delayed rectification processes, and the possibility of an additional rectification with a very short delay. For depolarizations, a short time-constant increase in the potassium conductance might occur and not be observed as such.

In Fig. 1*A*, the leakage current is plotted as a function of membrane potential, for three typical

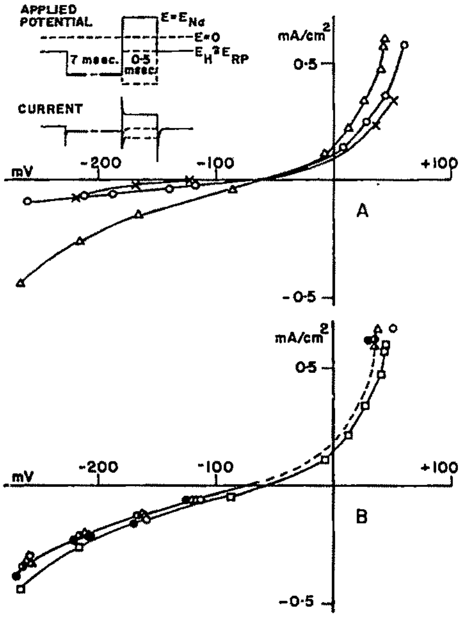

Fig. 1. *A*, leakage current versus membrane potential for three axons in varying concentrations of external sodium ion. Currents plotted were measured as indicated in the insert. E_H, holding potential just before the pre-pulse; E_{RP}, resting membrane potential; E_{Na}, sodium equilibrium potential. Zero current was taken as the current at 0·4 msec. after the application of test-pulse to the holding potential. Temperature, 10° C. ×, axon 60–47 with E_{RP} 67 mV.; ○, axon 60–61 with E_{RP} 66 mV.; △, axon 60–60 with E_{RP} 54 mV. *B*, leakage current versus membrane potential with 21 and 61 per cent of the normal external chloride. Curve for axon 60–60 replotted from Fig. 1 for reference. Temperature, 10° C. ○, artificial sea-water 1; ▲, 61 per cent chloride; ◑, artificial sea-water 2; △, 21 per cent chloride; ●, artificial sea-water 3; □, axon 60–60

axons. The insert in Fig. 1 indicates the method of measurement. The leakage current is not constant but exhibits marked rectification. The time-constant of delay was not obtainable with our system but is probably less than 100 µsec. In the hyperpolarized (more negative than the resting potential) region the curves showed no change on varying external sodium concentration from 430 to 43 m*M*/litre. The points associated with depolarizations to the sodium equilibrium potentials fall along a smooth curve. Axon 60–60 is typical of axons exhibiting low membrane resting and action potentials.

In an effort to identify the leakage-current charge-carriers we altered external chloride, potassium, calcium and magnesium. External chloride was altered by substitution with methyl sulphate.

Fig. 1*B* illustrates the results of measurements on axon 60–69 with one-half, and all, of the sodium chloride replaced by sodium methyl sulphate, giving a concentration of chloride of 61 and 21 per cent of the normal. The points in the depolarized region were obtained at the sodium equilibrium potential in normal sodium. For hyperpolarization there is clearly only negligible effect of chloride reduction. It is likely that this is true for the entire curve. The leakage curve for axon 60–60 is replotted from Fig. 1 for reference as being similar to axon 60–69. The steepness of the curve near the normal sodium equilibrium potential reduces sensitivity, but it would seem that here not more than 10 per cent of the leakage is accounted for by chloride ions.

In Fig. 2 the resting potential (*A*), and leakage current for a hyperpolarizing pulse to − 180 mV. following the standard pre-pulse (*B*), are plotted against time, while the external potassium, chloride and calcium and magnesium concentrations were varied. Since the resting potential, and probably the holding current, varied with time, there was some difficulty in comparing complete leakage curves. During periods of measurement, the membrane potential was held at a constant value regardless of the resting potential, introducing an uncertainty in the baseline to which leakage current is referred. However, the currents at a pulse potential of − 180 mV., measured in the usual way, are plotted as the circles in Fig. 2, giving the smooth curve through the four control values obtained in artificial sea-water. The current at 0·4 msec. following the pre-pulse relative to the current at the end of the pre-pulse is also plotted in Fig. 2*B* (triangles). For both cases the points obtained in 1/3 potassium and 1/5 chloride do not deviate from the line through the artificial sea-water points, while the points for 1/10 calcium and magnesium do. It is well known that lowering external calcium concentration tends to increase resting membrane conductance. It is important to distinguish, however, that here these currents do not significantly involve sodium or potassium. Further experiments are required to determine whether or not the increased inward current in low divalent ions is due to chloride.

For outward current 1/3 external potassium did not alter the leakage while low external divalent ions increased it. However, a fast time-constant potassium component might not be sensitive to external potassium changes.

Our conclusions are: (1) the leakage current, as defined, cannot be represented as a constant conductance and an apparent, constant, equilibrium potential; (2) the leakage current curve is not symmetrical about the resting (or zero) potential ; (3) the time-constant of the leakage rectification is shorter than 100 µsec.; (4) only a small fraction of the leakage current can be accounted for by the inward movement of potassium, chloride or sodium ions;

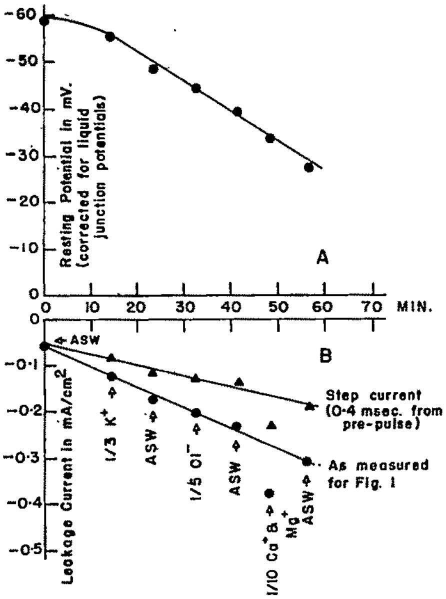

Fig. 2. *A*, Resting membrane potential versus time. *B*, Leakage current at −180 mV. (lower curve) and this current minus that at the end of the pre-pulse (upper curve) for variations in external potassium (1/3 *N*), external chloride (1/5 *N*) and external calcium and magnesium (1/10 *N*). Temperature, 10°C.

(5) lowering external divalent ions increases the leakage; (6) the chloride conductance of the resting membrane is probably negligible; and (7) it is necessary to suppose that the leakage is mainly the outward movement of so far unidentified internal ions—cations for outward and anions for inward current components. If the properties of the axon membrane were altered so that a large fraction of membrane current had properties of the leakage current discussed here, empirical utilization of conductances and equilibrium potentials, which has been so successful for the normal squid axon, might prove impracticable.

We wish to thank Dr. K. S. Cole, Dr. U. Kishimoto, Dr. W. K. Chandler and Mr. L. Binstock for helping us.

REPLACEMENT OF THE PROTOPLASM OF A GIANT NERVE FIBRE WITH ARTIFICIAL SOLUTIONS

By P. F. BAKER, Prof. A. L. HODGKIN, F.R.S., and Dr. T. I. SHAW

Laboratory of the Marine Biological Association, Plymouth, and Biochemical and Physiological Laboratories, University of Cambridge

SINCE the action potential of a nerve fibre almost certainly arises at the surface membrane, it should, in principle, be possible to replace the axoplasm by an aqueous solution of appropriate composition. The difficulty in carrying out this experiment is that the axoplasm of squid nerve fibres is a gel and is not easily washed out of an intact fibre. The method described here depends on the observation that the giant nerve fibres of *Loligo forbesi* retain their ability to propagate action potentials after the axoplasm has been squeezed out and replaced either with natural axoplasm or with an artificial solution[1]. Fig. 1 illustrates the replacement with natural axoplasm. Record *A* shows the action potential recorded with external electrodes from the central half of an intact axon. In *B*, the axoplasm from the central half had been extruded; the action potential was still present, but as a result of the increase in the internal electrical resistance, it was propagated more slowly and the component recorded with external electrodes was greatly reduced. On moving axoplasm from the distal to the central part of the fibre, the external action potential was restored to its original amplitude (*C*) and was still the same size 2 hr. later (*D*). Such experiments showed that the excitable properties of the membrane are not destroyed by extrusion and encouraged us to attempt the replacement of the axoplasm with artificial solutions.

The procedure for perfusing an axon consisted in: (1) dissecting, but not cleaning, 6–10 cm. of a fibre 500–900μ in diameter; (2) cannulating the axon at its distal end; (3) squeezing out axoplasm[2] by stroking the fibre in a series of sweeps, the first sweep starting at a distance of 2 cm. from the cut end, the second at 4 cm. and so on; (4) re-inflating the fibre at a steady rate by driving in an appropriate perfusion fluid at about 6 μl./min. After re-inflation, the electrical properties of the fibre were studied with external electrodes or, in the later experiments, with an internal electrode, using the method illustrated in Fig. 2.

For the normal perfusion fluid, isotonic solutions containing salts of potassium were employed: for example, isethionate (which is present in high concentrations in the axoplasm of squid nerve[3]), sulphate, methylsulphate or chloride. As a rule the solutions contained 30 m*M* phosphate buffer, normally at *p*H 7·7, and the tonicity was adjusted after the vapour pressure had been compared with that of the sea-water used as an external medium. Short-term experiments indicated that the action potential was little changed over a range of tonicity of ± 10 per cent and a range in *p*H of 7–8·5. A hydrostatic pressure of 2–3 cm. of water was required to keep the fibre inflated. If the pressure was released, the axon shrank to about a quarter of its original volume. In the shrunken condition the velocity of conduction was reduced but the action potential recorded with an internal electrode was little changed, as would be expected from the local circuit theory. Hydrostatic pressures of 10–20 cm. of water abolished the action potential if applied for more than a few minutes, but there was often a slow recovery after the pressure had been removed.

Potassium sulphate or isethionate media were used extensively, and with these solutions there was good evidence that the electrical properties of perfused axons were similar to those of intact axons. The action potential (100–110 mV.) and resting potential

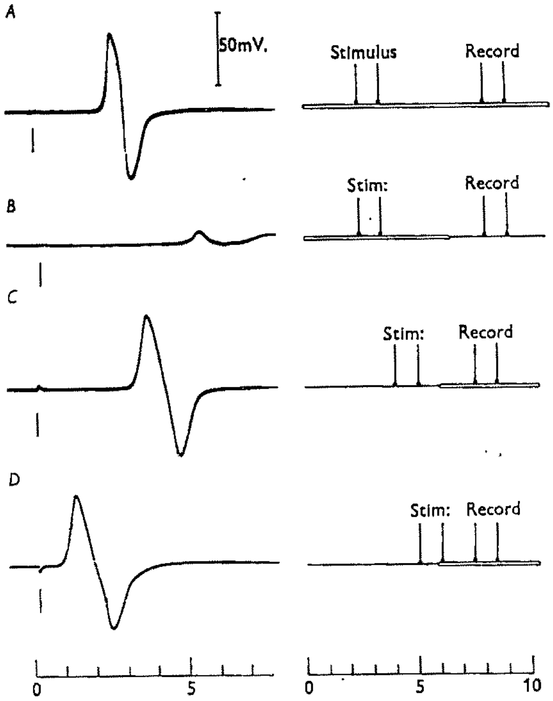

Fig. 1. Restoration of externally recorded action potential by filling 'sheath' with axoplasm. *A*, intact axon; *B*, right-hand half extruded; *C*, right-hand half filled by moving in axoplasm from left-hand half; *D*, as in *C* but 2 hr. later

A diphasic response was often observed at stage *B*, but in this experiment there was a local block between the recording electrodes which is attributed either to minor injury or to irregular flattening during extrusion

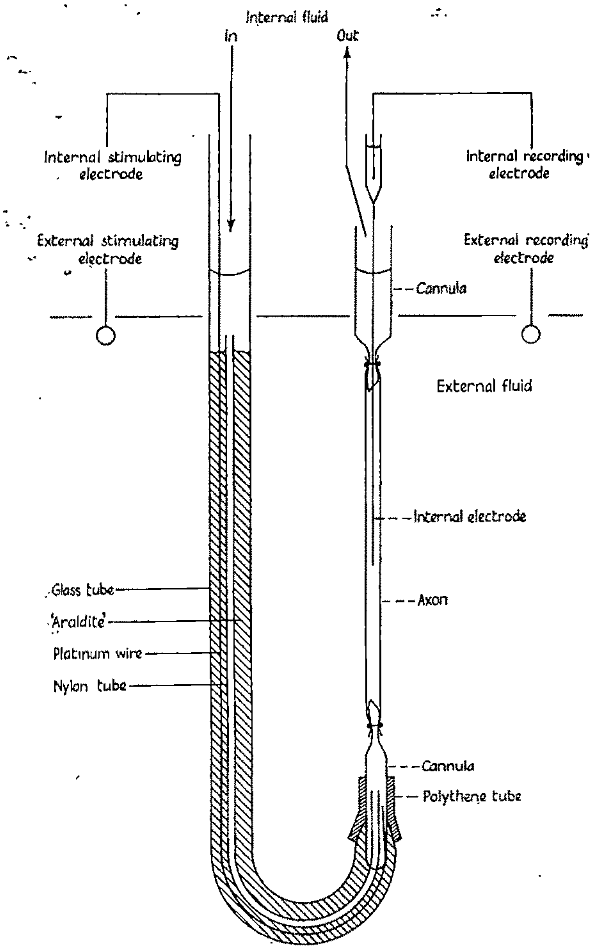

Fig. 2. Method used with internal electrodes; the drawing is not to scale

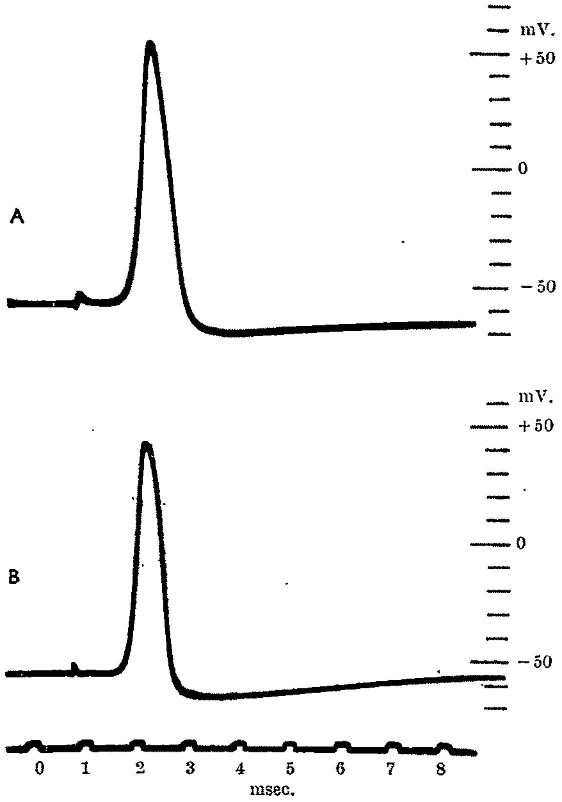

Fig. 3. *A*, action potential recorded with internal electrode from extruded axon filled with isotonic potassium sulphate (16° C.); *B*, action potential of an intact axon, with same amplification and time-scale (18° C.)
The voltage scale gives the potential of the internal electrode relative to its potential in the external solution (no correction for junction potential)

(50–70 mV.) were of the usual magnitude, and, as may be seen from Fig. 3, the time course of the action potential in a perfused axon resembled that in an intact axon. It is possible that prolonged perfusion may have some harmful effect, but a volume of 3–4 ml., which is more than one hundred times that of the fibre, could be perfused without making the fibre inexcitable. Axons filled with isotonic potassium solutions remained excitable for 3–5 hr. and were capable of carrying a large number of impulses, for example, 3×10^5 at 16° C.

Evidence that the perfusion fluid had rapid access to the surface membrane was provided by the speed with which the action potential was blocked by changing potassium for sodium ions in the perfusion fluid. With relatively short exposures, the effect of high sodium concentration was completely reversible, and both block and restoration might occur in 10–20 sec., the speed of the effect depending on the rate of flow and on the extent to which the dead space could be reduced.

Alterations in the ionic composition of the internal solution gave reversible changes in membrane potential, which were consistent with the view that the resting potential arises from the difference in concentration of potassium across a membrane which is selectively permeable to this ion[4]. Replacement of isotonic potassium sulphate with isotonic potassium chloride caused only a small decrease in resting potential, but replacement of potassium by sodium ions reduced the resting potential by about 50 mV.

Fig. 4 illustrates the effect on the resting potential of replacing potassium chloride by sodium chloride inside the axon, the external fluid being sea-water with the usual potassium concentration of 10 m*M*.

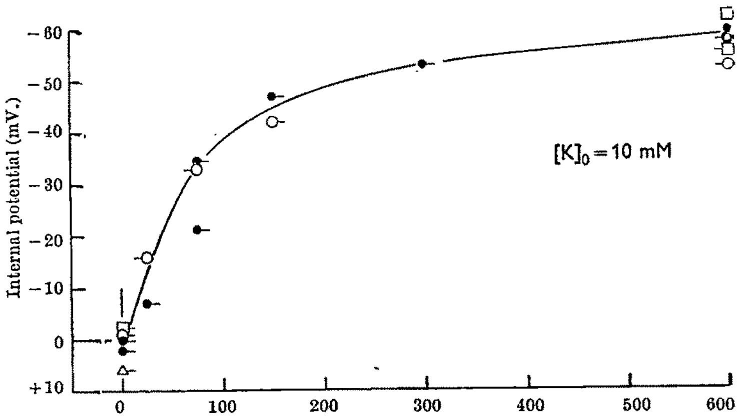

Fig. 4. Effect of internal potassium concentration on resting potential. External solution, sea-water; internal solutions, sodium chloride–potassium chloride solutions isotonic with sea-water

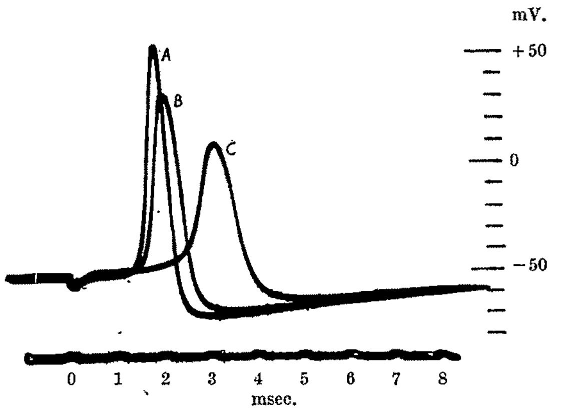

Fig. 5. Effect on action potential of replacing internal potassium with sodium ions. *A*, isotonic potassium sulphate; *B*, one quarter of the potassium ions replaced by sodium ions; *C*, half the potassium ions replaced by sodium ions. The records were taken from a long experiment and were obtained in the order *B*, *A*, *C*

With sodium chloride inside the fibre, the potential was close to zero, but it increased rapidly as potassium replaced sodium and reached a value of 40–50 mV. at an internal potassium concentration of 150 m*M*. A further rise from 150 to 600 m*M* potassium increased the resting potential by only 5–10 mV. as compared with the 35 mV. expected for a potassium electrode. This 'saturation' effect probably occurs because the permeability to potassium falls as the resting potential rises[5]. A similar hypothesis has been advanced to explain why the membrane potential ceases to behave like a potassium electrode at low external concentrations of potassium[6]. With isotonic potassium chloride outside the fibre and isotonic sodium chloride inside, the normal resting potential was reversed, the internal solution being 50–60 mV. positive to the external solution. The resting potential was close to zero if similar solutions were placed on both sides of the membrane.

The effects of varying the internal sodium concentration support the view that the action potential depends on a rise in permeability to sodium[5,7]. With sulphate as the internal anion, replacement of half the potassium by sodium caused little change in resting potential but decreased the action potential by 40–50 m*V*. Fig. 5 illustrates the effect of different concentrations of sodium ions on the action potential. From these and other records it appears that the membrane changes from a resting state, in which the permeability ratio $P_{\mathrm{Na}}/P_{\mathrm{K}}$ is about 0·1, to an active one in which $P_{\mathrm{Na}}/P_{\mathrm{K}}$ is 5–10.

The experiments described here raise the question of the extent to which the axoplasm is removed by extrusion and subsequent perfusion. Histological preparations showed that the volume of axoplasm in a perfused fibre was about 3 per cent of that in an intact fibre. A preliminary study of thin sections with the electron-microscope showed that the axon membrane and Schwann cell layer were present in perfused axons.

The general conclusion is that electrical changes in giant nerve fibres depend on differences of ionic concentration across the surface membrane and that the bulk of the axoplasm is not essential for the conduction of impulses.

We are indebted to Dr. J. S. Alexandrowicz for histological preparations, and to Dr. V. J. Howarth for help with the vapour-pressure measurements. Our thanks are also due to the Nuffield Foundation, the Medical Research Council, the Royal Society and the Wellcome Trust for financial support.

PARAPHENYLENEDIAMINE OXIDASE ACTIVITY AND COPPER-LEVELS IN MAMMALIAN PLASMAS

By P. J. McCOSKER

Department of Veterinary Clinical Studies, School of Veterinary Medicine, University of Cambridge

THE function and properties of the blue copper-protein cæruloplasmin have been the subject of much work since it was first isolated and purified from pig and human serum by Holmberg and Laurell[1] in 1948. Cæruloplasmin is an α_2-globulin containing 0·34 per cent of copper corresponding to 8 atoms of copper per molecule. The copper is very firmly bound to the protein, is non-dialysable and does not react with sodium diethyldithiocarbamate unless it has first been liberated by denaturation of the protein. Holmberg and Laurell[2] also showed that cæruloplasmin could oxidize *in vitro* a number of substances, including ascorbic acid, catechol, adrenaline and *p*-phenylenediamine (PPD), the latter being the best substrate. This PPD oxidase activity has been adopted as the basis of a number of methods for the estimation of cæruloplasmin in serum or plasma.

The concentration of cæruloplasmin oxidase activity in the serum has been shown to vary considerably in different clinical conditions in man; it is elevated in certain acute and chronic infections and in pregnancy, while it is usually depressed in Wilson's disease. A close correlation has been demonstrated between copper-levels in plasma and oxidase activity of the plasma of man[3] and rats[4].

Gubler and co-workers[5] have differentiated two fractions of plasma copper on the basis of their reaction with sodium diethyldithiocarbamate; these fractions were designated "direct reacting copper", in which the copper reacts directly with diethyldithiocarbamate, and "indirect reacting copper" in which the copper reacts with it only after acid deproteinization of the plasma. This indirectly reacting fraction of plasma copper, which is generally assumed to correspond to the cæruloplasmin copper, accounts for a different percentage of the total plasma copper in different species. Thus this fraction in man, rat, dog and pig represents 96, 99, 88 and 56 per cent respectively of the total plasma copper[5].

The object of the present work was to determine the copper-levels in plasma in several species of mammals including man, and to find to what extent

Table 1. Comparison of the Copper Content and *p*-Phenylenediamine Oxidase Activity of the Plasma of a Number of Mammalian Species

Species	No. of samples	Total plasma copper (μgm./ml.)	*p*-Phenylenediamine oxidase activity in 0·1 ml. plasma		
			Activity/ 0·1 ml.	Activity/ μgm. plasma total copper	Activity/ μgm. indirect-reacting copper
Man*	4	1·09	0·35	0·32	0·33
Pig†	9	2·20	0·92	0·42	0·73
Sheep†	10	1·09	0·12	0·11	0·14
Cattle†	10	0·99	0·12	0·13	0·17
Dog	1	1·12	0·15	0·14	0·16
Cat†	5	0·56	0·05	0·10	0·11

Plasma copper was estimated by the method of Gubler *et al.* (ref. 6) and oxidase activity by Ravin's method (ref. 7), in which results are expressed as E(1 cm., 530 mμ). Species in which a correlation between plasma copper and oxidase activity has been observed are marked * (ref. 3), † (McCosker, unpublished work). Oxidase activity/μgm indirect-reacting copper is calculated on the basis of the percentage of indirect-reacting copper of plasma.

the *p*-phenylenediamine oxidase activity of the plasma of different species could be correlated to the indirectly reacting fraction of the plasma copper. The results, which are summarized in Table 1, show that there are considerable species differences in the total copper-levels in plasma and in the *p*-phenylenediamine oxidase activity of the plasma when this is expressed either in terms of activity/0·1 ml. plasma (as used in Ravin's test[7]) or as activity/μgm. total plasma copper. If, however, the oxidase activity is expressed as activity/μgm. indirectly reacting copper, then we find that the species differences are even more marked and are in the order pig > man > cattle, dog, sheep and cat.

It has been assumed that the oxidase activity of the plasma of the different species of mammals (Table 1) is due to cæruloplasmin for the following reasons: (*a*) the oxidase activity observed is inhibited by sodium azide, (*b*) the oxidase activity is directly correlated with copper-levels in plasma over a wide range of copper values, and (*c*) variations in the oxidase activity and copper-levels in plasma in certain species (sheep, cattle and pig) are similar to those found in man; for example, these levels are elevated in acute infections in sheep and cattle.

To explain the marked differences obtained for the *p*-phenylenediamine oxidase activities/μgm. of indirect reacting copper of the plasmas of different mammals, which are in the order pig > man > cattle, dog, sheep and cat, we may consider three hypotheses which will then be discussed in detail: (1) the cæruloplasmin copper may correspond to the whole of the indirect reacting copper fraction, the species differences being due to enzyme activators or inhibitors characteristic to the particular plasma; (2) the cæruloplasmin may be of the same standard activity, but in different concentrations in each species; (3) the differences in activity may be a result of species differences in the copper–protein itself.

(1) The oxidase activity of purified cæruloplasmin is very sensitive to changes in *p*H, and to the concentrations of a number of different ions[8]. If the oxidase activity per molecule of purified cæruloplasmin were the same in all species, then the differences in activity encountered in the plasmas of various animals might be due to the presence of substances which either activate or inhibit the oxidase activity of the enzyme. Unfortunately, so far, only pig and human cæruloplasmin have been purified, and no comparative investigations of activity in terms of their copper contents have been carried out. Preliminary experiments in which the plasmas of sheep, pig and man were each dialysed extensively against water, failed to indicate the presence of any dialysable activator or inhibitor, while the oxidase activity of a mixture of equal proportions of plasma of two different species was that of the arithmetic mean of the activities of the two plasmas. The experiments therefore suggest that the activity of the enzyme in the plasma is not appreciably modified by a dialysable or non-dialysable substance characteristic of one plasma but not of the other.

(2) If the plasmas contain different concentrations of cæruloplasmin of uniform activity, then in the case of the pig, which has the highest oxidase activity observed so far, the cæruloplasmin might be assumed to account for the whole of the indirectly reacting copper fraction, whereas in man and other animals, which have a lower plasma oxidase activity, the cæruloplasmin copper would only account for a proportionally smaller percentage of the indirectly reacting copper. In these species one would have to postulate another copper-containing substance to account for the remainder of the indirect-reacting copper. As major changes in copper-levels in plasma under various physiological and pathological conditions are accompanied by proportional changes in *p*-phenylenediamine oxidase activity, this second copper-containing substance would have to change in concentration in the plasma at the same time and to the same extent as cæruloplasmin.

In the course of the purification of human cæruloplasmin by chromatographic methods, Curzon and Vallet[9] obtained a second protein peak with PPD oxidase activity. This fraction, which contained about 5 per cent of the eluted protein but only 2–3 per cent of the oxidase activity, was considered by them to be either "an active artefact" or a modified form of cæruloplasmin where the oxidase activity/protein ratio suggests that only half the active centres are functional. It is, however, unlikely that this small copper-containing fraction of lower activity could account for the species differences observed between the plasmas of man, pig and other animals, since in human plasma the oxidase activity/μgm. indirectly reacting copper is only about half that found in the pig, so that the second copper-containing substance postulated would have to account for about half the indirect reacting copper in man, and for an even greater proportion in other species, and yet be devoid of oxidase activity.

(3) From our present knowledge, it therefore appears that almost the whole of the indirect-reacting copper of the plasma is in the form of cæruloplasmin, and that the differences in oxidase activity observed in various animals are probably due to species differences in the copper–protein itself. That not all the 8 atoms of copper in the molecule of human cæruloplasmin have the same properties is indicated by the work of Scheinberg and Morell[10], who showed that in the presence of ascorbic acid only half the cæruloplasmin copper was exchangeable with copper-64, while Curzon[11] has shown that when human cæruloplasmin was digested with chymotrypsin, only 4 of the 8 atoms of copper became dialysable, the other 4 remaining in a core resistant to chymotrypsin.

Since, as is shown in Table 1, the PPD oxidase activity/μgm. indirect-reacting copper of the plasmas of different species which are in the order pig > man > cattle, dog, sheep and cat, bear an approximate ratio to each other of 8 : 4 : 2, and considering the evidence presented here that in human cæruloplasmin 4 of the copper atoms are more labile than the rest[10,11], it is tempting to suggest that the observed differences in *p*-phenylenediamine oxidase activity in the plasma of various mammals may be a reflexion of the number of catalytically active copper atoms in the molecule of the cæruloplasmin of each species.

I wish to thank Dr. J. Keilin for her advice and also the Animal Health Trust for a Junior Wellcome Fellowship.

PROTECTIVE ACTIVITY OF FRACTIONS OF TUBERCLE BACILLI AGAINST ISOLOGOUS TUMOURS IN MICE

By Dr. DAVID W. WEISS, ROSE S. BONHAG and Dr. KENNETH B. DeOME

Department of Bacteriology and Cancer Research Genetics Laboratory, University of California, Berkeley

TUBERCLE bacilli and some of their crude fractions have been reported to be capable of initiating a wide range of non-specific changes in the resistance of animals to infectious diseases[1]. Such changes are frequently found to be accompanied by a general enhancement of antibody responsiveness. They have also been shown to be associated with alterations in certain physiological processes believed to be concerned with other aspects of the clearing mechanisms by which micro-organisms as well as foreign, effete, and abnormal cells are removed from the tissues.

It was, therefore, thought of interest to determine whether the moieties of the tubercle bacillus which have proved most effective in eliciting non-specific anti-microbial immunity possess any tumour-inhibitory powers. It has already been reported that intact, living tubercle bacilli of the *BCG* strain retard the progress of several non-isologous cancers in mice[2]. In order to avoid the immunological artificialities inherent in the transplantation of homologous and heterologous tissues, or even of very old isologous ones, all the tumour transplants employed here were of fairly recent, isologous source.

The mice were of the *BALB/c Crgl* and the $C_3H/Crgl$ strains. The tumour tested in the former was a uterine sarcoma (*T*-66); those tested in the C_3H strain were two mammary carcinomas (*T*-32 and *T*-71), a hepatoma (*T*-46), and an osteogenic sarcoma (*T*-62). (The tumours are maintained in the tumour-bank of the Cancer Research Genetics Laboratory of the University of California in Berkeley; the *T* numbers refer to the tumour nomenclature used at the Laboratory.) The tubercle bacillus substances were the following: living *BCG* organisms; intact, phenol-killed and acetone-extracted *BCG*; and several methanolic extracts and their residues, obtained from the phenolized and acetone-treated bacilli. The preparation of these materials has been described elsewhere[3].

The experimental procedure was to subject groups of animals to a single intraperitoneal injection of different quantities of these substances, suspended in 0·5 c.c. saline. Control groups of saline-injected animals were included in every experiment. At different intervals after treatment, isologous tumours were transplanted subcutaneously into the animals by means of a trocar. The transplants consisted of pieces of tumour tissue approximately 0·5 mm.^{3} in size, and were placed on the right flank midway between the axilla and the last rib. Every attempt was made to ensure a maximum degree of sterility in the operation. The development of the tumours was followed by tri-weekly measurements of the two diameters evenly bisecting the palpable growths at right angles to each other.

The results obtained so far can be summarized as follows:

(1) Prophylactic effects of several types and of varying degree were exhibited by all the preparations tested, at certain dose-levels. Several of the non-living preparations were at least as effective as the living *BCG*, and in certain experimental circumstances more so.

(2) Several distinct types of protective effects were seen: an initial retardation of the onset of tumour development, followed by a normal rate of growth; a consistent reduction in the rate of growth; a total prevention of tumour development, with no traces of malignant growth found on autopsy of the animals killed several weeks or months after transplantation; a regression and disappearance of tumours after an initial period of development; an inhibition of metastatic spread; and a prolongation of life of animals which did develop massive tumours despite pre-treatment. Against some tumours only one, and against others several, of these manifestations of heightened resistance were displayed by the preparations.

(3) The dose of the materials was critical, the optimum quantities varying somewhat from one preparation to the next. On the whole, small quantities, of the order of 1·5 mgm., dry weight, or less, were most effective, thus paralleling the results obtained with these materials in protection experiments against heterologous bacterial infections. The optimum doses of the several vaccines differed somewhat *vis-à-vis* the various tumours. Excess quantities sometimes enhanced tumour development, even though the amounts were still considerably below the threshold of gross toxicity.

(4) The protection elicited by some of the preparations was as great, or greater, three months after

treatment as it was when only 2–4 weeks elapsed between vaccination and transplantation.

The results of four representative experiments are briefly shown here, in order to illustrate some of these findings:

Experiment 1. Groups of 7 *BALB/c* mice each were injected with one of the following substances: saline; living *BCG* grown for 7 days in liquid culture and then diluted ten-fold; 1·0 mgm. phenolized *BCG*; 1·0 mgm. of a methanolic extract obtained by extracting the organisms for 32 hr. (batch No. 1); 1·0 mgm. of an extract which went into the solvent between the 32nd and 82nd hr. of continuous extraction (batch No. 2); and 0·5 and 1·0 mgm., respectively, of a preparation of the exhaustively extracted residue. All animals received isotransplants of uterine sarcoma *T*-66 one month after vaccination. The number of animals which developed tumours, and the rate of growth of the cancers, are shown in Table 1.

Experiment 2. Groups of 10 C_3H mice each were vaccinated with the same materials described in Experiment 1. Isotransplantation with mammary carcinoma *T*-32 was performed one month later. The transplanted tumours grew in every animal, but differences were observed from group to group in the rate of growth. These are presented in Table 2.

* Product of bisecting diameters.
† Tumours grossly necrotic, experiment terminated.

Experiment 3. Groups of 8–10 *BALB/c* mice each were injected with saline; a 1 : 50 dilution of a living, 7-day-old liquid medium culture of *BCG*; or 1·5 mgm. phenolized *BCG*. Uterine sarcoma *T*-66 was transplanted into all animals three months later. It was found that the tumours placed into some of the animals regressed spontaneously after an initial period of development, while those of others progressed unchecked. These observations are illustrated in Table 3.

Experiment 4. Groups of 10 C_3H mice each received one of the following preparations: saline; 10-day-old living *BCG*, grown in liquid medium and then diluted 1 : 10; and 0·25 and 0·5 mgm., respectively, of the residue of a methanolic extraction. Four weeks later, isotransplants of osteogenic sarcoma *T*-62 were placed into the animals. The transplants grew progressively in most of the animals, but there were considerable differences in survival-time after transplantation. These are tabulated in Table 4.

These and related findings, as well as the observation that certain fractions of the tubercle bacillus possess the ability of retarding the development of already established cancers in mice, will be reported in detail elsewhere. It might be added that the protective activities of bacillary fractions against malignant tumours may bear some relation to the occasionally reported clinical and laboratory impressions that episodes of certain infectious diseases may have a beneficial influence on already-established cancers, or may reduce the likelihood of then cancer-free individuals developing neoplastic disease after recovery from the infection.

The present findings may also have some relevance for the more fundamental problem of why spontaneously arising tumours are able to grow progressively

in some individuals but not in others. Many aspects of the behaviour of malignant tumours in man and in experimental animals are consistent with the assumption that the ability of malignant cells to grow progressively in the animal body reflects a failure of the antibody or hypersensitivity-forming mechanisms, or of the phagocytic abilities of the reticulo-endothelial system[4]. Indeed, the idea has been advanced that the function of the homograft reaction is, primarily, to prevent the colonization of neoplastic cells in the normal individual[5]. Some support for this provocative suggestion comes from the clinical observations that individuals suffering from cancerous diseases show a poor ability to respond with hypersensitivity reactions to unrelated antigenic stimuli[6].

The firm establishment of an immunological theory of progressive malignancy depends, however, on the demonstration that the changes which cells undergo in the transition from normality to malignancy are accompanied by the acquisition of one or more new antigenic determinants. Largely because of the considerable technical difficulties encountered, this has not yet been shown unequivocally. It is possible, nevertheless, to secure further support for the immunological nature of the native defences against neoplastic growth and dissemination by a number of indirect approaches. The results of the present work might be taken to provide some such circumstantial evidence: If progressive neoplastic disease is, in fact, a manifestation of immunological deficiencies, it would be expected that substances which enhance both antibody production and the efficiency of the foreign body clearing reactions will also increase resistance to the development of malignant tumours. It appears that this expectation has been realized in the tumour systems which were the subject of this investigation.

This work was supported by grants from the United States Public Health Service (*E*-2309), the California Tuberculosis and Health Association, and the San Francisco Tuberculosis Association. We wish to acknowledge the assistance of Mrs. Judith Nelson and Miss Darlene Del Nero.

CHOICE OF ANIMALS FOR BIO-ASSAY

In marked contrast to earlier views, it is now generally accepted that, in naturally outbreeding organisms, F_1 hybrids between two inbred strains tend to show a lower level of phenotypic variability than do the parental inbred strains. The moral for the bio-assayist in search of uniformity of response, first pointed out by Mather[1], is that F_1 hybrids are, in general, to be preferred to inbreds. We have discussed this point in the course of a review[2] of methods of controlling variation in experimental animals.

The scope of the discussion has now been enlarged by C. K. Chai[3], who rightly points out that the variance of response is often not the only biometrical attribute which is of interest when assessing the suitability of a group of animals for bio-assay. In the case of quantitative (as opposed to all-or-none, or quantal) responses, the precision of the estimates is dependent not only on the variance, s^2, of the responses at a given dose, but also on the slope, b, of the dose-response line, which measures what Chai terms the 'sensitivity' of the animals.

This point was given quantitative expression thirty years ago by the introduction of λ, defined as s/b, as a suitable criterion for the comparison of the economic worth of various quantitative assay techniques for the estimation of a given substance. Thus for this type of assay it is not the absolute values of s and b which concern us, but their relative magnitude. The smaller the value of λ the more information will a given number of animals yield.

Chai also expounds the paradoxical, and potentially confusing, point that in 'quantal', or all-or-none assay the slope is merely an inverse reflexion of the variability of response, according to the relation $s^2 = 1/b^2$. It follows that no information on 'sensitivity' can be extracted from a quantal assay, and that the precision of the estimate is inversely related to the absolute value of b^2.

It is unfortunate that in the course of his further discussion of the question, Chai intermittently loses sight of these clear and valuable distinctions. The resulting confusion is such that the reader may gain an impression that the general superiority of F_1 hybrids over inbreds in respect of s^2 is in doubt. Such an impression is not justified by examination of the evidence presented by Chai. This falls into three main categories: (1) the results of a quantitative assay of testosterone, using the weights of seminal vesicles in castrated mice as the index of response: (2) the results of quantal assay of human chorionic gonadotrophin, using the percentage of immature female mice with hæmorrhagic ovarian follicles; and (3) a tabulation of published results concerning the responses of mice to hormones.

Response to testosterone. This assay was performed on the *C57BL/6* and *C57BR/cd* inbred strains and on the F_1 hybrids between them. Only animals were used the body-weight of which at weaning was in the range 9–12 gm. Although no doubt desirable for assay purposes, such a restriction renders the data of dubious value for a comparison of variation. As we have stated previously[2]: "Since the weight of the seminal vesicle is likely to be highly correlated with body weight, this restriction may have artificially brought the inbreds and F_1 hybrids being compared within the same range of variability".

The data given in Chai's Table 1 justify his conclusion that there are no differences between the inbreds and F_1 hybrids in sensitivity, measured as the slope, b, of the dose-response line. They do not justify the conclusion that the mice are equally suitable for use in the assay. The criterion for this is, as we have already said, the ratio s/b, where s^2 is the variance of response at a given dose. The relevant comparison cannot be made accurately from Chai's Table 1, since a scale has been used which makes the variances within each group grossly dependent on the value of the mean. However, inspection of the values suggests that s^2, and therefore λ also, would prove to be less for the F_1's than for the inbreds.

The hybrid mice would, therefore, be more efficient than the inbreds for the assay of testosterone. Chai reproduces in his Fig. 2 dose-response curves for another pair of inbred strains and their F_1 hybrids from an earlier publication on the same assay. Unfortunately, even from his published numerical data it is impossible to estimate λ; and the statistical manipulation of the data by which he obtained Fig. 2 is totally misleading, since λ must be computed in the scale in which the validity requirements are satisfied.

Response to chorionic gonadotrophins. In assessing the results of this experiment, we shall follow Chai's textual statement that the dependent variate was the percentage of animals with hæmorrhagic ovarian follicles, and not, as stated in the legend to Table 2, the percentage of follicles. The assay is quantal, and consequently irrelevant to the context in which Chai places it, namely, differences in sensitivity. As will be recalled, in contrast to the case of quantitative assay, the slope of the dose-response line in a quantal assay yields no information on sensitivity, but is an inverse measure of variability. Interpreting in this sense Chai's values for b, we find a four-fold difference in variance between the two parental inbred strains, with the F_1 closely resembling the less variable of the two. For all five groups of mice used, the values of the slopes are very low (0·62–1·27), and although the crucial information on their standard errors is not given, it seems likely that the five estimates of slope are not, in fact, significantly different.

Tabulation of published assay results. Chai's compilation is stated to refer to "sensitivity or magnitude of response", the latter being a measure of sensitivity on the assumption that the dose-response line passes through the origin. Several quantal assays appear in his Table 2, although, as has been stated, such assays yield no information on sensitivity. (The results of Claringbold and Biggers shown in Chai's Table 2 are only partially quoted, some in error. They compared both œstrone and œstradiol-3 : 17β (not œstrone-3 : 17β, an impossible compound) by both intravaginal and subcutaneous routes of administration. Only half these results are quoted—œstrone (intravaginal) and œstradiol-3 : 17β (subcutaneous)—and in the line incorrectly labelled œstrone-3 : 17β one inbred strain (*C57*) is omitted.) If we omit the quantal assays, and further confine our attention to relevant comparisons (that is, between F_1's and their parental strains), we are left with thirteen cases. In seven the hybrids are intermediate in "sensitivity or magnitude of response", in two they resemble the superior of the two parental strains and in four they are superior to both parental strains. Surprisingly, Chai bases on this result the generalization that "F_1 hybrids are not, in general, preferable to inbred mice in hormone assay in so far as the b value is concerned". A more illuminating formulation might be that, since they are apparently not inferior in this respect (and may even prove, on average, to be superior), their known tendency towards lower variability justifies the conclusion of earlier writers that F_1's are, as a rule, preferable to inbreds for bio-assay.

It is likewise indisputable that, "For the assay of a given substance, the choice of assay animal—either an inbred or an F_1 hybrid—cannot be made in advance; it has to be based either on existing data or determined experimentally". But our contention has been, and is now, that existing data sufficiently establish a generalization which can serve as a useful, although by no means an absolute, guide to the choice of experimental material. Chai's emphasis on the empirical approach is very welcome. It does not, however, gain in effectiveness if the known facts in this field are made to appear more arbitrary and unaccountable than they really are.

A word remains to be said about the position of random-bred animals. In 1939, Emmens showed that a random-bred colony of mice was less variable in response to œstrogen than an inbred strain (Strong's *CBA*). (He did not show, as Chai reports, "that some F_1 hybrid mice were less variable in response to œstrogen than their inbred parental strains".) Other relevant tests on random-bred animals are listed in our review. Chai misquotes us as concluding that random-bred strains are more uniform than inbreds. Our actual statement[2] was ". . . unlike the comparison with F_1 hybrids, no general law can be asserted on the comparison of inbred strains with random-bred stocks". This still holds to-day. Moreover, even in animal colonies primarily concerned with bio-assay, uniformity and sensitivity are not the only criteria that matter. If a 'mouse efficiency unit' were defined so as to include the economics of fecundity, viability and growth, there are many bio-assays for which a healthy and prolific random-bred strain might provide the most economical answer.

[3] Chai, C. K., *Nature*, **185**, 514 (1960).

Drs. J. D. Biggers, A. McLaren and D. Michie have commented on my article, "Response of Inbred and F_1 Hybrid Mice to Hormones", published in *Nature* of February 20, p. 514. The first of their comments supports my view that, in evaluating information of an animal in quantitative bio-assay, the slope of the dose-response curve needs to be considered. Some of their other comments, however, seem to be not much concerned with a choice between inbred and F_1 hybrid animals in bio-assay. Although I do not believe that clarification of the points which they have criticized will contribute much to the real issue at hand, I wish to make a brief defence of my position on these points. Following this I will discuss the unjustification of their conclusions.

Sensitivity. I have applied the basic principles determining the best measure of response in bio-assay as they were outlined by Gaddum and fully illustrated later by other biometricians in evaluating the bio-assay information obtainable in an animal experiment. It is necessary to draw a clear distinction between quantal and quantitative assays in terms of the importance of b. The papers published by Drs. Biggers, McLaren and Michie concerning information of an assay animal have been merely concerned with variation, and I do not think there is any need for them to restate the history of the statistics concerned. The qualitative experimental assays given in my article apply to the variance based on the relationship of $b^2 = 1/s^2$. I purposely avoided a discussion of variation in such assays and considered mainly the sensitivity measured by the slope of the dose-response curve. I do not believe that my presentation in this manner has caused confusion to readers. It may appear to be confusing to Biggers *et al.* because they have the impression that inbreds are more variable than F_1 hybrids in biological responses.

Androgen experiments. My presentation of the testosterone experiments was mainly to illustrate the point that the F_1 hybrids are not 'necessarily' more sensitive than inbreds as measured by the slope of the response curve. It is likely, when the sensitivity values of the parents differ widely, that the value of the F_1 hybrid will fall between them because of additive effects of polygenes. When the values of the parental strains are similar in sensitivity to a given stimulus, the values of the F_1 hybrids may be either greater, smaller or similar to the parental strains, depending on the degree of dominance, genic and gene-environment interactions. I used the *BALB/c*, *A/Jax* experimental results to illustrate the former case and the experiment with *C57* strains to illustrate the latter. I had no intention of concluding that inbreds or F_1 hybrids were more sensitive one than the other, but rather wished to give a possible interpretation of the results based on the polygenic theory of inheritance.

I did not transform the response to render the variance independent of the means as I was not concerned with variation, but simply gave the actual means and variances for the sole purpose of plotting the means. Crude as my method may have been, I think I illustrated my point by comparing the slopes. In the experiment using *BALB/c* and *A/Jax* mice, I tried many different transformations of the responses; the logarithmic transformation gave the best results although it was not fully satisfactory. Finney, in his *Statistical Method in Biological Assay*, p. 76, has pointed out that "In practice, slight heterogeneity of variance will not affect the statistical analysis very much, and a transformation that is approximately correct will be adequate . . .". In concordance with this statement, I used only the means in the comparison of bio-assay information between the inbred and hybrid mice. Also, there were no indications, from glancing at the variances, that the F_1 hybrids were less variable than the inbreds.

I judge from their criticism of my use of mice within a limited range of body-weights that Drs. Biggers, McLaren and Michie have confused 'normal variation' with 'variation in response to stimulus'. I used mice within a given range of body-weight as an aid in adjusting dosage of hormone, and to eliminate the need for correcting for differences of body-weight in the analysis of the data. Should the smaller variation in response of the F_1 hybrids be due merely to their being more uniform in body-weight, the increased variance in response could be corrected statistically. It is more likely that the differences in variation, if any, are a reflexion of physiological regulating abilities, which are, in turn, a reflexion of genetic-environment interaction.

Gonadotropin experiment and tabulations of published results. The comments concerning my experiment on response to gonadotropin and my tabulation of published data do not contradict my interpretation and conclusion that F_1 hybrids are not 'necessarily' more sensitive than inbreds. Furthermore, there seems to be no theoretical basis for them to be so.

It is mentioned that I quoted only half the results of Claringbold and Biggers. I did this because, in both their methods of administration of œstrogen, the relative order of response of inbred and F_1 hybrids was the same. I did mis-state Emmens's conclusions, and appreciate Drs. Biggers, McLaren and Michie's correction. However, I neither misquote nor mis-state the conclusion of Drs. McLaren and Michie, who have stated: " . . . On the contrary, the published facts suggest that inbred strains are usually more variable than inter-strain hybrids, with random-bred colonies occupying an intermediate position" (*J. Genetics*, 54, No. 3, p. 454). This obviously means that random-bred animals are less variable than inbreds. Dr. Biggers *et al.* pointed out that the name of the œstrogen was incorrectly cited from their paper and the title of Table 2 of my communication published in *Nature* was not clear. I sincerely regret this carelessness.

Unjustification. Drs. Biggers, McLaren and Michie draw their conclusions without considering the importance of the 'slope' of the dose-response curve in quantitative assay; they relied on 'variation' alone. They cited thirteen papers (*Nature*, 182, 77; 1958), including experiments using such animals as mouse, fowl and *Drosophila* for making comparisons between F_1 hybrids and inbreds. Among these thirteen papers only three dealt with biological responses: one, my paper on response to androgen, one by McLaren and Michie on the response to 'Nembutal', and the other by Claringbold and Biggers on the response to œstrogen. I have discussed my paper above and omit further discussion of it here. In the 'Nembutal' experiments (McLaren, A., and Michie, D., *J. Genetics*, 54, 440; 1956) the authors tested inbreds, F_1 hybrids and 'Mousery' mice (random-bred) by giving the drug to the same mice on days 1, 2, 3, 8, 9 and 10, and to 'fresh mice' on day 10. They observed the response each day, but only day 1 and day 10 'fresh mice' data were used for analysis.

The remaining five days records were omitted from analysis. I calculated the variances using the data which they excluded and found the combined variances (with the degrees of freedom in parentheses) to be: 0·0346 (45) for *C57BL*; 0·0849 (43) for *C3H*; 0·0396 (44) for the F_1 hybrid; and 0·0213 (44) for 'Mousery' animals. The variance for the F_1 hybrid is smaller than that for the *C3H* strain, but greater than that for *C57BL*, although not statistically significant. The variance for the 'Mousery' mice appears to be the smallest among them. The relative order is obviously different from that which they obtained (estimate of variance: 0·0552 for *C57BL*; 0·0778 for *C3H*; 0·0165 for F_1 hybrids; and 0·0176 for 'Mousery') based on two-days records. However, perhaps their selection of data was due to their lack of understanding of the biological nature of the experiment.

The other ten papers cited by Biggers, McLaren and Michie dealt with normal variation and not with variation of biological responses. Such data might be a basis for speculation, but could not be 'definitive' evidence for conclusions about biological responses. There seems to be a lack of distinction between normal variation and biological response.

It is clear that at the present time no one has sufficient amounts of critical evidence for the generalization which these investigators have made. It is true that Mather suggested the possibility of using F_1 hybrids in bio-assay, and Lerner pointed out that heterozygotes have better self-regulating ability than homozygotes. Moreover, I believe that under ordinary environmental conditions and without treatment, the F_1 hybrids may be more homogeneous in morphological traits than inbreds, but to equate this morphological homogeneity with response to chemical or biological stimuli requires further experimental evidence.

It is well established that there are species differences in sensitivity and that, in bio-assay, preference is given to certain species for certain assays; for example, metamorphosis in the tadpole for assay of thyroid hormone; comb-growth of chicken for androgen; crop-gland secretion of pigeon for lactogenic hormone; and uterus growth in mice for œstrogen. I believe that there are differences also in sensitivity between races, breeds and strains within species as well. Indeed, some differences have been shown to exist between mouse strains, as already illustrated in my article in *Nature*, 185, 514; 1960. Inbred strains can be very useful for assays of certain substances. This has been well illustrated and discussed by Becker and Berg (*Poultry Sci.*, 38, 362) in a paper in which they compared inbred and hybrid chickens in high and low planes of nutrition.

Finally, I reiterate that I do not underestimate the potentiality of F_1 hybrids for use in bio-assays. It has been claimed that the heterozygotes are better 'buffered' than the homozygotes, but differences between them in the mechanisms of reactivity are poorly understood. Our understanding of genetic pathways in the polygenic systems are practically nil, and reliable data from comparisons in bio-assay values between inbreds and F_1 hybrids are limited. Assay substances from synthetic and biological sources are numerous, and their end-points in assay vary widely from physiological and morphological measurements to rates of survival. In these circumstances, it seems wise to use an empirical approach, as I have, rather than to draw conclusions which might mislead the experimenter into believing that there is more evidence available for his making a choice of animal material than actually exists.

C. K. CHAI

Roscoe B. Jackson Memorial Laboratory,
Bar Harbor, Maine,
U.S.A.

Dr. Chai has now raised a criticism of an earlier paper of ours (*J. Genet.*, 54, 440; 1956). As explained in the paper in question, estimates of variance of response derived from animals which have acquired a degree of resistance through previous exposure to the drug have no simple interpretation. Our "selection of data" consisted of using only estimates of variance derived from mice not previously exposed to the drug. Furthermore, it is not statistically legitimate to pool variance estimates, as Chai has done, when the estimates are derived from the same mice on different occasions and when the responses on different occasions are correlated. As for Chai's distinction between "variation of biological responses" and "normal variation", in so far as these two categories can usefully be distinguished, it is not easy to see why they should not be subject to the same underlying mechanisms of genetic and developmental homœostasis. We have discussed these matters more fully elsewhere (*New Biol.*, 19, 48; 1955).

DONALD MICHIE

Department of Surgical Science,
University of Edinburgh.

Development of resistance to drugs, particularly those affecting the central nervous system, is well known. The analysis which Drs. McLaren and Michie made, testing the significance of this, was not convincing, for their interpretation (that response to 'Nembutal' is affected by previous dose) was based on only part of their results. The primary concern in pooling or comparing variances of different groups should be that the variance is independent of the mean, not that there was, or was not, previous exposure to the drug. McLaren and Michie used the logarithmic scale for correcting the dependence of the variance on the mean. This transformation was not adequate, as they themselves stated, ". . . this applies too strong a correction and results in a negative correlation between variance and mean". When I analysed their results, I noticed that they pooled the variance-estimate in the two-day tests and compared the variances without considering that the means were different and the transformation not adequate. Transformation of data for biological responses is often a troublesome matter and it is difficult to obtain an adequate scale. I reiterate that although "variation of biological response" and "normal variation" may be subject to the same underlying genetic and developmental mechanisms, further experimental evidence is necessary before this can be accepted as fact. Furthermore, there is little information available regarding differences in variability between inbred and F_1 hybrids in characters which have different evolutional significance. Speculation with regard to homœostasis, a concept which is theoretical and controversial, should not be substituted for proof.

LETTERS TO THE EDITORS

ASTRONOMY

Origin of Jupiter's Great Red Spot

THE Great Red Spot in the southern hemisphere of Jupiter's otherwise ever-changing surface of dense cloud has baffled astronomers for many years[1,2]. The purpose of this communication is to outline the results of elementary dynamical and hydrodynamical considerations which suggest a straightforward explanation of the phenomenon. Contrary to generally accepted views[3], the non-uniform rotation of the Great Red Spot does *not* rule out the possibility that its origin is in the 'solid planet'; I believe that quite a shallow 'topographical feature' of the surface of the 'solid planet' could account for the observations. The theory should be amenable to further observational tests, and an experiment is now in hand to check the chief theoretical argument on which it is based.

The mean radius of Jupiter is about 70,000 km. The Great Red Spot, which is elliptical in shape, having its long axis along zenocentric latitude 22° S., occupies 30° of longitude and 10° of latitude. According to observations of the motion of markings on Jupiter's visible surface[2], which go back more than a century, the rotation of this surface about the axis of the planet is non-uniform, being a complicated function of latitude which is unsymmetrical about the equator. The period of rotation of the equatorial zone is 5 min. less than that of other regions, and astronomers find it convenient to refer to the more rapidly rotating part of the disk as System I and the other parts as System II. Their average periods with respect to position and time are, respectively, 9h. 50m. 30s. and 9h. 55m. 40s. In System II, spatial variations of the mean period with respect to time range from 9h. 55m. 5s. to 9h. 55m. 54s. As regards variations in time of the rotation periods in System II, these are erratic and have a range from ±5 sec. to ±10 sec. depending on position on the disk. Within System I, the equatorial zone, the rotation is most rapid roughly on the equator itself. Temporal fluctuations in period over a range ±15 sec. are indicated by the observations.

During the past hundred years or so, the period of the Great Red Spot has varied between 9h. 55m. 31s. and 9h. 55m. 44s., the average value being 9h. 55m. 38s.; the corresponding amplitude of this drift in longitude with respect to the mean motion is 1,080°, and on the present hypothesis the motion of the Spot is also that of the 'solid planet'. The average (with respect to position) period of the South Tropical Zone, in which the Spot is embedded, has varied between 9h. 55m. 27s. and 9h. 55m. 36s. The corresponding average linear velocity of the South Tropical Zone with respect to the Spot is about + 2 m./sec., the positive sign indicating that this motion is in an eastward (westerly) direction. Points on the equator rotate about the axis of the planet at 12 km./sec.

The mean density of Jupiter is 1·34 gm./cm.^{3}. According to Wildt's theoretical model[4,8], the atmosphere has a depth d (say) of 12,000 km. and a mean density of 0·35 gm./cm.^{3}. The corresponding moment of inertia of the atmosphere about the rotation axis exceeds 0·2 of that of the whole planet. Assuming that the motions of the visible surface are representative of the flow at lower levels (and this assumption has some theoretical backing) it is possible to estimate the order of magnitude of temporal fluctuations in the angular momentum of the atmosphere. This turns out to be comparable with the fluctuations of the angular momentum of the 'solid planet' as evinced, on my hypothesis, by the motion in longitude of the Great Red Spot, and it follows therefore that transfer of angular momentum between atmosphere and 'solid planet' might account for this motion. Evidently, Jupiter's 'day' is subject to quite large variations, probably due to meteorological causes.

The variation of latitude of the Great Red Spot expected on the present model is utterly negligible, and this accords well with observation.

Hydrodynamical theory suggests that Jupiter rotates so rapidly that the effect on the general circulation of the atmosphere of quite a shallow 'topographical feature' of the 'solid planet' will be attenuated very slowly with height, and thus the 'feature' will make its presence manifest at the level of heavy cloud at the top of the atmosphere. Specifically, the atmospheric flow cannot surmount the 'feature' if h, the height of the 'feature' above (or depth below) the general level, exceeds:

$$h_c \equiv \alpha d(U/L\,\Omega) \qquad (1)$$

where α is a number of order unity, U is a characteristic wind speed in the vicinity of the 'feature', L is a typical horizontal dimension of the 'feature' and Ω is the angular speed of rotation of the solid planet. When this criterion is satisfied, there will be a stagnant column of fluid stretching, not necessarily in a vertical direction, from the 'topographical feature' at the bottom of the atmosphere all the way to the top of the atmosphere. This column of fluid will partake of the motion of the 'topographical feature' and virtually no mixing will occur between the fluid within the column and that without. Although effects of this kind were predicted and demonstrated long ago by Sir Geoffrey Taylor[5], the foregoing criterion for 'Taylor columns' to occur is only based on crude theoretical arguments of my own. The criterion is now being tested in my laboratory.

If L = 25,000 km., d = 12,000 km., U = 2 m./sec. and $\Omega = 1{\cdot}5 \times 10^{-4}$ rad./sec., according to equation (1), h_c = 6 km. Although geometrically shallow, stresses in the 'solid planet' due to the presence of a 'topographical feature' having this height would exceed 10^8 dynes/cm.^{2}. If the 'feature' cannot be supported elastically, it may be necessary to invoke slow convection in the 'solid planet' to account for it, assuming that to forces of slow period the 'solid' is really a very viscous liquid. The coefficient of viscosity of the 'solid' would then have to exceed 10^{19} gm. cm.$^{-1}$ sec.$^{-1}$.

Equation (1), which shows h_c is *inversely* proportional to L, suggests a possible explanation of the uniqueness of the Great Red Spot, for if there were no ‘topographical feature’ having L in excess of 40,000 km. and h nowhere substantially exceeding the critical value for the Spot, other ‘topographical features’ would only produce spots on those occasions when U has a sufficiently low value. This appears to be borne out by the occasional appearance of short-lived spots, slightly smaller than the more permanent Great Red Spot, and it will be of importance to scrutinize the observations more closely in this connexion. It is not permissible to apply equation (1) to very shallow ‘topographical features’, because then friction has to be taken into account.

Considerations of the atmospheric flow around the hypothetical column of fluid underlying the Great Red Spot account for the presence of the Red Spot Hollow[2] on the equator-ward side of the Spot and for the bizarre nature of the interaction of the Spot with the South Tropical Disturbance[2]. Atmospheric turbulence resulting from the presence of this column will be most intense on the poleward side of the column, and this may bear on the interpretation of radio astronomical observations of Jupiter[6,7]. Recently, bursts of radio noise have been reported, and the electromagnetic energy in a typical burst estimated at about 10^{18} ergs. As the kinetic energy of a typical turbulent eddy in Jupiter's atmosphere (about 10^{24} ergs) is several orders of magnitude bigger than this, one wonders whether radio bursts are due to lightning flashes associated with thunderstorm activity, or to strong interaction between this turbulence and Jupiter's ionosphere.

ASTROPHYSICS

Anomalies in the Light Curves of Meteors resulting from Fragmentation

IN one of a series of papers on the physical theory of meteors, Jacchia[1] has pointed out that while the observed decelerations and light curves of bright meteors are in good agreement with the simple ballistic theory, the fainter meteors photographed with the Baker Super Schmidt cameras show startling anomalies. He has adduced evidence to show that the theory of progressive fragmentation of the meteoroid offers a simple explanation of the observed anomalies.

In a recent communication[2], I have shown that the observed light curves of a random sample of 360 meteors studied by Hawkins and Southworth[3] suggest that the luminous efficiency factor τ in the luminosity equation for meteors has to be regarded as a variable along the trail of an individual meteor and proportional to the atmospheric density ρ at every point of the trail. It was shown that the normalized light curve, when the theory is thus modified, fits better with observational data than the corresponding curve of the conventional theory. For a single-body meteoroid, if we denote by α and β the height-intervals from the level maximum luminosity (corresponding to stellar magnitude $M_{\max.}$) to levels of equal luminosity (corresponding to stellar magnitude M) on the ascending and descending branches of the light curve, then the ratio $\alpha/(\alpha + \beta)$ is related to $M - M_{\max.} = \Delta M$. For a given value of ΔM, the values of this ratio as given by the conventional and modified theories are nearly the same as can be seen from Table 1.

Table 1

ΔM	$\alpha/(\alpha+\beta)$		ΔM	$\alpha/(\alpha+\beta)$	
	Conventional theory	Modified theory		Conventional theory	Modified theory
0·5	0·631	0·613	4·0	0·814	0·798
1·0	0·680	0·663	4·5	0·827	0·813
1·5	0·713	0·691	5·0	0·839	0·827
2·0	0·737	0·720	6·0	0·858	0·846
2·5	0·761	0·747	7·0	0·871	0·861
3·0	0·782	0·769	8·0	0·883	0·873
3·5	0·799	0·788			

I directed attention to the fact that, according to the single-body theory, the height-interval from the level of maximum luminosity to the level of complete ablation is independent of the mass of the meteoroid and is uniquely related to the scale-height a of the atmosphere, being equal to $1 \cdot 1a$ according to the conventional theory and $0 \cdot 7a$ according to the modified theory. The effect of fragmentation on the light curve is, in general, to shorten the ascending part of the curve (α), and, in a good many cases, to lengthen the descending part of the curve (β). Without going into details, it may be mentioned that the ratio $\alpha/(\alpha + \beta)$ will decrease from the theoretical value as a result of fragmentation. I have therefore made use of this parameter as a rough index to study the behaviour of the 360 meteors listed by Hawkins and Southworth. The value of the ratio is found to be less than 0·6 for nearly two-thirds of the meteors. Rejecting these, the values of α and β for the remaining meteors are plotted in Fig. 1 against the appropriate values of ΔM. By this process of selection, I have eliminated the large majority of the fragmented meteors, so that the behaviour of the light curves of those remaining may be expected to show a close

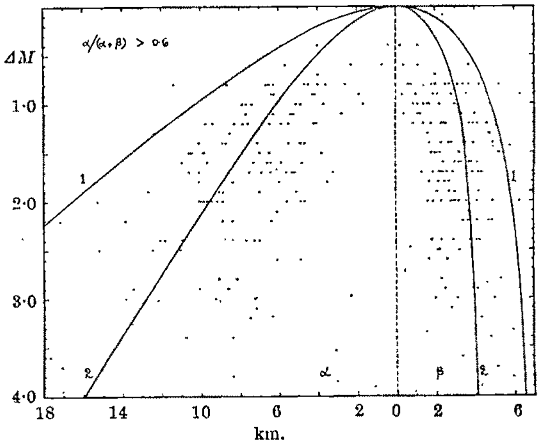

Fig. 1

degree of approximation to the theoretical light curve. Curves 1 and 2 in Fig. 1 are the normalized light curves according to the conventional and modified theories for a scale-height value of $a = 6\cdot38$ km. It is clearly seen that the observational data are in accord with the light curve 2 of the modified theory.

To study the behaviour of meteors brighter than those in the random sample of Hawkins and Southworth, I have examined the data of 144 meteors listed by Whipple[4]. Whereas less than 3 per cent of the meteors in the random sample had the end-points of their trails below 75 km., nearly 50 per cent of Whipple's meteors had their trails ending between 75 and 40 km. For about a third of these meteors the ratio $\alpha/(\alpha + \beta)$ was found to be less than 0·6. Rejecting these, and plotting the data of the remaining meteors in a manner similar to that of Fig. 1, it is found that the light curves of the brighter meteors too are in better conformity with the normalized light curve of the modified theory than with that of the conventional theory.

The Draconid shower meteors of October 1946 gave, for the first time, the clearest indication of the need to revise the concept of the single-body meteoroid, and to replace it with the concept of the meteoroid being 'a cluster of breaking fragments' (refs. 1 and 5). The data relating to these meteors taken from the paper of Jacchia, Kopal and Millman[6] have been plotted in Fig. 2. Comparison of Figs. 1 and 2 brings out strikingly the effect of fragmentation on the light curves of meteors.

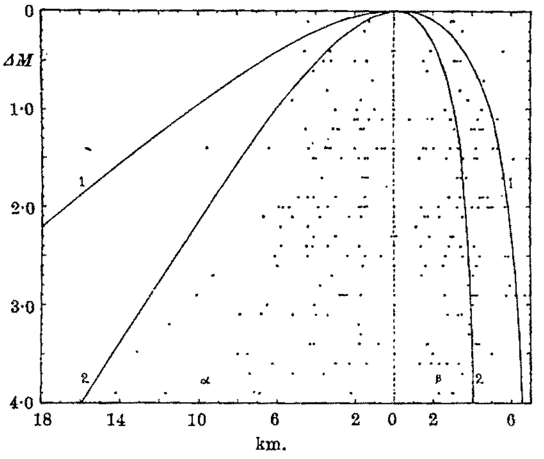

Fig. 2. Draconid shower meteors (Jacchia, Kopal and Millman)

For the luminous efficiency factor τ in the luminosity equation for meteors, Whipple derived the relation:

$$\log \tau = \log \tau_0 + \log v = -9\cdot07 + \log v$$

where v is velocity of the meteor in cm./sec. It is significant to note that the value of $\log \rho$ at 100 km. for the Rocket Panel Atmosphere (1952) is $-9\cdot065$, which is practically equal to $\log \tau_0$ in Whipple's equation. It is also of interest to note that the mean value of $\log \rho$ between 120 km. and 80 km. for the Rocket Panel Atmosphere is $-9\cdot02$. Whipple's equation is, therefore, very nearly equivalent to:

$$\tau = \tau_0 v \sim \bar{\rho} v$$

where $\bar{\rho}$ is the atmospheric density at 100 km. or the mean atmospheric density between 120 and 80 km. The observational data relating to light curves of meteors are in better accord with the relation:

$$\tau \propto \rho v$$

where ρ is a variable along the meteor trail.

Nanometeorites

THIS communication is a preliminary report of our work on a high-altitude airborne particle collection obtained in the Arctic on November 15, 1960. The collector was exposed from a *U*-2 aircraft at an altitude of 60,000 ft. at longitude 144° W. and at latitudes ranging from 71° to 73° N. for a duration of 366 min.

The particle collector was of an impact type which could simultaneously expose four collection surfaces each with a different effective collection area and consequently different particle-size cut-offs. The smallest particles which could be individually collected were approximately 0·2μ in diameter. The particles were collected directly on high-purity 'Formvar' films approximately 70 Å. thick supported by 200 mesh/in. copper screening. The exposed screens were examined by electron microscopy without any chemical treatment after exposure. The moving and exposed parts of the collector were either coated with 'Teflon' or constructed from 'Teflon' to eliminate the need for lubrication for de-icing.

Examination of the exposed samples revealed enormous numbers of ultra-small, high-density particles of the order of 75 Å. in size in addition to the solid and 'fluffy' particles larger than 0·2μ normally seen in previous high-altitude collections at lower latitudes.

Fig. 1 shows an electron micrograph of a portion of a cluster of these ultra-small particles, a 0·1μ scale and unresolved background material with some holes from which very small spherical particles appear to have evaporated. Table 1 shows approximate particle-size distributions for these high-density spherical particles and for some ultra-small irregular particles which were also found.

These extremely small particles and the background material have also been studied by selected-area electron diffraction. The high-density spherical particles have given diffraction patterns indicating

Table 1

Diameter size-range (Å.)	No. of small spherical particles per size-range	No. of irregular solid particles per size-range
0–50	1.092	107
50–100	735	137
100–150	256	145
150–200	72	127
200–250	16	57
250–300	2	10
300–350	—	3
350–400	—	1

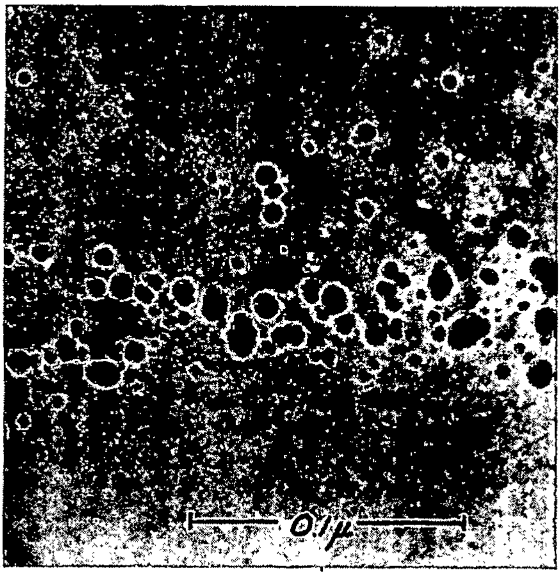

Fig. 1

compositions of nickel monoxide and also of taenite. The background material and the irregular particles appear to be partly nickel monoxide and ferric oxide.

The following additional comments concerning these ultra-small particles are appropriate:

(1) They are always found clustered, suggesting that at the altitude of collection they were within a larger particle which has afterwards evaporated, probably under electron-beam bombardment in the electron microscope.

(2) The small spherical type and the background material have been occasionally detected by us in other high-altitude aircraft collections and in balloon collections during the past four years.

(3) This collection was made during a period of unusual solar activity in the auroral zone. Major solar flares were observed on November 12 and November 15, 1960.

(4) The ultra-small particles appear to be about 100,000 times more numerous than particles 0·2μ in size or larger.

(5) The four simultaneously exposed collection areas showed an approximately correct decrease in particle numbers per unit area with an increase in collection aperture and particle-size cut-off, indicating freedom from contamination of samples.

(6) Previous high-altitude collections at lower latitudes have indicated that, at altitudes greater than 50,000 ft., one is substantially free of contamination by terrestrial particles and that numbers of particles collected are roughly proportional to duration of exposure.

We feel that the evidence is strong for the existence of a previously unsuspected class of meteoric bodies entering the Earth's atmosphere. Since these ultra-small bodies are approximately a thousand times smaller in diameter than the expected sizes of micrometeorites, and since the forces acting on them are likely to be critically dependent on their electrical charge and velocity in the Earth's ionosphere and magnetic field, we propose, for convenience, to label these ultra-small particles nanometeorites.

Nanometeorites may in part result from meteorite ablation, or meteor fragmentation. We are inclined, at present, to favour a lunar dust origin for these particles. A full report on nanometeorites will be published at a later time.

We wish to thank Mr. Herbert Cohen and Mr. Joseph Frissora, of the Space Instrumentation Division of the Technology Instruments Corporation of Acton, Mass., for the design and construction of this particle collector, and Dr. James Friend, of Isotopes, Inc., at Westwood, New Jersey, for arranging to have this collector flown for us by the Armed Forces Special Weapons Agency.

This work was sponsored by the Geophysics Research Directorate of the Air Force Cambridge Research Laboratory, under contract *AF* 19(604)–5884.

GEOPHYSICS

Possible Identification of Atmospheric Waves associated with Ionospheric Storms

It has been noticed that ionospheric storm effects are not simultaneous at polar and more temperate regions. The purpose of this communication is to present the results of an inquiry into the nature of travel of these storms.

Mason[1] has described the general properties of night-time storms at Christchurch, and has noticed that one class of storm has relatively simple characteristics. These were storms with magnetic sudden commencement followed by easily identifiable storm features in the ionosphere. The latter were characterized by rise in virtual height of *F* layer and drop in critical frequency often accompanied by oblique echoes and enhanced *E* layer ionization. Such storms were chosen for study as they gave the least ambiguous effects.

Night-time ionograms were studied at Christchurch (43° 34′ S., 172° 48′ E.) and at Campbell Island (52° 33′ S., 169° 09′ E.) in order to measure the northward component of any travelling phenomena. Periods immediately preceding and following a local night-time magnetic sudden commencement with *K*-index disturbance of 5 or more, during July 1957–February 1961, were used. These times included the eighteen months of the International Geophysical Year, during which the standard of recording was particularly suited to the project. The criteria of an ionospheric storm were a sudden drop in the critical frequencies and a rise in virtual height of the *F* layer, and other features—oblique echoes, retardation of extraordinary ray, and night *E*—noted. The first rise in virtual height of the *F* layer was taken as the onset of the storm, though the changes in height were usually more extreme at Campbell Island than at Godley Head.

32 storms in all were studied; but for the following reasons 24 were discarded: (*a*) 7 were discarded as their onset-time was obscured by continuing effects of earlier storms; (*b*) 8 were discarded because sunrise occurred before storm onset; (*c*) 4 were discarded as onset at Campbell Island was obscured by polar cap absorption; (*d*) 5 were discarded as no storm developed at Christchurch.

The remaining 8 storms were considered sufficiently reliable to measure the apparent velocity between

these two stations. With ionograms taken only at certain fixed times, the velocity may only be stated between limits. Table 1 gives the list of storms with sudden commencement times, followed by onset times at Campbell Island and Christchurch. The spherical distance between these two stations was 1,105 km. at a height of 150 km., and using these data the velocity limits were calculated.

The K-index first used was that describing the maximum disturbance period in the course of the magnetic storm, but for this work, the K-index for the actual period involved from sudden commencement until storm onset was more appropriate. These figures were more consistent with a correlation between delay time and magnetic activity, the event on July 8, 1958, having greatest activity and least delay until storm onset. As the K-index figures were only available for successive 3-hr. periods daily they are still not a sufficiently accurate measure for detailed work of this nature.

In several cases the readings from ionograms were taken from 15-min. records, giving correspondingly wider limits to the observed velocity.

It is obvious from Table 1 that the northward component of apparent velocity is well defined and, as this is also the most probable direction for any storm effects originating in the polar or auroral regions, this will be taken as the apparent velocity.

From the results it is suggested that this velocity is that of a neutral gaseous wave, being of the same order as that found for the limiting velocity of the disturbance from the Johnston Island nuclear explosion, that is, 470 m./sec. at 150 km. (ref. 2). It is further suggested that the apparent vertical movement of the ions is caused by the interaction of the ionized component of the disturbed atmosphere with the magnetic field. The dissipation of this wave would also explain the more pronounced effects at Campbell Island than at Christchurch, and also the five cases where no storm developed at Christchurch.

This work is part of the research programme of the Christchurch Geophysical Observatory, Department of Scientific and Industrial Research, New Zealand, under the superintendent, Mr. J. W. Beagley. I wish to thank Mr. C. H. Cummack for his guidance and also Mr. G. A. M. King for helpful discussions.

GEOLOGY

Granite beneath the Northern Pennines

A FULLY cored borehole sited at Rookhope (*NY*35/937,428), West Durham, has proved the existence of granite at 1,281 ft. depth directly beneath Lower Carboniferous (Viséan) strata. The drilling, which is still in progress, is financed by the Department of Scientific and Industrial Research, and forms part of a programme of geological and geophysical investigation by the Durham Colleges Geology Department.

The background of the operation is as follows. The lead–zinc–fluorine–barium deposits, which occur as veins and replacements in the Carboniferous rocks of the northern Pennines, were shown by K. C. Dunham[1,2] to exhibit a concentric pattern of regional mineral zones, suggesting that mineralization was due to heated solutions, rising at a limited number of centres, and thereafter distributed laterally along channels conditioned by hard beds in the Yoredale sequence. Acid magmatic activity at depth was considered to be a possible source of the solutions. Later on, M. H. P. Bott and D. Masson-Smith[3], following up a strong negative Bouguer anomaly, first noticed during a traverse by J. Hospers and P. L. Willmore[4], made a detailed gravimeter survey of the region. This revealed a negative gravity anomaly of 35 milligals amplitude closely similar in character to the gravity field over exposed granitic batholiths with roof cupolas, such as the Cornubian batholith. Furthermore, certain features of the anomaly were considered to be inconsistent with interpretation as a sedimentary basin. Under the Alston Block, the cupolas indicated by the gravity survey correspond exactly with the postulated emanative centres of the mineralization. When the gravity survey was published, it was suggested that the most probable explanation was that a granite of Permo-Carboniferous age underlay the area, and that it not only supplied the mineralization, but also contributed to the devolatilization of the coal seams in the area. Using a method of calculation devised in collaboration with R. A. Smith, Bott[5] showed from the magnitude of the second derivative of the anomaly that the top surface could not be deeper than 3,500 ft. below Weardale. No upper limit to the depth can be placed from the gravity data, but having regard to the fact that no contact metamorphism is seen in the exposed Carboniferous rocks except near the Whin Sill, he concluded that the probable depth was between 2,000 and 3,000 ft. The postulated granite has become known as the 'Weardale granite'.

The borehole commenced near the top of the Great Limestone, 350 ft. from the surface position of the hanging wall of the Red Vein, one of the most powerful W.N.W. channels of mineralization in the district, with a yield so far of 460,000 tons of fluorspar and 48,000 tons of galena. The collar of the boring is also 500 ft. from the hanging wall of the E.N.E. Boltsburn Vein, a weak but very persistent fracture, which has yielded 143,000 tons of galena, mainly from associated replacements. Both veins dip towards the boring, which was sited so as to pass through them at depth. Below the Great Limestone, the base of which is taken as the Viséan–Namurian boundary in northern England, a normal Middle Limestone Group succession was encountered. Two quartz-dolerite sills were proved in these beds; the Little Whin Sill, 6 ft. thick, is intruded into the Three Yard Limestone, and the Great Whin Sill, 200 ft. thick, lies beneath the Jew Limestone. The base of the Middle Limestone Group remains to be defined exactly when the faunal study of the cores has been carried out, but the expected change from dark blue-grey limestone to pale grey limestone shows the approximate position of this boundary. The Lower Limestone Group is represented by an alternation of light grey limestones, shales and sandstones; no massive Melmerby Scar Limestone such as is present below Cross Fell is developed; but the typical 'pseudo-breccia' lithology characteristic of this limestone is present in some of the bands. Beneath these light-coloured limestones, black shale with very thin quartz- and feldspar-bearing conglomerate beds rest directly on weathered granite which in a few feet gives place to fresh, well-foliated microcline-quartz-muscovite-oligoclase rock. The foliation is nearly horizontal, and aplite and pegmatite bands occur at various angles.

So far, ten intersections of metalliferous mineralization have been made. Of eight in the Carboniferous, three are horizontal replacements in limestone and one of these is 16 ft. thick, rich in green fluorite and sphalerite. Two typical Pennine Zone I veins, carrying pyrrhotite, fluorite, quartz, have been intersected within the granite at 1,349–1,363 ft. and at 1,585–1,656 ft., the latter being accompanied by extreme alteration of the granite.

Two definite conclusions may be drawn at this stage: (1) the granite so far proved is of pre-Carboniferous age; (2) the mineral veins were fed from some source beneath that part of the granite so far drilled. To these may be added the suggestion that the buried pre-Carboniferous cupolas served to localize the upward flow of mineralizing fluids into the Carboniferous rocks.

Isotopic Ages of the Weardale Granite

AGE determinations have been carried out on muscovite from the Weardale Granite[1] by both the rubidium–strontium and potassium–argon methods. One specimen from a depth of 1,396 ft. in the borehole was measured by both methods, while another from 1,314 ft. was measured by the potassium–argon method only.

Isotopic dilution techniques were employed for the determination of rubidium, strontium and argon. A flame photometric method was employed to determine potassium. The results for the rubidium–strontium method are given in Table 1, and those for the potassium–argon method in Table 2.

Table 1. RUBIDIUM-STRONTIUM DETERMINATIONS ON MUSCOVITE

Depth of sample (ft.)	Rubidium (p.p.m.)	Normal strontium (p.p.m.)	Radiogenic strontium (p.p.m.)	Age (m.yr.)
1,396	763	19·4	1·15	360 ± 12
1,396	757	19·6	1·15	365 ± 12

Decay constant of rubidium-87 = $0{\cdot}1475 \times 10^{-10}$ yr.$^{-1}$

Table 2. POTASSIUM–ARGON DETERMINATIONS ON MUSCOVITE

Depth of sample (ft.)	K_2O (per cent)*	Weight fused (gm.)	Radiogenic argon (p.p.m.)	Atmospheric argon (per cent)	Age (m.yr.)
1,396	10·01	2·034	0·240	17·4	370 ± 10
1,314	10·26	3·291	0·239	24	356 ± 12

Decay constants of potassium-40: $\lambda_K = 0{\cdot}584 \times 10^{-10}$ yr.$^{-1}$
$\lambda\beta = 4{\cdot}72 \times 10^{-10}$ yr.$^{-1}$
Isotopic abundance of potassium-40 = 0·0119 atom per cent
* Potassium analyses by Dr. N. J. Snelling.

All the results agree within the limits of error. Agreement between the two methods makes it highly probable that the weighted mean of the four figures is close to the true age of emplacement of the granite.

The following points may be noted: (i) The weighted mean of 362 ± 6 million years corresponds to a Middle or Late Devonian age of emplacement, according to the latest time-scales[2,3]. The isotopic results therefore agree with the borehole evidence for the pre-Carboniferous age of the granite. (ii) The age of the Northern Pennine mineralization from the field evidence[4] is undoubtedly post-Carboniferous and probably pre-Tertiary. From lead isotope measurements by Moorbath[5] the mean model age of Northern Pennine galenas is 280 ± 30 million years, indicating that the mineralization is in fact of Hercynian age. Thus, from the lead isotope data and the absolute ages, as well as from the observations reported in the preceding communication, the northern Pennine mineralization is not connected with the emplacement of the Weardale granite. (iii) The weighted mean of 362 ± 6 million years for the Weardale granite is significantly younger than the dates for the Shap granite given by Kulp *et al.*[6]. These authors obtained 391 ± 7 million years by the potassium–argon method and 381 ± 7 million years by the rubidium–strontium method. Unpublished rubidium–strontium results obtained at Oxford on the Skiddaw granite suggest that the latter may be contemporaneous with the Weardale granite.

We are indebted to Prof. Dunham for supplying the material for this investigation.

CRYSTALLOGRAPHY

Highly Oriented Boron Nitride

Pyrolytic graphite deposited on a hot target[1] has been found to have a structure with highly oriented crystallites[2]. We have now prepared, similarly, by vapour phase pyrolysis and deposition on a hot target, a boron nitride the structure of which also has a high degree of orientation of its crystallites. Utilizing boron-bearing gases and regulating the parameters of the treatment, we have been able to control the deposit of the pyrolytic boron nitride.

The X-ray diffraction pattern of pyrolytic boron nitride, Fig. 1, shows the structure to be composed of crystallites which are highly oriented with respect to each other and essentially parallel to the deposition surface. The stacking of the basal planes within the crystallites is considered to be turbostratic as indicated by the expanded unit cell height. On the other hand, the diffraction pattern of normal boron nitride reflects the random orientation of the crystallites, but within these the basal planes are well ordered. The diffraction patterns are compared in Fig. 1 with the powdered sample scan intensity having twice the scale factor of the pyrolytic. The trace of the pyrolytic material has been amplified to enhance the low-intensity peaks.

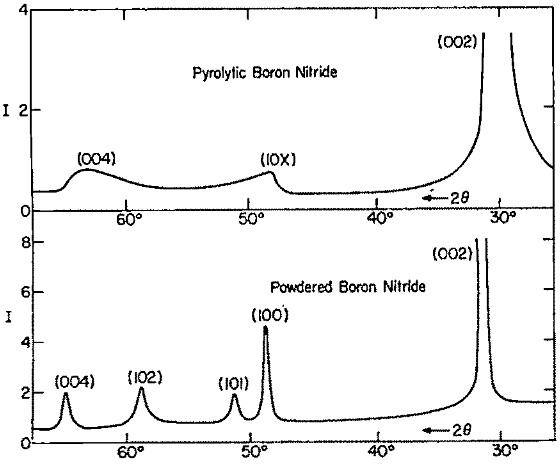

Fig. 1

Boron nitride has a simple hexagonal lattice with unit cell dimensions of $a = 2{\cdot}50399 \pm 0{\cdot}00005$ Å. and $c = 6{\cdot}6612 \pm 0{\cdot}0005$ Å. (ref. 3). The height of the unit cell of the pyrolytic material has been measured as 6·72 Å. using iron-filtered cobalt $K\alpha$ radiation on a General Electric *XRD*-5 diffractometer. Our experience indicates that the a-dimension of the unit cell, the chord of the hexagonal net in the basal plane, is not significantly different in pyrolytic graphite from natural graphite. Therefore, we do not expect any significant change in the edge-length of the pyrolytic boron nitride compared with the published data; this value has been assumed for calculation. The measurement of the edge-length of the pyrolytic unit cell is planned. Crystallite size has been determined to be approximately 140 Å. The theoretical density of normal boron nitride is reported[3] as 2·27 gm./c.c., compared with 2·26 gm./c.c. for pyrolytic boron nitride calculated with the above data.

Spectrochemical analysis of the pyrolytic material shows a relatively pure material with only trace concentrations of impurities. Observed impurities are magnesium, molybdenum and silicon at levels of about 10 parts per million or less.

The material is deposited on the hot target as a dense, fine-grained piece. Thin pieces are transparent and fairly thick (1/2 mm.) pieces are translucent. Samples have been obtained with either white or yellow colouring. Specimens of the white and yellow material have been examined by X-ray and chemical analysis and by neither method can we discriminate between the colours. Microstructure of the material shows the columnar cones characteristic of those found in the vapour deposition of the pyrolytic graphite. Fig. 2 is a photomicrograph of a representative section, the surface of the initial deposit being at the apex of the growth cones. Examination of the optical characteristics has been initiated, but results are not available for this preliminary report.

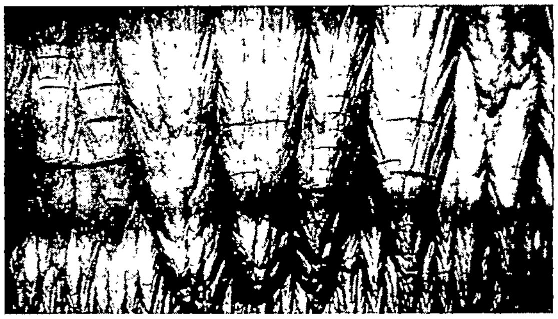

Fig. 2

These are the initial results from the investigation of pyrolytic boron nitride. The work reported is one phase of a broader programme to gain better understanding of the single crystal properties of selected refractory materials such as graphite, graphitic alloys, carbides, nitrides and related compounds for which adequate single crystals are not available. The technique of pyrolytic preparation produces samples with highly oriented structures that can be used in place of single crystals for investigation of some properties of the materials. Thus, the preparation of the highly oriented boron nitride is an approach to, and will permit the examination of, single-crystal characteristics of boron nitride so that the effect of its lattice anisotropy can now be investigated. It is expected that the wide interlayer spacing compared with the interatomic distance within the plane will generate significant anisotropy of the fundamental physical properties of boron nitride.

PHYSICS

Rates of Recombination in Hydrogenic Plasmas

In common with other experimental determinations of rates of recombination of ions with electrons[1], recent spectroscopic observations of the afterglow of the *Zeta* discharge have indicated that these rates are much greater than simple theory predicts. When comparison has been made with the theory of radiative recombination[2-4], including recombination into all the excited levels of the atom, the theoretical value falls short of the experimental. Another primary process is three-body recombination. This is the inverse of ionization by electron collision to which it is related by the principle of detailed balance in thermodynamic equilibrium. The theory of collisional ionization was developed classically by Thomson[5], and if three-body recombination-rates into the ground-state are computed from this theory they also are found to be quite inadequate to explain the experimental observations.

In this communication there is proposed a more complex recombination mechanism which is based on well-known atomic collision processes, and which may help to explain the observed values. The three-body recombination-rate (derived from the classical ionization-rate) is proportional to the fourth power of the principal quantum number of the state into which the electron falls. Thus there is the possibility of three-body recombination into an excited state followed by spontaneous radiative decay being an effective recombination mechanism. This possibility is the kernel of the physical problem investigated here.

Specifically computations have been made of the rate at which the ground-states of hydrogen atoms and of hydrogen-like boron ions (B V, $Z = 5$) are populated as a result of the following processes among the first 20 quantum states of the atom (or B V), the continuum of free electrons and the corresponding bare nuclei: (1) collisional ionization; (2) three-body recombination; (3) collisional transitions between bound states; (4) radiative recombination; (5) spontaneous radiative transitions. The plasma was assumed to be optically thin.

The total rate at which the ground-state is populated is the sum of: (1) direct three-body recombination; (2) direct radiative recombination; (3) collisional transitions from all the excited states; (4) spontaneous decay from all the excited states.

This rate therefore depends on the instantaneous populations of all the excited states. Thus the solution was required of the following set of equations:

$$\frac{\mathrm{d}n_{0,i}}{\mathrm{d}t} = (\text{rate of populating state } i) - (\text{rate of depopulating state } i)$$

where $n_{0,i}$ is the population of the state having main quantum number i. Low-energy collisions are assumed to be sufficiently frequent to ensure that the substates are populated relatively according to their statistical weights. These equations were solved using the steady-state approximation $\left(\frac{\mathrm{d}n_{0,i}}{\mathrm{d}t} = 0, i \neq 1\right)$.

This is legitimate for hydrogen atoms and hydrogen-like ions because transitions among the excited states and the continuum are much more probable than transitions to and from the ground-state. Excluded from the computed rate of populating the ground-state are processes where the ground-state electron is raised to an excited state by collision and then returns to the ground-state by either a radiative or collisional transition.

In deciding the uppermost quantum state to be taken into account I noted the equivalence of situations (*a*) where states have a Saha distribution of populations and (*b*) where there is an imaginary continuum of electrons having a Maxwellian distribution of velocities, extending over the same energy region, and being suitably quantized. Thus, in making the discrete states merge into the imaginary continuum at the twentieth state, it was necessary to check in each case considered that at least the states immediately below twenty were Saha-populated. This was shown to be so for the range of conditions considered.

Cross-sections, due to M. J. Seaton (private communication), and *f*-values calculated by Green *et al.*[6], were used. Seaton derived his expression specifically for ions, but its similarity to the classical Thomson expression justifies its use for atoms. The calculations were done on a *Mercury* (Ferranti) electronic computer.

The results are presented in Fig. 1 in terms of a correction factor which is the amount by which the ground-state radiative recombination-rate has to be multiplied to give my computed-rate of populating the ground-state.

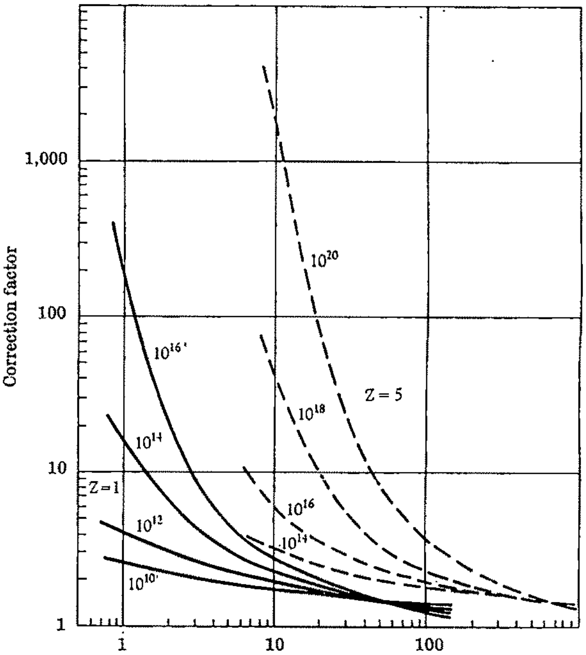

Fig. 1. Computed rates of populating the ground-states. The curves are for ions having nuclear charges 1 and 5 and for various electron densities (cm.$^{-3}$)

$$\text{Correction factor} = \frac{\text{Computed rate of populating the ground-state}}{\text{Radiative recombination-rate into the ground-state}}$$

The departures of the populations of the states from their Saha values is illustrated in Fig. 2 ($kT_e = 1$ eV.). In this connexion it is useful to designate a particular state which approximately marks the lower limit of the Saha region of the term scheme as the 'collision limit'. I define it as the lowest state for which the bound electron has a greater probability of making a transition to an upper state than to a lower state. The collision limits are marked on Fig. 2. The broken curve of this diagram depicts

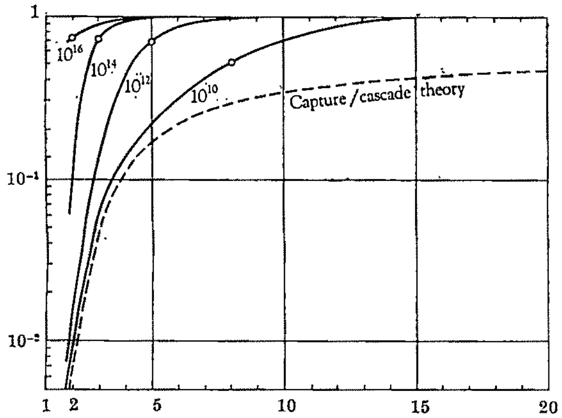

Fig. 2. Populations of the excited states of hydrogen in a recombining plasma at an electron temperature $kT_e = 1$ eV. The curves are for various electron densities (cm.$^{-3}$)

$$b_i = \frac{\text{Calculated population of state } i}{\text{Saha population of state } i}$$

O, Collision limits.

the case where radiative processes only are taken into account. This case was worked out by Seaton[7].

The set of curves of Fig. 2 illustrates clearly the effect of increasing density on the mechanism by which electrons leave the continuum and become bound. In the limit of very low density, radiative recombination is the only mechanism, and the states are populated according to the capture-cascade theory. However, the curves of Fig. 1 do not tend to unity because radiative recombination into upper states followed by spontaneous decay make a contribution. Such processes are more important at low density and this explains the cross-over of the curves of Fig. 1. As the density increases, the upper states progressively become populated more closely according to the Saha distribution. This is due to the increasing influence of collision processes (including three-body recombination).

The computed values for the rate of populating the ground-state may be compared with the experimentally observed ion decay-rates for the hydrogen plasma of *Zeta*[8]. For the conditions of the measurement the plasma parameters were (to a factor 2) $n_e = 10^{14}$ cm.$^{-3}$, $kT_e = 1$ eV. The rate at which the ion population decayed was about ten times greater than the radiative recombination-rate, in agreement with my computed value.

Since the work reported here was done, there have appeared two reports on similar calculations[9,10]. The results of Bates and Kingston are in good agreement (±30 per cent) with mine. Besides providing useful confirmation of this other work, I have investigated the effect of ionic charge, have extended the calculations to higher-electron temperature, and have presented the computed populations of the excited states.

Doubling of the Proton Magnetic Resonances of Certain Organophosphorus Compounds

We have found that some of the proton magnetic resonances of the alkyl groups of several types of organophosphorus compounds are doubled. This doubling is in addition to the resonance multiplication that would be predicted from coupling with other magnetic nuclei in these compounds. So far we have observed resonance doubling for three types of structures. Type (I) is exemplified by 2-propyl phenylphosphinyl chloride. In compounds of this type, the alkyl group is directly linked to the phosphorus atom. Type (II) is exemplified by di-2-butyl phenylphosphate or di-2-butyl phenylphosphonate. In such compounds the alkyl group is linked through an oxygen atom to the phosphorus atom. Type (III) is exemplified by di-2-propyl phenylphosphonite, in which the phosphorus is trivalent.

It seems probable that the resonance doubling with type (I) compounds is due to the same sort of hindered rotation that produces resonance multiplication in substituted ethanes[1,2]. However, in the case of type (I) compounds the axis of rotation is the bond between the α carbon atom and the phosphorus atom rather than between two carbon atoms. A Fisher–Hirschfelder–Taylor model of the 2-propyl phenylphosphinyl chloride shows that if one of the rotational isomers is energetically preferred over the other two, then, on the average, one of the methyl groups is closer to the benzene ring than is the other. Since the benzene ring possesses a relatively strong induced magnetic field, the methyl groups would, on the average, be in different magnetic environments, and two sets of resonance signals would result.

We have, at present, only an incomplete concept of the structural features that cause resonance doubling in type (II) compounds. It seems likely that the same structural effects that cause doubling in type (I) also cause the resonance doubling for type (II). However, the situation is complicated by the intervention of an oxygen atom between the phosphorus atom and the α carbon atom of the alkyl group. The resonance doubling in type (II) compounds was observed only when the molecule contained one aromatic substituent and when the alkyl group was linked through an internal carbon atom. Di-1-alkyl phenylphosphates and di-1-alkyl phenylphosphonates did not exhibit the doubling. Qualitative proton

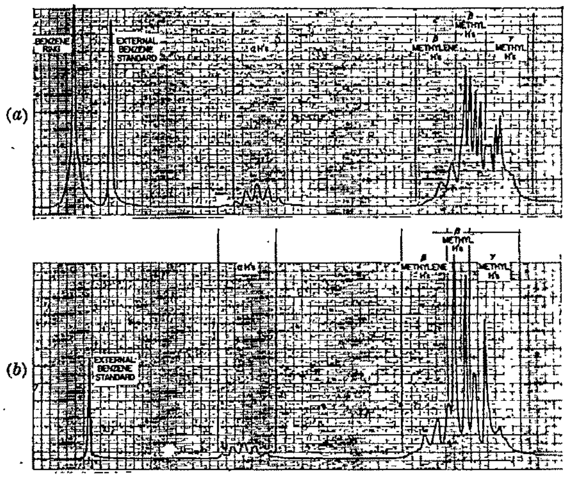

Fig. 1. (*a*) Di-2-butyl phenylphosphate. (*b*) Tri-2-butyl phosphate

resonance spectra of (*a*) di-2-butyl phenylphosphate and of (*b*) tri-2-butyl phosphate are given in Fig. 1. These spectra were run at 40 Mc./s. on a Varian nuclear magnetic resonance spectrometer, model *V*-4300*B*.

There is no background of experience with this type of resonance doubling in structures similar to that of type (III). However, it is perfectly evident that there must be conformations of type (III) that represent lower potential energies than other conformations. If in these conformations the two methyl groups in a 2-propyl radical are not interchanged with respect to their proximity to the benzene ring, then resonance doubling can occur. This is true since the average magnetic environment of the protons of the two methyl groups would be different.

We are continuing our investigations of the proton magnetic resonances of these three types and related compounds.

This work was carried out under contract *AT* (07-2)-1 with the U.S. Atomic Energy Commission.

RADIATION CHEMISTRY

Photoemission into Liquid *n*-Hexane

RECENT measurements of conduction[1] and of ion transit time[2,3] in liquid *n*-hexane have made use of the fact that electrons can be released into the liquid by the incidence of ultra-violet illuminations on the cathode surface. These measurements have been interpreted with the assumption that the ultra-violet light can be passed through the liquid to the cathode surface without producing ions in the liquid or otherwise disturbing it. Even in the most highly purified *n*-hexane it is not certain that this is true, particularly when subject to electric stress. The method described here attempts to overcome this difficulty.

Ultra-violet light is directed through a quartz window, attached to the liquid cell, on the inside of which is deposited a thin metal film cathode. Electrons are ejected from the opposite surface of the film into the liquid. By depositing a film of suitable thickness it is possible to produce a reasonable emission current without appreciably irradiating the liquid. Other advantages are that the area of the cathode illuminated can be controlled accurately and localized within the uniform field region, an important factor if current saturation is to be examined; and the spacing between electrodes in the cell can be made very small if desired, since the need for a large spacing for oblique illumination is removed. This will allow much higher fields to be attained with reasonable voltages.

The test cell was constructed from a short length of 2-in. diameter glass tubing, with a ground-glass flange at one end to hold the anode assembly. The opposite end was carefully ground to ensure that the electrodes were parallel. Both electrodes were sealed to the cell with cold-setting 'Araldite' since it was found that neoprene 'O' rings contaminated the liquid. The anode was a stainless steel disk, 1 in. in diameter; and in the present experiments the cathode film was aluminium with a transmission for visible light of about 50 per cent. The spacing between the electrodes was $3{\cdot}74 \times 10^{-2}$ cm., and they were parallel to within ± 2 per cent over the uniform field region. Finally, the cell was incorporated into a simple distillation system which allowed the liquid to be degassed at a pressure of about 10^{-3} mm. mercury.

After 24 hr. at a stress of 10 kV./cm., the residual conductivity of the liquid was less than 10^{-18} mho./cm., and on irradiating the outside of the cathode with ultra-violet light the current increased initially by a factor of 10^3. However, this did not remain constant but decreased slowly over a period of 20 min. by a factor of about 3. On switching off the ultra-violet illumination, slow-time effects were also observed in the decrease of conductivity. Morant[1] found similar slow variations for the case of direct illumination of the cathode through the liquid.

By reversing the polarity it was found that the current injected into the liquid with the metal film as cathode was about 100 times that injected with the film as anode. The fact that there was a current when the film was positive indicated that some radiation was passing through the film and either releasing electrons from the stainless steel electrode or photoionizing the liquid. The ratio of the two currents remained the same when the cell was emptied and evacuated, and this suggests that the currents originated at the electrodes and not in the bulk of the liquid. More careful control of the film thickness should allow the amount of radiation passing into the liquid to be reduced.

With the cell evacuated the current from the film became saturated with increasing voltage, and was about 10^{-8} amp. In the liquid for the same field and illumination intensity the current was approximately 10^{-11} amp. The variation of photocurrent with increasing field up to 700 V./cm. in *n*-hexane has been reported by Morant[1], and with the present experimental arrangement a similar variation was observed over the same field-range (curve *a*, Fig. 1). At higher fields,

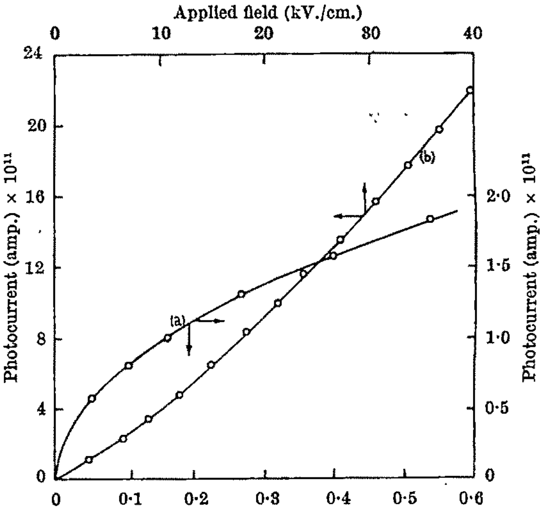

Fig. 1. Photocurrent injected into *n*-hexane for various field strengths with constant ultra-violet illumination

however, there is a marked change, and the current increases with increasing field (curve *b*, Fig. 1). Above 10 kV./cm. the current varies with field as $E^{1 \cdot 21}$.

Although the equipment used was not designed for mobility measurements, an estimate of the mobility of the negative ion in *n*-hexane can be made from the transient growth of current immediately after switching on the ultra-violet light, and the value so obtained (about 8×10^{-4} cm.²/V. sec.) is in rough agreement with other published data[2,3].

The experiments described here show that it is possible to inject an appreciable current into a dielectric liquid without having to subject the liquid to intense radiation. The fact that the current can be confined to the centre of the uniform field region is of great importance in the study of transient phenomena in which electrode edge effects can give rise to appreciable error. Also, the long time decay of current which is observed after the ultra-violet light is switched on would not be important if pulsed illumination were used, and the amount of charge injected into the liquid during the pulse would be considerably greater than that calculated from the magnitude of the steady current.

This work is part of a programme which is receiving financial support from the Department of Scientific and Industrial Research. I wish to thank Prof. M. W. Humphrey Davies for facilities provided, and Dr. T. J. Lewis for his encouragement and helpful discussions.

The Importance of Hydroxyl Radicals as Intermediates in the Cross-linking of High Polymers by γ-Irradiation

We have irradiated thin gelatin films (thickness 0·5–1·0 mm.) with cobalt-60 γ-rays at a dose-rate of $4 \cdot 2 \times 10^4$ r. hr.$^{-1}$ at 10° C. The film was either suspended in a stoppered bottle containing oxygen or nitrogen or immersed in a liquid which filled the bottle. After irradiation of the film, attempts were made to dissolve it in 19 times its own weight of water at 40° C., and the viscosity of any resultant solution was measured. No increase in relative viscosity was observed when the irradiation was carried out in an atmosphere of oxygen or nitrogen, or when the film was suspended in liquid paraffin, benzene, ether, *cyclo*hexanone, pyridine, acetone or an alcohol, even when the dose exceeded 1 mega-roentgen. In the presence of water, however, the gelatin became cross-linked, as was shown by the fact that it was merely swollen by treatment with boiling water.

In a second series of experiments, gels prepared by dissolving 50 gm. of gelatin in 1 litre of water at 40° C. followed by 1 hr. in an ice-bath were irradiated at 10° C. immediately after covering with a layer of an organic liquid. Liquids such as methanol, glycerol and ether markedly reduced the cross-linking in that part of the gel which they had penetrated. These experiments indicate that cross-linking of gelatin induced by radiation is dependent on generation of free radicals by the action of the γ-rays on water, and that these radicals attack gelatine in reactions which probably involve abstraction of hydrogen atoms, thereby forming free radicals on the gelatin chains which become the cross-linking sites. Any organic liquid present diminishes the cross-linking either by competing with the gelatin for radicals from the water or by interfering with the cross-linking process.

If, as our results suggest, radicals play an important part in radiation-induced cross-linking of polymers, the otherwise anomalous results of Okada, Ito and Amemiya[1] may readily be explained. These authors observed that an atmosphere of nitrous oxide promotes the cross-linking of polyethylene induced by γ-irradiation, whereas an atmosphere of oxygen retards it. Dainton *et al.*[2] have shown that nitrous oxide reacts rapidly with hydrogen atoms (reaction 1) with formation of hydroxyl radicals and nitrogen,

$$H\cdot + N_2O \rightarrow HO\cdot + N_2 \qquad (1)$$

and it is known that oxygen 'scavenges' hydrogen atoms to form $HO_2\cdot$ radicals which are likely to be less effective than $HO\cdot$ radicals in causing cross-linking.

CHEMISTRY

Prediction of Retention Data in Gas–Liquid Chromatography from Molecular Formulæ

As a result of the introduction of the R_{x9} method[1-3] of presenting gas–liquid chromatographic retention ratios, it has been possible to derive a simple method of predicting retention data from a knowledge of molecular weight and structure. Preliminary investigations have indicated its value in the structural analysis of organic compounds.

The retention index (I) of Kovats[4] is closely related to R_{x9} by the following expression (ref. 2):

$$I' = \frac{\log R_{x9}}{b} + 9$$

where I' is $I/100$ and b the slope of the log plot for *n*-paraffins. I' can be interpreted as the carbon number of a hypothetical *n*-paraffin having the same retention as the solute to which I' refers. The formula of the hypothetical *n*-paraffin equivalent to the solute is $C_{I'} \cdot H_{2I'+2}$ and will have a molecular weight given by $M_e = 14 \cdot 026\, I' + 2 \cdot 016 = 14 \cdot 026 \dfrac{\log R_{x9}}{b} + 128 \cdot 25$. This can be regarded as the 'effective' molecular weight of the solute. We have found the difference between the effective and true molecular weights of the solute (ΔM_e) to be a useful parameter for correlating retention data with chemical structure for the following reasons:

(1) ΔM_e is a conceptually simple parameter having the familiar dimensions of molecular weight.

(2) It is virtually constant throughout a homologous series (Table 1).

(3) It has no, or only a slight linear, variation with temperature (Table 2).

(4) ΔM_e is an additive function of the structural features of a molecule (Table 3) (except when specific group–group interactions occur).

Table 1. ΔM_e VALUES OF HOMOLOGOUS SERIES (65° C.)

Table 3. EFFECTIVE MOLECULAR WEIGHTS OF $\alpha : \omega$ DITHIOLS ON SQUALANE AT 65° C.

Compound	Calculated*		Found	
	M_e	R_{x_9}	R_{x_9}	M_e
Ethane-1 : 2-dithiol	111·9	0·350	0·320	110·5
Propan-1 : 3-dithiol	126·0	0·866	0·838	125·5
Butan-1 : 4-dithiol	140·0	2·268	2·268	140·0

* Using ΔM_e for SH group of 8·88.

(5) For a proposed structure, M can be computed and ΔM_e for the various structural features obtained from correlation tables. Thus M_e and hence R_{x_9} can be predicted. This has proved invaluable in identifying the products of a reaction where only a few alternatives are possible. Thus, once ΔM_e functional group correlation charts are available, retention times can be predicted without any prior chromatography. This is not practicable with the methods at present available.

(6) ΔM_e values of selected functional groups may be used to characterize chromatographic columns, particularly when the retention data are to be published. Thus, it should be possible to use the gas-liquid chromatography data confidently in the literature for the solution of everyday analytical problems.

(7) In general, ΔM_e values need to be expressed to fewer significant figures than I' contributions.

Work on the compilation of ΔM_e values and the application to column characterization, structural analysis and intramolecular interactions is proceeding in these laboratories and will be published in due course.

Trimerization of Nickel-(II) Acetylacetonate in Solution

FOLLOWING Bullen, Mason and Pauling's confirmation of the trimeric structure of anhydrous nickel-(II) acetylacetonate[1], we report evidence for the persistence of the trimeric structure in solution.

We have prepared the anhydrous compound from the dihydrate both by vacuum sublimation and by azeotropic drying of toluene solutions, the latter method providing a particularly convenient means of obtaining water-free solutions. Cryoscopic molecular weight determinations on solutions of the anhydrous compound in benzene (dried over anhydrous magnesium perchlorate) gave the following results:

Weight of benzene (gm.)	23·12	23·12	23·12
Weight of acetylacetonate (gm.)	0·0985	0·2050	0·3185
Depression of freezing point (° C.)	0·027	0·059	0·093
Molecular weight	819	770	759

the mean molecular weight of 779 comparing well with a theoretical value for the trimer of 771.

Addition of water to solutions of the anhydrous compound in toluene precipitated the dihydrate; addition of ethanol precipitated the corresponding di-ethanolate and of pyridine the di-pyridine adduct, the solubility of which was high enough to permit spectrophotometric examination of the equilibrium:

$$\text{anhydrous compound} + \text{pyridine} \rightleftharpoons \text{pyridine adducts.}$$

Absorption curves for various ratios of the reacting species passed through one of two distinct isosbestic points, indicating a two-stage addition, but with considerable overlap of the two stages. However, by taking advantage of the variable reactivity of different heterocyclic bases we have been able to examine the two stages independently; thus, 4-methyl-pyridine gave virtually complete conversion to the 1 : 1-adduct and incomplete conversion to the 1 : 2-adduct, whereas 2 : 6-dimethyl-pyridine gave incomplete conversion to the 1 : 1-adduct without detectable formation of the 1 : 2-adduct. The form of the equilibrium constants for the two stages:

$$k_1 = \frac{[\mathrm{Ni(acac)_2.base}]^3}{[\{\mathrm{Ni(acac)_2}\}_3] \times [\mathrm{base}]^3};$$

$$k_2 = \frac{[\mathrm{Ni(acac)_2.base_2}]}{[\mathrm{Ni(acac)_2.base}] \times [\mathrm{base}]}$$

correspond to the reactions:

$$\{\mathrm{Ni(acac)_2}\}_3 + 3\,\mathrm{base} \rightleftharpoons 3\,\mathrm{Ni(acac)_2.base}$$

$$\mathrm{Ni(acac)_2.base} + \mathrm{base} \rightleftharpoons \mathrm{Ni(acac)_2.base_2}.$$

The constancy of the equilibrium constants obtained over a wide range of completion of each reaction is shown in Tables 1 and 2.

Bullen, Mason and Pauling's crystal structure determination shows that each nickel atom in the anhydrous trimer is octahedrally co-ordinated by six oxygen atoms, trimerization presumably occurring so as to maintain the co-ordination number of the nickel atoms. It is rather surprising therefore that the intermediate 1 : 1-adducts appear to be monomeric where we might expect dimerization to occur. Recent X-ray analyses of zinc acetylacetonate monohydrate[2] and a triarsine nickel bromide complex[3], however, suggest that five co-ordination may be more common than is often supposed.

Our observation that the trimeric structure, and hence the octahedral co-ordination of the nickel

atoms, is preserved in solutions of anhydrous nickel acetylacetonate clarifies the difficulties which have been met in attempts to interpret the absorption spectra of these solutions. Both Jørgensen[4] and Maki[5] have commented on the similarity between the absorption spectra of the anhydrous and hydrated compounds, interpreting this in terms of ligand-field effects due to axial perturbations by the solvent in solutions of the anhydrous compound or to the smallness of the axial perturbations in the dihydrate. It is now apparent that both substances are examples of nickel-(II) cations in an octahedral environment of six oxygen atoms and the similarity of spectra is to be expected.

Mullite Formation in the Aluminium Fluoride–Silica System (AlF_3–SiO_2)

The role of mullite, the conditions and kinetics of its formation are among the main problems of ceramic theory. The equilibrium conditions of the alumina–silica system have been established[1-3]. Grofcsik and Vago[4,5] have given an answer to the problems of kinetics on the basis of results obtained from their investigations carried out on silica gel and alumina. Several authors have dealt with the mineralization of mullite formation too[6-8]. The examination of the AlF_3–SiO_2 system suggests a way which may clear up the problem of possible mullite-formation mechanisms in ceramic products.

The following materials have been used: reagent grade aluminium fluoride with or without structural water, silica gel produced by the hydrolysis of ethyl silane, cristobalite obtained by 1,300° C. heat treatment of the latter, rock crystal and silica glass. All materials were finer than 60μ with similar particle-size distributions. Mixing was done mechanically in an agate mill, the heat treatment in an oxidizing atmosphere.

The gross process may be described by the following equation:

$$12\ AlF_3 + 13\ SiO_2 = 2(3Al_2O_3.2SiO_2) + 9\ SiF_4$$

using materials with structural water[9] by the reaction:

$$AlF_3 + SiO_2.\,xH_2O \rightarrow 3Al_2O_3.2SiO_2 + HF$$

is mentioned, too.

Examinations, however, have been carried out with a slight excess of silica. The samples were measured separately and dried at 105° C.

The reaction kinetics, as a function of heating time and temperature, have been determined by differential thermal analysis and thermogravimetric analysis. The formation of mullite has been detected microscopically and by X-ray diffraction patterns and determined quantitatively by a Muller diffractometer.

The following statements are made:

(1) The formation of silicon fluoride in the AlF_3–SiO_2 system begins at 600 ± 15° C. and is intense at 850–1,000° C.

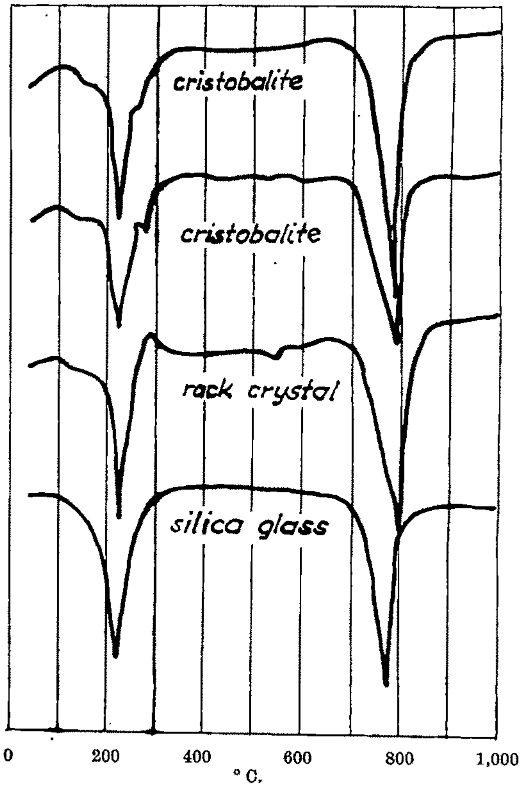

Fig. 1. Differential thermal analysis of various compositions

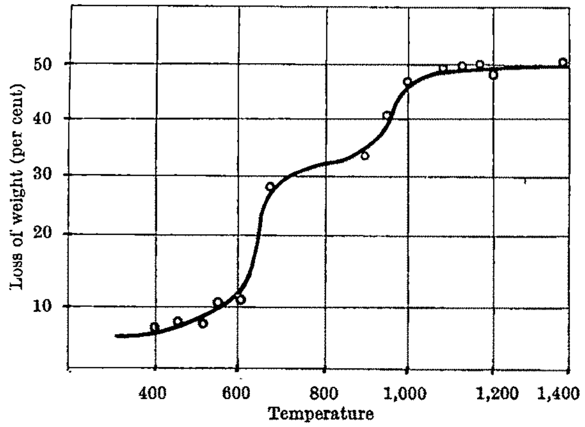

Fig. 2. Aluminium fluoride–cristobalite; loss of weight as a function of temperature

(2) The beginning and development of the reaction is a function of the particle size and the space between particles of the mix.

(3) The beginning of mullite formation does not coincide with the silicon fluoride formation, having a temperature higher by 300–400° C.

(4) The activation energy of mullite formation is lowest in the case of silica glass and higher with all other silica modifications.

(5) The initial temperature of mullite formation is 900 ± 15° C., using a mix of silica glass and aluminium fluoride (particle size less than 60μ) and agglomerated by a pressure of 50 kgm./cm.².

(6) The quantity of developed silicon fluoride increases at the start exponentially with temperature and is followed by a temporary quasi-steady state. The complete development of silicon fluoride and the simultaneous mullite formation needs further activation energy.

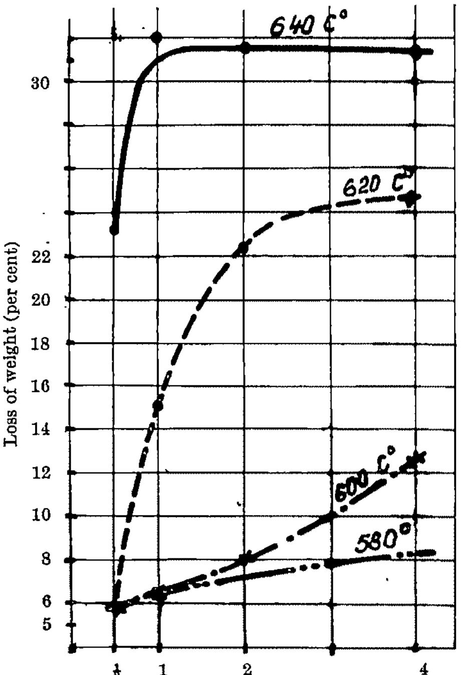

Fig. 3. Aluminium fluoride–cristobalite; loss of weight as a function of temperature and time of thermal treatment

Table 1. X-Ray Diffraction Pattern of the Silica Gel AlF_3 Mixture, Heat treated 2 hr.

d (kX.)	Intensity	Material	d (kX.)	Intensity	Material
3,718	3	$2Al_2O_3.2AlF_3.3SiO_2$	1,872	3	$2Al_2O_3.2AlF_3.3SiO_2$
3,216	3	,,	1,684	3	,,

2,502	1	,,	1,473	1	,,
2,377	3	,,	1,453	1	,,
2,191	1	,,	1,423	2	,,
2,127	3	,,	1,406	2	,,
2,062	2	,,	1,369	3	,,
1,993	1	,,	1,333	1	,,

Loss of weight against temperature plots, being similar in the case of all silica modifications, are shown in Figs. 2 and 3.

(7) Two endothermal effects are shown by differential thermal analysis in the case of a raw mix made of water containing aluminium fluoride and different silica modifications; the first from 105° to 330° C. and the second from 680° to 850° C. (Fig. 1).

(8) In the case of the aluminium fluoride–silica system the formation of silicon tetrafluoride ensures conditions in which mullite develops more rapidly than in the alumina–silica system. The velocity of mullite formation shows a rapid increase with temperature.

A crystalline and an amorphous fluorine-bearing body is formed at 600 ± 15° C. as proved by X-ray diffraction patterns of materials heat-treated in the interval 600–900° C. (Table 1).

BIOCHEMISTRY

Reactions of Cytochrome-c with Methyl Linoleate Hydroperoxide

It is now well known that the oxidation of unsaturated fatty acids and esters is catalysed by a variety of hæmatin protein compounds[1,2]. The effect of cytochrome *c* has been of particular interest to us since we have evidence which conflicts with existing theories regarding the effect of cytochrome *c* on olefinic oxidation.

In our attempts to elucidate the apparent catalytic effect of cytochrome *c*, it was discovered that under certain conditions it could act as an antioxidant, particularly at *p*H's greater than 6·0. With freshly made emulsions of linoleic acid[3] prepared by adding phosphoric acid to a previously heated and then cooled solution of potassium linoleate in a slight excess of alkali, increasing amounts of cytochrome *c* produced longer and longer induction periods, and provided that sufficient cytochrome *c* was added, oxidation could be delayed for hours. Table 1 summarizes the kind of result that has been obtained by measuring the oxygen uptake of 3·3 ml. of an *M*/20 suspension of linoleic acid in *M*/20 phosphate buffer with gelatine as a stabilizer in Warburg manometers at 30°.

Table 1

$2\cdot05 \times 10^{-5}$ *M*	2	4	2½	5	6½	8	10½
$1\cdot75 \times 10^{-5}$ *M*	2	3	3	6	7½	10	12½

Oxygen uptake in the absence of catalyst is very slow, hours being required for the absorption of the first 10 c. mm. or so. The above results, however, show that cytochrome *c* at high concentrations has an antioxygenic effect in comparison with its behaviour at low concentrations. At $3\cdot5 \times 10^{-5}$ *M*, 72 min. are required for the absorption of the first 50 c. mm. and the maximum rate of absorption is reached after about 83 min. At half this concentration of cytochrome, the first 50 c. mm. of oxygen were absorbed in 5 min. and the rate of absorption was at its maximum at this time.

Changes in cytochrome *c* during oxidation experiments have been followed spectroscopically and have shown rapid falls in concentration coinciding with termination of the induction periods.

It seems to us that these phenomena can only be explained by assuming that cytochrome *c* catalyses the breakdown of unsaturated fatty acid peroxides into inactive products, but that during this catalytic process, the cytochrome becomes 'denatured', which is not unusual in enzymatic reactions of this kind, and that the 'denatured' cytochrome has the typical property of catalysing olefinic oxidation. The results that we have obtained depend on the suspensions used being free from traces of peroxides. It has been found, for example, that suspensions prepared by shaking linoleic acid with gelatin solution in an inert atmosphere do not exhibit the above phenomena with these concentrations of cytochrome *c*, and that the amount of heating the potassium soap is subjected to during the preparation of the precipitated suspension has an influence on the length of the induction period produced in the presence of cytochrome. It is thought that trace amounts of peroxide are removed from the linoleic acid in the present instance when the potassium soap is heated in order to bring it into solution.

The effect of cytochrome *c* on pure *trans-trans* methyl linoleate prepared as previously described[4] has now been studied. Working with a 5×10^{-3} *M* suspension of the pure hydroperoxide in a very weak solution of sodium dodecyl sulphate, it has been observed that cytochrome *c* at a concentration of $1\cdot6 \times 10^{-4}$ *M* will cause the almost instantaneous destruction of 80–90 per cent of the peroxide, and that about a third of the cytochrome is 'denatured' at the same time. Oxygen gas is not liberated during the reaction but there is a loss of conjugated di-ene unsaturation, just slightly less than the loss of peroxide. The reaction is not affected in any way by diluting the peroxide with an equal quantity of pure methyl linoleate, or by a change in *p*H over the range 5·8–8·0. Hæmatin and porphyrin *c* are both inactive; the former is slowly destroyed by the peroxide.

Work is continuing with the object of identifying the products of the reaction; in particular, it is hoped to identify the reduced hydroperoxide and to obtain further knowledge of the 'denatured' cytochrome *c*.

This work was carried out as part of the programme of the Department of Scientific and Industrial Research.

Isolation of Peptides containing Hydroxyproline from Animal Tissues

The idea that fibrogenic cells secrete peptide which, in extracellular spaces, is built into collagen fibre has been postulated repeatedly in the course of the past thirty years[1,2]. There is no direct evidence, so far, of the existence of a peptide which, as a precursor of collagen, should contain the typical collagen imino-acid hydroxyproline. Peptides containing hydroxyproline isolated from urine[3,4] can be considered rather as products of collagen catabolism than as steps in the course of biosynthesis of collagen.

In 1959 we found peptide-bound hydroxyproline in ultrafiltrates of extracts from different animal tissues; for elucidation of its biological significance we have presented some work[5–7] which favours the hypothesis that peptides represent non-protein precursors of collagen protein.

In this communication we give the results of experiments dealing with the isolation and identification of peptides containing hydroxyproline.

We have experimented mostly with the skin of 2–4-months-old pig embryos. Apart from that we have investigated the granulation tissue after the application of carrageenin under the skin of guinea pigs, and we have examined growth-zones of bones in bovine embryos. Results presented in this communication involve peptides from pig embryo skin.

Fresh tissue was homogenized, immediately after freezing with liquid air, by pulverization in a mortar and shaken in a mixture of ethanol and 0·5 per cent of acetic acid (3 : 1 v/v). The suspension warmed to boiling point was kept overnight at 0° [8]. After centrifugation, the ethanol in the supernatant was removed by low-pressure distillation at a temperature not exceeding 20° and condensed by freeze-drying. For deproteination we used a metal ultrafilter with membrane 'Nojax' cellulose casings, Visking Corp., Chicago, at a pressure of 7 atm. approximately and a temperature of 1°. The ultrafiltrate was independent of the total ultrafilterable hydroxyproline condensed again by freeze-drying. Fractionation of ultrafiltrate was carried out first by column chromatography (100 cm. × 1 cm.), using 'Dowex 50 × 4', mesh 200 in ammonia cycle. The column was developed by passing the system through a solution of 0·2 *M* ammonium formate (*p*H 3·3) and 0·2 *M* ammonium acetate (*p*H 5·3) into the mixing chamber used for gradient elution at 20–30 ml./hr. and effluent was collected in 5-ml. fractions. Fractionation was followed by determining the content of free and bound hydroxyproline in different fractions. Bound hydroxyproline was ascertained from the difference in hydroxyproline

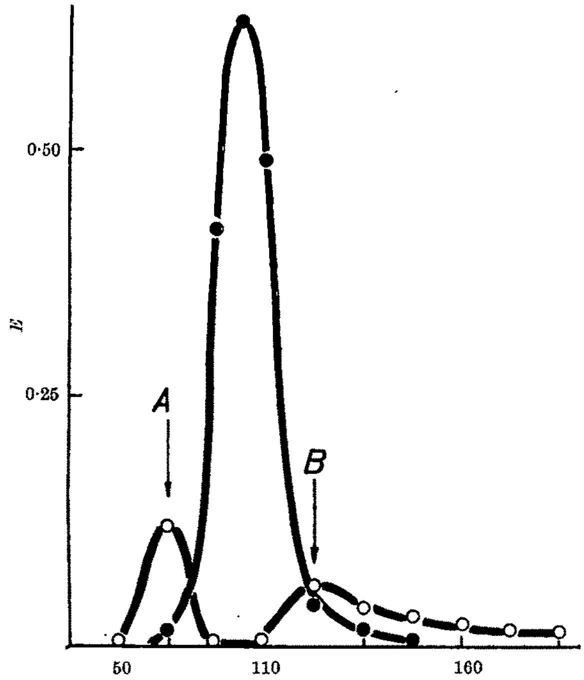

Fig. 1. Free hydroxyproline and peptide in ultrafiltrate of extract from pig embryo skin fractionated on 'Dowex 50 × 4'. ○, Peptide-bound hydroxyproline; ●, free hydroxyproline; the amount of hydroxyproline is given by extinction of sample.

content before and after acid hydrolysis of the sample (3 hr., 140°, 6 *N* hydrochloric acid). Fractions containing bound hydroxyproline were re-chromatographed on Whatman 4 (descending) in butanol/acetic acid/water (4 : 1 : 1). Peptides and amino-acids were detected by 0·1 per cent ninhydrin solution in acetone, by a specific method for detecting hydroxyproline[9] and after chloration of peptide bonds by iodostarch reagents. Strips of chromatograms containing peptides were eluted by water and re-chromatographed in a similar way. Hydroxyproline[10] and proline[11] were determined colorimetrically in aliquots of extract. The amino-acid composition of individual peptides was ascertained after acid hydrolysis, using paper chromatography as mentioned.

As shown in Fig. 1 with column chromatography, we found two fractions, *A* and *B*, with peptide hydroxyproline. By preparative paper chromatography we identified in fraction *A* at least four other peptides in which the content of proline and hydroxyproline was determined. It was found that molar relation of proline to hydroxyproline in individual peptides deviates from 5 : 1 to 1 : 1. Owing to the fact that the ratio of both imino-acids mentioned is 1 : 1 in mature mammal collagens, this finding is in good agreement with the generally accepted opinion, that hydroxylation of proline proceeds after its incorporation into peptide. Homogeneous spots of peptides A_1–A_4 obtained by re-chromatography were hydrolysed and the amount of amino-acid determined. The list of amino-acids is given in Table 1. This examination proved that peptides with greater mobility on paper chromatography contain a lower number of different amino-acids. But glycine, glutamic acid, proline and hydroxyproline were always found. Some spots have not been identified so far.

Demethylation in the Metabolism of (−)-Nicotine *in vivo*

THE physiological disposition of nicotine randomly labelled with carbon-14 has been subjected to investigation by many authors[1–3]. After intravenous administration to mice[1] and to dogs[2] analyses of the expired air showed no radioactive carbon dioxide. In an extension of this work, in which degradation of nicotine was investigated, the methylamine fraction of dog urine was examined for radioactivity and found[3] to contain none.

If the foregoing results are accepted as being completely definitive for the metabolism of nicotine, the inevitable conclusion is that nicotine undergoes an unusual metabolism with no degradation to single-carbon metabolites. This conclusion would tend to contradict our work[4] in which demethylcotinine, 5-(3′-pyridyl)-pyrrolidone-2, has been identified in urine after administration of nicotine. The need for a direct experimental resolution of this apparent contradiction has led to our employment of labelled nicotine containing a high level of activity in the methyl group.

Nicotine-methyl-^{14}C was conveniently synthesized in high yield by methylating (−)-nornicotine with formaldehyde-^{14}C in the presence of formic acid. This methylation reaction has been previously employed as a quantitative analytical procedure[5].

Male albino rats, weighing approximately 250 gm. and housed in glass metabolism cages, received the labelled nicotine intraperitoneally (0·2 mgm./100 gm.). The approximate radioactivity of the dose was 24·8 × 10^3 c.p.m. Expired carbon dioxide was collected in sodium hydroxide traps and then precipitated as barium carbonate for counting at infinite thickness. Radioactivity was readily demonstrated in the expired air. During the first 6-hr. period after administration of the nicotine, the respiratory carbon dioxide from three animals contained an average of 5·7 per cent of the administered radioactivity with individual values: 7·5, 4·0, and 5·6 per cent. Further elimination as radioactive carbon dioxide was observed in a subsequent 18-hr. period to give cumulative values of 12·8, 6·2 and 8·4 per cent of the administered dose. In addition, a small but significant amount of carbon-14 activity was present as urea (as determined from carbon dioxide evolved by urease) in the individual 24-hr. urines (0·26, 0·17, and 0·24 per cent).

The fact that previous workers did not obtain any indication that nicotine is degraded to carbon dioxide may be attributed to a lower level of methyl-^{14}C activity of the nicotine used in their experiments. Although our work with nicotine-methyl-^{14}C has not included any experiments on the dog, and does not indicate the precise point at which demethylation occurs, the fact that demethylcotinine arises from both (−)-nicotine and (−)-cotinine[4] in the dog points to the importance of single-carbon compounds in the metabolism of nicotine in this species.

Since the radioactivity of randomly labelled nicotine-^{14}C is excreted[2] to the extent of 94 per cent in the urine of rats, the addition of carbon-14 determined as carbon dioxide in our investigations gives a total elimination which approaches 100 per cent. This provides convincing evidence that, after single doses, storage of nicotine or its metabolites occurs to only an extremely limited extent.

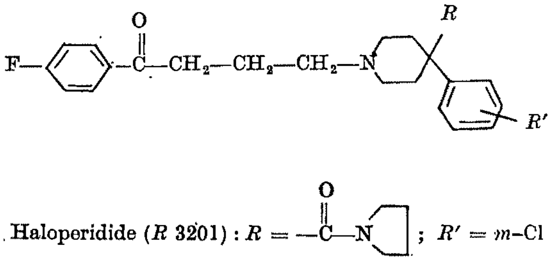
Haloperidide (*R* 3201), a Highly Potent and Selective Anti-emetic Agent in Dogs

HALOPERIDIDE, the proposed generic name for 4′-fluoro-(4-(4′-pyrrolidin-amido-4′-*m*-chlorophenyl)-piperidino)-butyrophenone (serial number *R* 3201), was synthesized in the Organic Chemistry Department of this Laboratory. It is a new member of the butyrophenone series of neuroleptic compounds (Fig. 1). The prototype of this series, haloperidol (*R* 1625), has been described in a number of pharmacological and clinical publications. It has been shown that haloperidol is pharmacologically related to the potent neuroleptics of the phenothiazine-series[1–6].

Both haloperidol and perphenazine are potent inhibitors of the emetic effect of apomorphine in dogs[2,3,5]. After subcutaneous injection, haloperidol has a quicker onset and a considerably longer duration of action than perphenazine, the estimated potency ratios varying considerably as a function of the time-interval between the injection of the drug and of the apomorphine challenging dose (Table 1). Haloperidide is considerably more active than either haloperidol or perphenazine in this test. It has a somewhat longer duration of anti-emetic action than perphenazine, but the onset of its effect is much shorter (Table 1).



Haloperidide (*R* 3201): *R* = —CO—N ; *R′* = *m*-Cl

Haloperidol (*R* 1625): *R* = OH; *R′* = *p*-Cl

Table 1. POTENCY RATIOS IN DOGS

Hr. after subcutaneous injection	Drug	*A* anti-emetic potency	*B* 'jumping box'	Ratio *A*/*B*
1–5	perphenazine	1	1	1
	haloperidol	1	4	1/4
	haloperidide	10	4	5/2
25–30	perphenazine	1	1	1
	haloperidol	4	6	2/3
	haloperidide	20	4	5

In an effort to evaluate the selectivity of these anti-emetic effects, we investigated the influence of the three drugs on avoidance and escape behaviour of trained dogs in a 'jumping box' situation. The details of the procedure, similar to the well-known Warner technique for rats, are described in a previous communication[6].

Briefly, the 'jumping box' consists of two compartments, separated by a partition. The floor of each compartment is a grill which can be charged electrically. The animal can escape shock or avoid it by jumping into the other compartment when presented with a warning signal (buzzer; maximum duration of 15 sec.). After adequate training, the dogs are treated at random at weekly intervals with selected doses of each compound, the effects on reaction-time, avoidance and escape being investigated 1, 5, 25 and 30 hr. after dosage.

The potency ratios in Table 1 are derived from two separate Latin square experiments. In one experiment four doses of haloperidol and four doses of haloperidide were investigated in eight dogs (8 × 8 design). In the other experiment six dogs were treated with three doses of haloperidol and three doses of perphenazine (6 × 6 design). The results obtained with all three substances are qualitatively similar. At low dose-levels, reaction times are prolonged. With increasing dosage, this effect leads to gradual and transient loss of learned avoidance and of escape behaviour.

It is concluded that haloperidide is a more potent, more selective, faster and longer acting antagonist of the emetic effects of apomorphine than perphenazine.

It is also more potent and more selective than haloperidol, but shorter acting.

Effect of Erythropoietine on Incorporation of Formate labelled with Carbon-14 into the Nucleic Acids of Normal Rabbit Tissues *in vitro*

It has previously been shown that the blood and urine of rabbits suffering from hæmolytic anæmia contain a mucoprotein humoral factor, hæmopoietine or erythropoietine, which on injection into normal animals stimulates erythropoiesis[1]. The present experiments were undertaken to find out what effect this factor might have on nucleic acid biosynthesis in normal rabbit tissues *in vitro*. A crude preparation of erythropoietine was obtained from the urine of animals made anæmic with phenylhydrazine. The urine was brought to *p*H 4·5 with hydrochloric acid, and 4 volumes of ethanol were added. After standing overnight at 4° C. the precipitate was centrifuged down, washed with ethanol and ether, and dried. The dry powder was extracted with a small volume of Krebs–Ringer bicarbonate buffer. The protein concentration of this 'anæmic urine extract' was determined by the biuret method. A 'normal urine extract' was similarly prepared from the urine of normal rabbits. The effects of both extracts on the incorporation of formate labelled with carbon-14 into the nucleic acids of bone marrow, spleen and liver *in vitro* were determined by the methods of Smellie *et al.*[2].

Table 1. Incorporation of ^{14}C-formate* into Nucleic Acid Bases of Normal Rabbit tissues *in vitro*

Additions	Product analysed	Specific activity (counts/min./μmole)					
		Bone marrow		Spleen		Liver	
		RNA	DNA	RNA	DNA	RNA	DNA
Nil	Adenine	2,495	1,183	426	188	128	406
	Guanine	539	631	167	113	100	102
	Thymine		24,500		317		1,026
'Normal urine extract'†	Adenine	980	536	489	159	240	486
	Guanine	335	395	202	108	167	—
	Thymine		16,200		438		675
'Anæmic urine extract'†	Adenine	3,080	963	3,750	662	3,055	734
	Guanine	—	374	1,205	372	1,220	425
	Thymine		28,400		730		671

Incubation time, 4 hr. * Isotope concentration, 5 μc./ml. † Concentration of extracts, 2·3 mgm. protein/ml. RNA, ribonucleic acid; DNA, deoxyribonucleic acid.

The results obtained are shown in Table 1. In agreement with results previously reported[3], the pattern of incorporation in normal bone marrow is characterized by the very high activity of the deoxyribonucleic acid thymine relative to the purines of both ribonucleic acid and deoxyribonucleic acid. In contrast, in spleen and liver deoxyribonucleic acid the activity of the thymine is generally only slightly greater than that of the purines. In previous papers[2,3] it has been argued that these observations may indicate that bone marrow, unlike the other tissues, may be incapable of synthesizing purine nucleotides fast enough to meet its own requirements. Bone marrow also differs from spleen and liver in its response to the urine extracts. The 'anæmic extract' produces virtually no effect on it, while the 'normal extract' tends to depress the activity of the nucleic acid purines and to a lesser extent, of the deoxyribonucleic acid thymine. In liver and spleen, on the other hand, the 'normal extract' has little or no effect, while the 'anæmic extract' causes a dramatic increase in the activity of the purines in both nucleic acids. In spleen, though not in liver, the anæmic extract also increases the activity of the deoxyribonucleic acid thymine.

These observations suggest that *in vivo* erythropoietine may stimulate *de novo* nucleic acid synthesis in liver and spleen, but not in bone marrow. However, Smellie *et al.*[4] have found that, in the rabbit, hæmolytic anæmia results in increased incorporation of $^{32}PO_4$ into the nucleic acids, not only of spleen, but also of bone marrow. An explanation of this latter observation may perhaps be found in the relationship between liver and bone marrow. Lajtha and Vane[5] have shown that *in vivo* hepatectomy greatly diminishes incorporation of ^{14}C-formate into the nucleic acid purines of rabbit bone marrow. Clearly, therefore, the liver must play some part in the synthesis of the purines which the bone marrow requires (for example, for nucleic acid synthesis), but which it cannot synthesize for itself. It is therefore quite possible that erythropoietine might stimulate erythropoiesis in the bone marrow indirectly by acting on the liver. The increased incorporation of ^{14}C-formate into liver nucleic acid purines produced by erythropoietine in the present experiments might be a reflexion of such action.

Adrenocorticotrophin and the Sugar-level in Plasma in Young Fowls

THIS communication is prompted by the finding of Urist and Deutsch[1] that large doses of freeze-dried adrenocorticotrophin of mammalian origin were without effect on the blood sugar of adult cocks (Black Minorcas) and hens (White Leghorns). Some years ago, work in this laboratory required the intramuscular injection of Brown Leghorn pullets and cockerels (5 weeks of age, body-weight 500 gm.) with large doses of long-acting adrenocorticotrophin ('Acthar', Armour). It was found that the hormone could produce a marked rise in the level of plasma sugar in these young birds, which were kept in brooders with free access to food and water throughout the experimental period.

Trichloroacetic acid filtrates of the plasma were analysed by my adaptation[2] of Jones and Pridham's method[3] (1954). Injections (0·5 ml.; 20 I.U.) of 'Acthar' were made into the pectoral muscle and the birds returned to the brooder. These injections were repeated on the two following days. The birds at no time showed signs of distress or lack of appetite. On the fourth day, blood was again taken for analysis; in some instances further samples were taken on the 5th, 8th and 18th days after the start of the experiment. Control birds were not injected.

The results are summarized in Table 1. While injection of adrenocorticotrophin was followed on the 4th day by a marked rise in the plasma sugar in seven out of eight experiments, by the 5th day the sugar had fallen to, if not below, the normal level. The responses of the two sexes were indistinguishable. It will be noted that the effect of the long-acting 'Achthar' was not observed 48 hr. after the last injection.

The present findings, along with those of others, on the effects of adrenocorticotrophin, raise the question whether the stage of development of the fowl is a factor in relation to the effects of the hormone. Urist and Deutsch[1] found no effect on the sugar-level of whole blood from adult birds when this hormone was administered, in contradistinction to mammalian species. Perek and Eckstein[4], and Perek and Eilat[5] showed that the adrenals of the young immature bird failed to respond to adrenocorticotrophin with respect to ascorbic acid depletion, again in contradistinction to the mammal, due to the activity of a lymphoepithelioid organ of as yet incompletely defined function, the bursa of Fabricius. This, situated at the dorsal aspect of the proctodæum, involutes during the approach to maturity. The ascorbic acid of the adrenal of the bursectomized chick is responsive to adrenocorticotrophin. (*Note added in proof.* H. S. Siegel and W. L. Beane (*Poultry Sci.*, 40, 216; 1961) have also observed hyperglycæmia subsequent to intramuscular adrenocorticotrophin-gel in 6–7-week-old fowls.)

Table 1. EFFECTS ON REDUCING SUGAR OF PLASMA OF INTRAMUSCULAR 'ACTHAR' GEL ON FIVE-WEEK-OLD PULLETS AND COCKERELS
Injections were given on days 1, 2 and 3

Exp. No.	Injection Days	Plasma reducing sugar (mgm./100 ml.) *D*1	*D*4	Change *D*1 to *D*4	*D*5	*D*8	*D*18

—		190	205	+ 15	—	—	—
—		190	200	+ 10	—	—	—

Drs. J. Beattie and J. G. Campbell and I find that bursectomy does not alter the positive response of the 5-week-old bird to long-acting adrenocorticotrophin. Adults, 24 hr. after 40 I.U., show 500–600 mgm. of reducing sugar per 100 ml. of plasma along with diuresis and glycosuria. On the other hand, I have so far failed to find any hyperglycæmic effect, on young intact and bursectomized birds, after freeze-dried adrenocorticotrophin.

Presence of Sialic Acid in a Granuloma Pouch

THE presence of sialic acid in connective tissues has already been described[1]. It is well known that by means of a granuloma pouch newly formed connective tissue can be induced; this is very important for the evolution of inflammation. The presence and the concentration of sialic acid in the granuloma pouch have now been investigated.

Granulomas were induced in 150-gm. male rats by the use of 10 ml. of air and 0·4 ml. of croton oil solution (4 per cent in olive oil). The animals were killed 1, 3, 5 and 8 days after treatment. The dissected granulomas were homogenized in acetone and stirred for 48 hr.; after centrifugation, the sediment suspended in ethyl ether was dried in vacuum. The powder so obtained was employed to determine nitrogen and sialic acid content by Svennerholm's method[2].

For the last determination the powder was hydrolysed with 0·1 *N* sulphuric acid at 80° C. for 1 hr.; the hydrolysate was filtered on a sintered glass filter and chromatographed on a 'Dowex 2 × 8' column; after elution with 1 *M* acetate buffer *p*H 4·6, the eluate was tested by the resorcinol reaction and sialic acid was identified by the absorption spectrum of the reaction.

A control determination was carried out using an untreated region of the abdomen (non-inflamed tissue).

Table 1. PRESENCE OF SIALIC ACID IN A GRANULOMA POUCH INDUCED IN RAT

Days after treatment	Values referred to 100 mgm. of acetonic powder: Granuloma pouch	Non-inflamed tissue
1	480 μgm.	96 μgm.
		91 ,,
3	426 ,,	78 ,,
	473 ,,	
5	319 ,,	
	386 ,,	
8	313 ,,	47 ,,
	343 ,,	

N-acetyl neuraminic acid, kindly supplied by Prof. G. Blix, was used as a standard to determine the sialic acid quantitatively. The results are presented in Table 1.

The results indicate that the content of sialic acid in a granuloma pouch is much greater than in a corresponding abdominal region not involved in the pathological process.

Content of Sialic Acid in Serous Glands of Equines

In histochemistry it is well known that an objection to the specificity of the periodic acid–Schiff reaction for mucopolysaccharides is due to the possible interference of some amino-acids. This objection is particularly important when the periodic acid–Schiff reaction is applied to serous glands, in which the secretion is essentially proteins. However, Junqueira *et al.*[1] found material giving a positive reaction in the parotids of many mammals, and concluded that substances other than proteins were present in the secretion of parotid gland. This observation opened up an interesting problem of cellular biology, regarding the possibility of a multiple secretion from serous glands.

In order to confirm this observation, a comparative histochemical investigation of material positive to the periodic acid–Schiff reagent and the ribonucleic acid content of some serous glands was carried out by Bignardi *et al.*[2]. This investigation, using pancreas, parotid and orbital glands of equines, demonstrated that the intensity of periodic acid–Schiff reaction varied inversely with the ribonucleic acid content. On the basis of general views on the function of ribonucleic acid in protein biosynthesis, this result was interpreted as indirect evidence that positive reaction to the periodic acid–Schiff reagent was really due to carbohydrate material.

Since more direct evidence for this view could be obtained by chemical analysis of some constituent of mucopolysaccharides, we have investigated the content of sialic acid in serous glands. The emphasis on sialic acid was due to its presence in submaxillary mucin[3] and to its strong reactivity for periodic acid. (In a very recent paper of Quintarelli *et al.*[4], a relation between sialic acid and positive periodic acid–Schiff reaction has been reported.)

Sialic acid has been determined in orbital glands (lacrimal gland and gland of the third eyelid), parotid and pancreas of ass and horse.

The glands were removed and stored under acetone. About 50 mgm. (dry tissue) of each gland was used for sialic acid determination, which was carried out by Svennerholm's method[5]. The tissue was homogenized with 5 ml. of 0·1 *N* sulphuric acid by Potter–Elvehjem homogenizer and refluxed at 80° C. for 1 hr. The hydrolysate was centrifuged and the supernatant chromatographed on 'Dowex 2 × 8'; the sialic acid was eluted by acetate buffer 0·1 *M*, *p*H 4·6, and sialic acid determined by the resorcinol reaction.

Table 1. Content of Sialic Acid in Serous Glands of Equines
(Values are referred to 100 mgm. of dry tissue)

Horse*				
1	621 μgm.	408 μgm.	157 μgm.	134 μgm.
2	778 ,,	427 ,,	138 ,,	168 ,,

* The presence of sialic acid in parotid gland of the horse has been reported by Svennerholm (ref. 5).

The standard curve was obtained with N-acetylneuraminic acid isolated from sheep submaxillary gland and kindly supplied to us by Prof. G. Blix. The results are reported in Table 1.

The results show that the highest content of sialic acid is in the orbital glands, a low content in parotid and the lowest in pancreas. Since positive periodic acid–Schiff reaction is also highest in glands of the orbit, is less in the parotid and is weakly positive in the pancreas, there seems to be a relation between the periodic acid–Schiff reaction and sialic acid content.

The presence of sialic acid and, probably, of a sialopolysaccharide, in serous glands shows that these glands elaborate not only protein but also carbohydrate material.

In vivo Metabolism of N-Acetylhexosamine ^{35}S-Sulphate Esters

In a previous report[1] evidence was presented indicating that the monosulphate ester obtained as the principal product of the direct sulphation of N-acetyl-D-glucosamine with chlorosulphonic acid was identical with N-acetyl-D-glucosamine 6-O-sulphate prepared by definitive synthesis. In addition, following preliminary observations on the structure of the monosulphate ester prepared by the direct sulphation of N-acetyl-D-galactosamine[1], independent results from work on tritylation (triphenylmethylation)[2], and infrared spectroscopy[3,4], indicate that this material is also a 6-O-sulphate ester. Since available information suggests that N-acetyl-D-glucosamine 6-O-sulphate and N-acetyl-D-galactosamine 6-O-sulphate exist *in vivo* as part of the polymer chains of keratosulphate and chondroitin sulphate-C respectively[5,6], it was of interest to examine the *in vivo* metabolism of these N-acetylhexosamine sulphate esters.

The direct action of chloro-^{35}S-sulphonic acid on N-acetyl-D-glucosamine and N-acetyl-D-galactosamine yielded in each case a mixture of the mono-^{35}S-sulphate derivative together with the di-^{35}S-sulphate and unchanged parent compounds[1]. These preparations were fractionated by zone electrophoresis on

Table 1. DISTRIBUTION OF RADIOACTIVITY IN RAT URINE, FÆCES AND CARCASE AFTER THE INJECTION OF N-ACETYL-D-GLUCOSAMINE 6-O-^{35}S-SULPHATE

Results (expressed as percentage of the injected dose) are average values for 3 animals in each instance. The radioactivity of the doses corresponded to $1{\cdot}3 \times 10^5$ counts/min. cellulose columns[2] and the 6-O-^{35}S-sulphate esters finally isolated as the potassium salts. Chromatography of the products on Whatman No. 1 filter paper using downward irrigation with butan-1-ol/acetic acid/water, 50 : 12 : 25 (by vol.) or *iso*butyric acid/0·5 *N* ammonium hydroxide, 5 : 3 (by vol.) showed that each contained only a single component. The N-acetyl-D-glucosamine ester labelled with sulphur-35 was identical in chromatographic mobility with authentic N-acetyl-D-glucosamine 6-O-sulphate in both the solvents named above.

Male and female M.R.C. hooded rats (aged 2–3 months and weighing 130–150 gm.) were injected intraperitoneally with aqueous solutions of the labelled esters. The animals were housed separately in the funnel-type of metabolism cage and the urine and fæces collected at 24-hr. intervals up to 96 hr. Samples of the urine and fæces were taken for the determination of radioactivity according to Dodgson and Tudball[7]. At the end of the experimental period the animals were killed by a blow on the back of the head and the carcase used for the determination of retained radioactivity. The results of these experiments are recorded in Tables 1 and 2.

The striking feature of the metabolism of both N-acetyl-D-glucosamine 6-O-^{35}S-sulphate and N-acetyl-D-galactosamine 6-O-^{35}S-sulphate is the rapid elimination of radioactivity, 87–94 per cent of the injected doses appearing in the combined inorganic and ester sulphate fraction of urine in the 24-hr. period immediately following administration. The appearance of 9·0–11·5 per cent of the dose as inorganic ^{35}S-sulphate in the urine during the 96-hr. period after the injection of both esters is also of interest since it supports previous observations of the release of inorganic ^{35}S-sulphate in the urine of rats following the administration of labelled polysaccharides containing N-acetylhexosamine ^{35}S-sulphate residues[8,9]. It was found that radioactivity was retained in the carcase after 96 hr. in all instances. However, in view of the appearance of inorganic ^{35}S-sulphate in the urine, it is not possible to differentiate between the specific uptake of the intact labelled esters into the keratosulphate and chondroitin sulphate-C fractions of rat and a general incorporation of inorganic ^{35}S-sulphate into all the ester sulphates of rat tissues. A detailed account of these and other observations will be given elsewhere.

This work was supported by a grant from the Empire Rheumatism Council and in part by a grant (*A* 1982) from the Arthritis and Metabolic Diseases Division of the U.S. Public Health Service.

Identification of Sugars in the Manna of Northern Iraq

MANNA is found in the Middle East in the Sinai peninsula and in Northern Iraq. Bodenheimer and Theodor[1] claimed that the manna they found on the leaves of *Tamarix* in Sinai is the excretion of the scale insects *Trabutina mannipara* and *Najacoccus serpentinus*. However, it is generally believed in northern Iraq (Allos, H. F., private communication) that manna is an exudate of *Fraxinus ornus* L. (West, W. A., private communication), probably from insect-produced wounds. The exudate usually accumulates on the leaves until they fall to the ground. The sugars are extracted from the raw material with boiling water and mixed with eggs to make a popular dessert. While sucrose and invert sugar have been identified in manna collected from Sinai[2], the Iraqi manna was shown to contain sucrose and melezitose[3] as well as trehalose[4].

Table 1. IDENTIFICATION OF SUGARS IN MANNA

Fraction		R_g values*		Response to reagents†						Hydrolysis products‡	Identity of Unknown
				I	II	III	IV	V	VI		
Monosaccharides	1	Unknown	112	*bn*	+	+	+	–	–		Fructose

* Chromatograms were developed in butanol/pyridine/water (2 : 2 : 1); other developers gave comparable results.

† I, Aniline-diphenylamine (*b*, blue; *bn*, brown; *g*, grey; II, silver nitrate; III, 2 : 4-dinitrophenylhydrazine; IV, phloroglucinol; V, vanillin; VI, ammonium molybdate.

‡ These were identified by their R_g values and response to above-mentioned reagents.

Samples of manna collected in the Suleimaneyeh District in northern Iraq were kindly supplied to us by Dr. H. F. Allos. The sticky mass was dark grey in colour and contained some soil particles and leaf residues. Approximate analysis showed it to contain 5·9 per cent moisture, 0·2 per cent fat, 2·8 per cent protein, 5·2 per cent ash, 6·7 per cent fibre and 79·2 per cent carbohydrates (by difference).

The sugars were extracted from the manna with hot 80 per cent ethanol and the extract was desalted on 'Amberlite' resins '*IR*–120' and '*IRA*–410', then concentrated under vacuum to a thick syrup. The extract was chromatographed on a charcoal column, according to Whistler and Durso[5] and mono-, di- and tri-saccharides were eluted with water, 5 and 15 per cent ethanol, respectively. The adsorbent was then treated with 30 per cent ethanol to elute polysaccharides. Each of the four fractions was concentrated under vacuum and chromatographed on Whatman No. 4 paper strips (4 cm. × 60 cm.). The di-, tri- and poly-saccharide fractions were hydrolysed by refluxing with 50 volumes of *N* sulphuric acid for 6 hr., neutralizing with solid barium carbonate to congo red paper, centrifuging and chromatographing the supernatant. Paper chromatography was also carried out on the sugar extract from the manna.

The sugar constituents of the manna were identified according to:

(1) Their R_g values as compared with those of standard sugars and sugar derivatives developed simultaneously. The following developers were used and gave comparable results: 2-propanol/water (4 : 1), 2-propanol/pyridine/acetic acid/water (8 : 8 : 1 : 4), propanol/ethyl acetate/water (7 : 1 : 2), butanol/pyridine/water (2 : 2 : 1), phenol/water (4 : 1) and ethylacetate/pyridine/water (2 : 1 : 2).

(2) Specific reactions of sugars and sugar derivatives on the chromatogram:

(I) Aldoses and ketoses by aniline–diphenylamine spray, according to Buchan and Savage[6].

(II) Reducing sugars by the silver nitrate reagent described by Trevelyan and his associates[7].

(II) Fructose, sucrose and raffinose by spraying with saturated solution of 2,4-dinitrophenylhydrazine[8].

(IV) Ketoses by phloroglucinol–trichloroacetic acid mixture according to Horrocks and Manning[9].

(V) Sugar alcohols by vanillin–perchloric acid reagent[10].

(VI) Phosphate esters by ammonium molybdate spray[11].

The results indicate the presence of glucose, fructose, sucrose, trehalose, raffinose and melezitose, as shown in Table 1. While the polysaccharide fraction hydrolysed into glucose only, it gave no colour with iodine and showed no reducing power.

It is of interest to note that with the exception of glucose and fructose, which together constitute about 10 per cent of the carbohydrates in manna, all the other sugars are non-reducing.

Molecular Mechanisms for Hydrolytic Enzyme Action

FROM kinetic and other studies of hydrolyses catalysed by enzymes several important conclusions have emerged. One of these, coming particularly from *p*H studies, is that both an acid (–*A*–*H*) and a basic (–*B*) group are in some way involved in the reaction. A second conclusion is that there are two reaction intermediates, an addition (Michaelis) complex (ES) and an acylated enzyme (ES'), so that the process may be represented as :

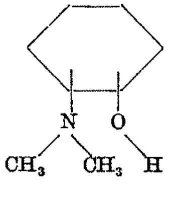
$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} ES \xrightarrow{k_2} \underset{+P_1}{ES'} \xrightarrow{k_3} E + P_2$$

The site that becomes acylated has been a matter of some controversy, both imidazole and serine being possibilities.

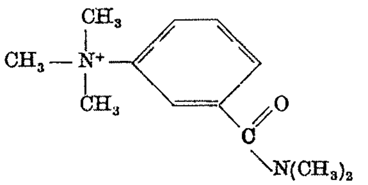
We have recently carried out a series of investigations on the enzyme acetylcholinesterase, and have studied the effects of *p*H changes and of various inhibitors. On the basis of a kinetic analysis, the details of which will be published elsewhere, we have arrived at certain conclusions which seem to be consistent with the results for other enzyme systems. These conclusions relate to the detailed configuration of the active centre of the enzyme and to the way in which the substrate and inhibitors interact with the various components of the active centre. Acetylcholinesterase has an important advantage from the point of view of elucidating these problems owing to its possession of an anionic site which serves as an 'origin' from which distances to other parts of the active centre can be deduced.

By working with two substrates, for one of which $k_2 > k_3$ and for the other $k_3 > k_2$, it has proved possible to separate effects on ES from those on ES'. Proceeding in this way, so far as *p*H changes are concerned, we find that the basic group on the free enzyme has a *pK* of 6·5 and the acid group one of 9·3. In the Michaelis complex ES the basic group is no longer able to add on a proton at *p*H 6·5, but in the acyl enzyme ES' the proton can be added on at about this *p*H. The group of *pK* 6·5 is believed to be the imidazole group, and our conclusion is that this group interacts with the carbonyl group of the substrate in the Michaelis complex, but does not do so in the acyl enzyme. There must therefore be a transfer of the carbonyl group to another group, presumably serine, during the process $ES \rightarrow ES'$.

There are two types of inhibitor for this enzyme ; those of the first class, which is exemplified by *cis*-2-dimethylaminocyclohexanol (I), give inhibition of the mixed competitive and non-competitive types, whereas those of the second, of which prostigmine (II) is an example, show pure competitive inhibition.



(I)



(II)

In (I) the distance between the nitrogen atom and the OH group is about 2·5 Å., whereas in (II) the distance between the nitrogen atom and the carbonyl carbon atom is about 5 Å. The difference between competitive and non-competitive inhibition is conventionally ascribed to differences in binding of inhibitor to the enzyme-substrate complex ; but this interpretation is excluded by our kinetic results for this system. We find that inhibitors of both classes can become attached to E and to ES' but not to ES. The difference between the types is that inhibitors of type I block the deacetylation reaction, whereas those of type II do not do so.

Support for this conclusion is provided by work we have done on the effects of the various inhibitors on the inhibition by substrate that is found with this enzyme. The results show that substrate inhibition is due not to the formation of a complex in which two substrate molecules are attached to the enzyme, but to the attachment of a substrate molecule to the acetyl enzyme with blocking of the deacetylation process. It can be shown from the steady-state equations that if an inhibitor blocks deacetylation the square of the concentration of substrate, $[S]_{\text{opt.}}$, corresponding to the maximum velocity, should vary linearly with [I] ; if it does not, $[S]_{\text{opt.}}$ itself should vary linearly with [I]. These predictions have been confirmed for inhibitors of each type, studied by Augustinsson[2], Augustinsson and Nachmansohn[3], and ourselves.

These facts lead to a clear-cut picture of the active centre of the enzyme and of the course of reaction. We conclude that when type I inhibitors become attached to the free enzyme they do so at the anionic site and at the acid (*A–H*) site, a hydrogen bond being formed between the hydrogen of the acid site and the oxygen atom on the inhibitor. The presence of the substrate prevents a similar attachment in ES, but since in ES' the acyl group of the substrate has become transferred to serine a two-point attachment of the inhibitor is now possible. Since deacetylation is now blocked, the hydrogen atom of the acid site must be required for this process.

In type II inhibitors the attachment to the free enzyme is at the anionic site and at the imidazole nitrogen, which forms an electrostatic bond with the C=O dipole of the inhibitor. Again, no attachment to ES is possible. For ES' we conclude that attachment is only at the anionic site ; the acyl group on the serine prevents attachment at the imidazole nitrogen. Since the inhibitor does not interact with the hydrogen atom of the acid site there is no inhibition of deacetylation.

These facts, and the deductions from them, lead to the picture of the active centre shown in Fig. 1. The acid and basic sites are situated 2·5 Å. and 5·0 Å. respectively from the anionic site, and the serine OH group is somewhat farther away. The figure also shows how, in our view, the substrate becomes attached to the enzyme. A more detailed

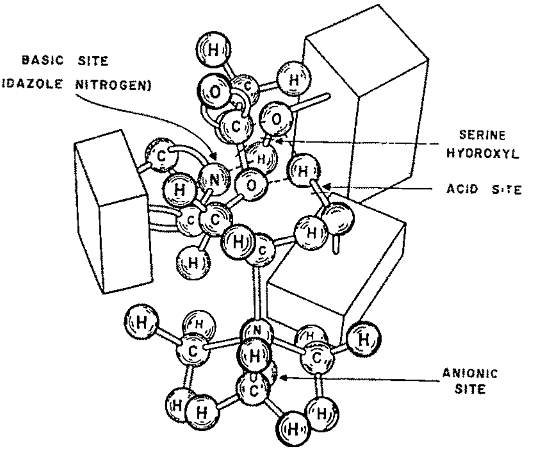


Fig. 1. Proposed arrangement of functional groups at the active centre of acetylcholinesterase. The substrate is shown in position, and electrostatic attractions occur at the dotted lines and also between the imidazole nitrogen atom and the carbonyl carbon atom. The dotted lines also indicate bonds formed during the acetylation process; the three bonds broken are marked on the diagram

discussion of the mechanism of the acetylation and deacetylation processes has been given elsewhere[4].

PHYSIOLOGY

Spontaneous Potentials from Explants of Human Adult Cerebellum in Culture

Using techniques and supernatant similar to those used to demonstrate spontaneous potentials from explants of chick embryo cerebellum in tissue culture in Kahn tubes[1], spontaneous potentials have been demonstrated in explants from the surface of the upper postero-lateral aspects of human adult cerebellum. The explants were thin slices of the full thickness of cerebellar grey matter together with some of the related white matter. The control used was dead chick cerebellar tissue, side by side with the living culture material in the same incubator, with identical amplification and recording apparatus. The living brain tissue gave the same form and magnitude of potentials on any recording channel which was tried. The form of the potentials is shown in Figs. 1 and 2. Fig. 1 shows the typical activity after 12 hr. in culture. This consists of pairs of potentials having a complex wave-form. The first of the potentials in each pair has a magnitude of 75 μV. and the other, which follows after an interval of 12–15 sec., has about one-third of this potential. The interval between the pairs of spikes is about 45 sec. Fig. 2 shows the typical activity after 24 hr. in culture. The pairing of the spikes is much less common, and when it does occur the interval between the two members of the pair is very irregular. The interval between the potentials is more irregular and varies about 20 sec. The potentials at this time have a magnitude of about 20 μV. The culture continued to have spontaneous electrical activity until more than 72 hr. after explantation. No record of spontaneous potentials from adult brain in culture have been found in the literature. Further investigations of these potentials are in progress.

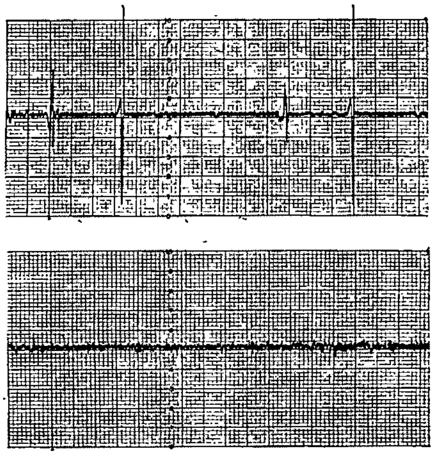

Fig. 1. Upper trace, spontaneous potentials from an explant of adult human cerebellum 12 hr. after explantation. Vertical lines 1 sec. apart; amplitude scale—distance between two horizontal lines equals $1\frac{1}{2}$ μV. Lower trace, control of dead cerebellar tissue under identical conditions and with identical time and amplitude scales

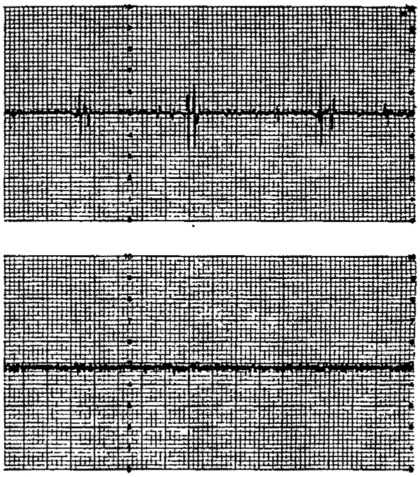

Fig. 2. Upper trace, spontaneous potentials from an explant of adult human cerebellum 24 hr. after explantation. Vertical lines 1 sec. apart; amplitude scale—distance between two horizontal lines equals $1\frac{1}{2}$ μV. Lower trace, control of dead cerebellar tissue under identical conditions and with identical time and amplitude scales

Assay of 5-Hydroxytryptophan Decarboxylation in Intact Brain

Intraperitoneal injection of 5-hydroxytryptophan (5HTP) shortly before death causes a considerable post-mortem rise of 5-hydroxytryptamine (5HT) in the brain of rats. This may be explained by the fact that 5HTP decarboxylation continues during the first few hours post-mortem whereas monoamine degradation by monoamine oxidase is probably considerably reduced[1]. In the work reported here the question was investigated whether this 5HTP induced post-mortem increase of brain 5HT might be used as a test for decarboxylase inhibitions. D,L-α-Methyl dihydroxyphenylalanine (α-methyl DOPA)[2–6] served as a model inhibitor.

Male Wistar rats weighing 60–80 gm. and fasted for 16 hr. were given 75 mgm. D,L-5HTP/kgm. by subcutaneous injection $\frac{1}{2}$ hr. before decapitation. The 5HT content was determined by a spectrophotofluorometric method[7]: (*a*) in brain homogenized in 0·1 *N* hydrochloric acid immediately after death; (*b*) 2 hr. after incubation of the severed heads at 37° C. in small closed wet chambers. The 5HT difference between group (*a*) and (*b*) served as a measure for decarboxylase activity. α-methyl-DOPA was injected intraperitoneally at various intervals before decapitation and the post-mortem rise of 5HT compared with that of controls.

In 5HTP pretreated rats the level of brain 5HT measured immediately after decapitation was 1·00 ±

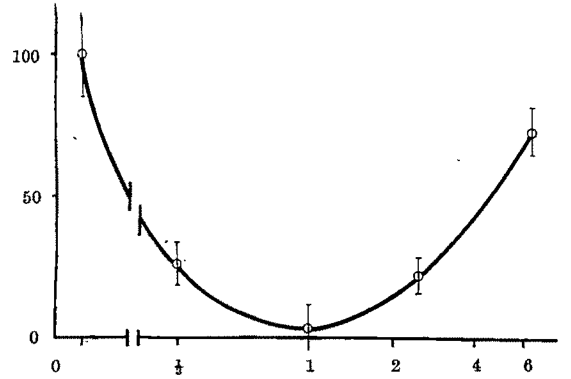

Fig. 1. Inhibition of post-mortem decarboxylation of 5-hydroxytryptophan (5HTP) by D,L-α-methyl dihydroxyphenylalanine (α-methyl DOPA) in intact rat brain in relation to time. Abscissa, hours after intraperitoneal injection of 105 mgm./kgm. α-methyl DOPA (logarithmic scale); ordinate, percentage 5-hydroxytryptamine (5HT) increase during the first 2 hr. after decapitation as compared with animals not receiving α-methyl DOPA. Subcutaneous injection of 75 mgm./kgm. D,L-5HTP ½ hr. prior to decapitation. Each point represents average and standard error of nine 5HT determinations

0·06 γ/gm. (controls 0·63 ± 0·02 γ/gm. 5HT). Incubation of the severed heads at 37° C. caused a further increase of 5HT of 0·86 ± 0·10 γ/gm. (considered as 100 per cent). α-methyl DOPA inhibited the post-mortem increase of 5HT considerably. The dose-dependent effect was maximal after 1 hr. and almost completely abolished after 6 hr.; 50 per cent inhibition was obtained by about 25 mgm./kgm. within 1 hr. (Figs. 1 and 2).

These findings show that the 5HTP induced post-mortem rise of 5HT is suitable for the investigation of decarboxylase inhibitors in brain. The results are in agreement with those obtained by measurement of decarboxylase activity in brain homogenates after injection of α-methyl DOPA into mice[6]. This method has the following advantages:

(1) Decarboxylase exerts its action in intact brain and not in disintegrated and diluted tissue (homogenates, supernatant, etc.).

(2) Monoamine oxidase activity does not interfere to any great extent, since under the almost anaerobic conditions post mortem it is nearly completely abolished[1]. Pharmacological inhibition of monoamine oxidase (for example, with iproniazid) is not necessary for the measurement of decarboxylation.

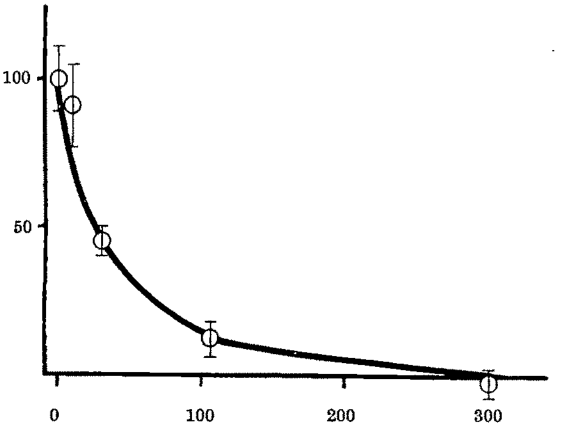

Fig. 2. Inhibition of post-mortem 5-hydroxytryptophan (5HTP) decarboxylation in intact rat brain, by D,L-α-methyl dihydroxyphenylalanine (α-methyl DOPA) in relation to dose. Abscissa, dose of α-methyl DOPA in mgm./kgm.; ordinate, percentage 5-hydroxytryptamine (5HT) increase within 2 hr. after decapitation as compared with animals not receiving α-methyl DOPA. Intraperitoneal injection of α-methyl DOPA 1 hr., subcutaneous injection of 75 mgm./kgm. D,L-5HTP ½ hr. before decapitation. Each point represents average and standard error of 5–11 5HT determinations

(3) The sensitivity is probably superior to that obtained by measurement of endogenous 5HT in brain. In the post-mortem method with rat brain 50 per cent decarboxylase inhibition can be obtained by about 25 mgm. α-methyl DOPA. A slight but significant decrease of endogenous 5HT in mouse brain, however, becomes evident only after 100 mgm./kgm. of the inhibitor[4].

Investigations on the decarboxylation of dihydroxyphenylalanine using the post-mortem method described are under way.

Sodium Transport and Oxygen Consumption in the Mammalian Kidney

IN the isolated frog skin, it was found by Zerahn[1] and by Leaf and Renshaw[2] that the amount of sodium actively transported had a fixed relationship to the net oxygen consumption (sodium/net oxygen ratio), as about 18 sodium ions were transported per molecule of oxygen consumed under a variety of experimental conditions. Net oxygen consumption was defined as the difference between the total oxygen uptake and the basal uptake, that is, the oxygen uptake when no sodium transport took place. In the mammalian kidney, active re-absorption of sodium (anions and water following passively) represents on a molar basis the overwhelming part of all tubular transport processes. On the assumption that sodium re-absorption does therefore require the bulk of the oxidative energy supplied, we have determined the sodium/net oxygen ratio in the intact kidney of the dog.

The basal oxygen consumption of the dog kidney, here defined as the oxygen consumption when no filtration and hence no re-absorption take place, was determined in four anæsthetized dogs during hypotension induced by bleeding. The absence of filtration was evident from an inulin extraction close to zero. During twelve observation periods, in which the mean arterial blood pressure varied from 30 to 67 mm. mercury, renal blood-flow (in ml./gm./min.) was measured by the free outflow method, and the arteriovenous oxygen difference (in μmol./ml.) was determined manometrically[3]. It can be seen from Fig. 1 that the arteriovenous difference for oxygen rose sharply as blood-flow fell to less than 1 ml./gm./min., causing relatively constant consumption of oxygen over a wide range of variation in the rate of perfusion. This value was 0·215 ml. oxygen/gm. kidney/min. or 1·0 μmol./gm./min. (*S.E.* of mean, 0·04), and was considered to represent the basal oxygen uptake of the kidney. A basal oxygen consumption of a similar

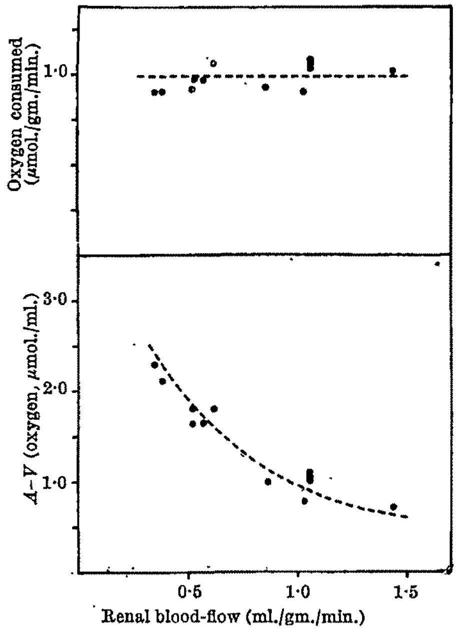

Fig. 1. Relationship between renal blood flow (in ml./gm./min.) and the arteriovenous oxygen difference (in μmol./ml.) of the non-filtering kidney during hæmorrhagic hypotension. The calculated oxygen consumption has a mean value of 1 μmol./gm. kidney/min. and is seen to remain relatively independent of wide variations in the rate of blood perfusion

magnitude has been found in various exocrine glands of the dog: submaxillary[4] 1·4 and 1·2, parotid[5] 1·4, and pancreas[6] 1·3, μmol./gm./min.

The relationship between sodium re-absorption and suprabasal (net) oxygen consumption of the normally filtering kidney was determined on eight anæsthetized dogs. The femoral artery, the left renal vein and both ureters were cannulated, and standard clearance techniques were used involving inulin and sodium *p*-aminohippurate. Sodium re-absorption (in μequiv./gm. kidney/min.) was calculated from the amount filtered minus the amount excreted in the urine. The net consumption of renal oxygen (in μmol./gm. kidney/min.) was calculated as the product of the arteriovenous difference for oxygen and renal blood-flow, subtracting the basal oxygen consumption of 1·0 μmol./gm./min. The results are shown in Table 1. Despite large variations in the rate of sodium re-absorption, the sodium/net oxygen ratios remained fairly constant in the eight dogs. The mean ratio was 28·5 (*S.D.* 2·9) and is in agreement with the value of about 30 which can be estimated from data in the literature on normal man.

Table 1. RENAL OXYGEN CONSUMPTION AND SODIUM RE-ABSORPTION OF THE DOG

Dog No.	No. of observations	Sodium re-absorption (μequiv./gm./min.)	Total oxygen consumption (μmol./gm./min.)	Net oxygen consumption (μmol./gm./min.)	Sodium/net oxygen ratio
8	4	91·3	4·0	3·0	30
12	7	172·5	6·9	5·9	29
13	3	192·1	8·6	7·6	25
15	6	113·5	5·2	4·2	27
16	6	126·0	5·9	4·9	26
17	5	122·4	5·5	4·5	27
V	3	100·6	3·9	2·9	35
VII	3	103·1	4·6	3·6	29
Average		127·7	5·6	4·6	28·5 (*S.D.* 2·9)

The present results thus suggest that the intact mammalian kidney, like the isolated frog skin, has a fixed relation between sodium transport and net oxygen consumption. The sodium/net oxygen ratio has a somewhat larger value in the kidney (about 29) than in frog skin (about 18), but it is of interest that the consumption of one equivalent of oxygen (1/4 mole of oxygen) generates sufficient energy for the transport of several equivalents of sodium in both systems.

The concept that the renal oxygen uptake can be divided into a relatively small but constant basal uptake and a variable functional uptake, which is dominated by, and bears a constant relationship to, tubular sodium re-absorption, may explain some classical observations in renal physiology.

A large arteriovenous oxygen difference has been found in uncompensated heart disease, where the filtration fraction is large and the renal blood-flow reduced[7]. Conversely, a small arteriovenous oxygen difference results from infusion of albumin, which causes a reduction of the filtration fraction and an increase in blood-flow[8]. It is evident from the present hypothesis that variations in the filtration fraction may influence the arteriovenous oxygen difference; but it is important to consider also variations in renal blood-flow, since the basal oxygen consumption of the kidney must influence the arteriovenous oxygen difference the more the lower the rate of perfusion. Theoretically, variations in the arteriovenous oxygen difference $(A-V)O_2$, can be predicted if the following variables are determined: renal blood-flow (RBF), hæmatocrit (H), filtration fraction (FF), plasma sodium (P_{Na}), excretion fraction of sodium (E_{Na}), and renal weight (W):

$$(A-V)O_2 \text{ in ml./100 ml.} =$$

$$2{\cdot}24\left[W/RBF + \frac{1}{29}(1-H)(1-E_{Na})P_{Na}FF\right]$$

In contrast with other organs, a moderate reduction of renal blood-flow results in a decrease in renal uptake of oxygen. Since the filtration and hence re-absorption of sodium is also reduced in this situation, the observed correlation is readily explained. Only when blood pressure is reduced below the limit where filtration ceases, the kidney—like any other organ—extracts more oxygen per millilitre of blood in response to a reduction of the rate of perfusion, maintaining constant consumption of oxygen.

Thus, in both situations the kidney conforms to the general physiological principle first formulated by Barcroft[4], that oxygen consumption is directly related to function. Hence the seemingly puzzling difference between the oxidative metabolism of the kidney and other organs becomes merely a consequence of the unique fact that renal work is determined by, and roughly correlated to, renal blood-flow.

Renal oxygen consumption is not correlated to tubular *para*-aminohippurate transport or to urinary urea excretion[9]. These observations fit well into the theory of the dominant role of sodium transport, since no gross changes in the re-absorption of sodium occurred during the experiments, in which the effect of variations in renal handling of these two substances were studied.

The efficiency of the kidney is approximately 1 per cent when thermodynamic considerations are applied to the composition of the urine relative to plasma[10].

Such calculations disregard the oxygen cost of isotonic re-absorption of sodium. If renal oxygen uptake is stoichiometrically related to the quantity of sodium re-absorbed, then the oxygen uptake cannot be expected to bear a fixed relation to the thermodynamically calculated (minimal) work involved in producing the final urine. Hence the concept of 'renal efficiency' may be considered physiologically meaningless.

This discussion has directed attention to some of the implications of applying the concept of a fixed sodium/net oxygen ratio to the mammalian kidney. More experiments are clearly needed in order further to investigate the validity and possible limitations of this concept.

Demonstration of Nucleases on Mammalian Skin Surface and in Saline Extracts of Hair

In the course of experiments on the effects of β-irradiation on the nucleases of guinea pig epidermis we washed thin strips of peeled tissue (25–60μ thick) before homogenization, in an attempt to demonstrate release of enzyme[1]. Approximately 50 per cent of total deoxyribonuclease (DNase) and 75 per cent of ribonuclease (RNase) activity were thus removed from normal or irradiated epidermis, indicating that considerable amounts of these enzymes may be in the stratum corneum or in the interstitial fluid. This led us to test for the presence of enzymes on the closely clipped skin surface of living animals. For this purpose we adapted the plastic cup technique used by Peiss *et al.*[2] and Szakall[3] for the study of water and ion exchange between a chemically defined medium and the skin. Albino guinea pigs of either sex (500–900 gm.) were fed a vitamin C-enriched diet, anæsthetized with veterinary 'Nembutal' and clipped with an electric shaver. Plastic cups were secured to appropriate areas of the animals' flanks by means of ½ in. 'Trimtex' rayon elastic, and small alligator clamps or paper clips were used to fasten the elastic (No. *S*-2 plastic stoppers were supplied by Pioneer Plastics, Box 8066, Arlington Branch, Jacksonville 11, Fla.). Two small needle holes were punched 180° apart and about 6 mm. from the closed end of each cup; 1·5 ml. of 0·9 per cent saline was injected with a No. 22 needle and syringe, and samples were withdrawn for enzyme assay.

DNase activity was determined by the method of Schuster[4]. Assay solutions contained 1 mgm. of calf thymus DNA (Worthington) or salmon sperm DNA (California Foundation). Blanks were subtracted for enzyme added at zero time and substrate after 30 min. at 37° C. The increases in 260 mμ readings (Δ260) were proportional to DNase and RNase concentrations up to 0·2 *O.D.* RNase was determined by the method of Dickman *et al.*[5]; some of its characteristics have been described[6]. Saline in contact with normal epidermis was found to have considerable nuclease activity (Table 1). Since there was no increase in the nuclease content of these saline washings after 45 min. contact with the skin surface, this interval was chosen for sampling.

Table 1 Nuclease Activity of Saline Washings derived from 2·54 cm.^{2} Normal Skin Surface and from Clipped Hair*

Animals	Sex	DNase Δ260/ml.			RNase Δ260/ml.		
		Initial sample	After 48 hr.	After 72 hr.	Initial sample	After 48 hr.	After 72 hr.

DNase assay: 1 mgm. DNA, 0·1 *M tris* *p*H 7·4, 0·005 *M* magnesium sulphate and 0·1 ml. enzyme in 0·8 ml. final volume, 30 min. at 37°. Δ260 × 2 equals γ-crystalline DNase. RNase assay: 1·3 Michaelis (ref. 13) veronal-acetate buffer, *p*H 7·7; 0·2 ml. enzyme and 0·5 ml. 1 per cent dialysed yeast RNA, 15 min. at 37°. Δ260 × 0·1 equals γ-crystalline RNase.

* 1·5 gm. hair extracted in 10 ml. 0·9 per cent saline, for 48 hr. at 4° C.; 0·1 ml. aliquots for assay.

† Pigmented guinea pig.

The average enzyme activity of 1 ml. washings (4 animals) was equivalent to about 2 and 0·03γ of crystalline pancreatic DNase and RNase (Worthington), respectively (Table 1). Washing or wiping the skin surface prior to sampling removed most of it. About 24 hr. were required for surface nucleases to return to their initial level. In some instances, when the initial activity was low it rose to a high level after the second or third sampling of the area, 48 or 72 hr. later (Table 1). We have no explanation for this increase of enzyme after repeated sampling. Clipping the hair without touching the skin surface, in order to avoid trauma, results in levels comparable with closer clipping. The nucleases appear to be fairly uniformly distributed on the skin surface of the flanks. Nuclease activity can be leached out of the clipped hair (Table 1), but equally high levels are present on the depilated skin surface (Tabachnick, J., and Freed, R. M., unpublished results). Since there was no significant change in activity of the supernatant after centrifugation for 1 hr. at 100,000*g*, these enzymes are considered to be in solution in the saline washings and not associated with any cell particulate.

Skin surface DNase was inactive in the absence of magnesium ions. The optimal ionic strength (*p*H 7·0, Michaelis[13] veronal-acetate buffer), was about 0·17 in a complete medium to which sodium chloride had been added in varying concentrations. Heating the saline washings for 10 min. at 60° C. in a *p*H 4 or *p*H 7·4 buffer solution resulted in 90 per cent and 80 per cent losses of activity, respectively. As further evidence of enzymic hydrolysis of DNA we observed a change in viscosity of a 0·1 per cent substrate solution from a gel-like consistency to a watery one within minutes after addition of an aliquot of active saline solution. In addition, paper chromatograms (70 per cent *iso*propanol-ammonia) of aliquots of DNA solutions, incubated 24 hr. with saline washings or crystalline DNase, showed similar broad bands of ultra-violet absorbing oligonucleotides which had left the origin. In controls, the ultra-violet absorbing material did not leave the origin.

The *p*H activity curve of skin surface DNase is similar to that of crystalline pancreatic DNase (DNase I), the optimum being at about 7·0 with little or no activity at or below 5·3. This indicates absence of an acid DNase (DNase II) which is present in many tissues[7]. Epidermis, washed free of extracellular enzyme prior to homogenization, contains DNase with a similar *p*H optimum, suggesting that the skin surface enzyme may be of epidermal origin. Unlike DNase I of liver or kidney, which may be masked by a specific inhibitor[7], the relatively high DNase activity at neutral *p*H on the skin surface or in guinea pig epidermis points to the absence of an inhibitor. Whether an activator[8] for DNase I is present remains to be determined.

In two human subjects (the authors) no nuclease activity was detected on the normal or sweating surface of the forearm, the palm, the nape of the neck, or in saline extracts of hair. The presence of non-specific esterases on human skin has been demonstrated with histochemical methods[9]. While skin bacteria play a part in the production of free fatty acids, some of the lipolytic activity was attributed to esterases of animal origin[10]. We found no significant changes in the amount of nuclease after reducing the bacterial count of guinea pig skin surface to 0 or 5 per cent by topical application of the antibiotics, 'Surgamycin' or 'Achrosurgic' (kindly supplied by the Lederle Laboratories Division, American Cyanamid Co., Pearl River, New York).

Steigleder[11] has referred to human skin surface as covered with an "esterase mantle", and regards human sebum and sweat as the chief carriers of the non-specific esterases. The present report suggests that other mammals, such as guinea pigs, have a nuclease coating. Since this species has no eccrine sweat glands, surface nucleases cannot originate there. In addition, in healed, β-irradiated guinea pig skin in which the dermal adnexal structures had atrophied or had been completely destroyed[12], we observed increases in surface DNase and RNase (Tabachnick, J., and Freed, R. M., unpublished results). Hence, in this animal, surface nuclease activity is probably of epidermal and/or humoral origin.

As shown in Table 1, rat and rabbit skin may also function as an excretory organ for nucleases. The question arises, Is there a selective removal of blood nucleases through the cutaneous blood vessels or are these enzymes a natural product of epidermal cell turnover and keratinization ? This technique, applied to the surface of healed, irradiated skin with atrophied or destroyed adnexal structures, may prove to be a useful tool for obtaining answers to this and other questions relating to the *in vivo* permeability of the epidermis.

We are indebted to Dr. Peter Flesch, Department of Dermatology, University of Pennsylvania, Philadelphia, for directing our attention to the plastic cup technique[2,3]. A detailed report is in preparation. The work was supported by Contract *AT* (30–1)–1727 with the U.S. Atomic Energy Commission.

Note added in proof. The low levels of nuclease activity in the initial samples (column 3, Table 1) are the result of sampling immediately after close clipping of the animal's hair. Through the generosity of Prof. P. C. Trexler, Lobund Department of Biology, Notre Dame University, we recently had the opportunity of assaying saline extracts of germ-free hair obtained from guinea pigs, rats, and rabbits, and found levels of DNase and RNase activity as high or higher than the values in Table 1.

Transplacental Passage of Red Cells in Man

THE purpose of this communication is to report the results of an investigation into the frequency and magnitude of hæmorrhage from the fœtal to the maternal circulation in a random series of deliveries. The total separation of the maternal and fœtal circulations was a long-held biological belief, and was only first seriously questioned in 1941, when the mechanism of hæmolytic disease of the newborn was elucidated and Levine[1] showed that Rh iso-immunization occurred less often than expected in ABO incompatible matings. Because of these Rh findings, it was postulated that the antigen was carried across the placenta into the maternal circulation by intact erythrocytes.

Several investigators have since succeeded in demonstrating the passage of cellular elements across the placenta ; radioactive tagged red cells, elliptocytes and sickle cells have been injected into the maternal circulation prior to delivery, and later recovered from the fœtal circulation[2,3]. Fœtal red cells have been detected in the maternal circulation by means of differential agglutination by Chown[4] and by Zipursky *et al.*[5], using the histochemical technique developed by Kleihauer *et al.*[6].

The technique used in the present work was that of Kleihauer, with the modification that the final preparation was unstained. The principle of the method is to elute hæmoglobin A from the adult red cells by means of a citric-phosphate buffer ; hæmoglobin F remains in any fœtal red cells and these stand out as dark refractile bodies (see Fig. 1).

To establish the sensitivity of the technique, 50 male bloods were examined along with 50 specimens of blood from post-partum women, the observer being unaware of the source of the specimens. Each specimen was given a quantitative score, this being the average of the number of refractile cells counted in four 3-min. scans. No male score exceeded 0·5.

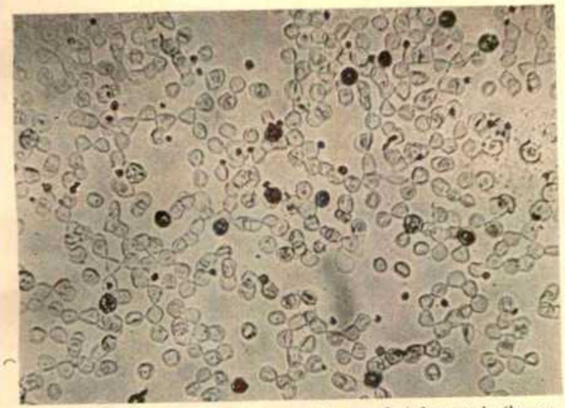

Fig. 1. Maternal blood from case of severe fœtal anæmia (hæmoglobin, 73 per cent) due to massive transplacental hæmorrhage. The fœtal red cells stand out darkly compared with the pale ghosted adult cells

Artificial mixtures of maternal and fœtal blood were next made at varying dilutions for the purpose of correlating the scores with actual amounts of fœtal blood. At a dilution of 1 : 5,000, the score was 5 ($S.D. \pm 1\cdot5$). Assuming an average maternal blood volume of 5 litres, this would represent 1 ml. of fœtal blood in the maternal circulation.

200 specimens of maternal blood were examined within 72 hr. of delivery. The average of two 3-min. counts was recorded, and scores of 2 or more were regarded as indicating definite transplacental hæmorrhage. This was detected in 12 per cent (24) of the women (Table 1).

Table 1. FŒTAL RED CELLS IN 200 SPECIMENS OF POST-PARTUM MATERNAL BLOOD. SCORES RECORDED AS WHOLE NUMBERS; FOR EXAMPLE, 2·5 IS SCORED AS 2

Fœtal red cells score	No. of specimens of post-partum blood	Fœtal red cells score	No. of specimens of post-partum blood
0	159	6	3
1	17	7	0
2	3	8	1
3	5	9	0
4	5	10–19	3
5	1	20–29	3

Scores of 10 or more were recorded on only six occasions (3 per cent), and this suggests that fœtal bleeding is rarely more than 1–2 ml. Work is in progress to find out the precise amount that is necessary to stimulate the formation of antibodies.

Though the amount noted in this random series was always less than 5 ml., we have investigated a case of marked neonatal anæmia (hæmoglobin 73 per cent) in which it was calculated that about 100 ml. of fœtal blood had entered the maternal circulation (see Fig. 1). It was shown afterwards that the mother was blood group S-negative and the fœtus S-positive, and *in vitro* it was clearly demonstrated that, on adding anti-S to the maternal blood, differential agglutination was produced (Fig. 2).

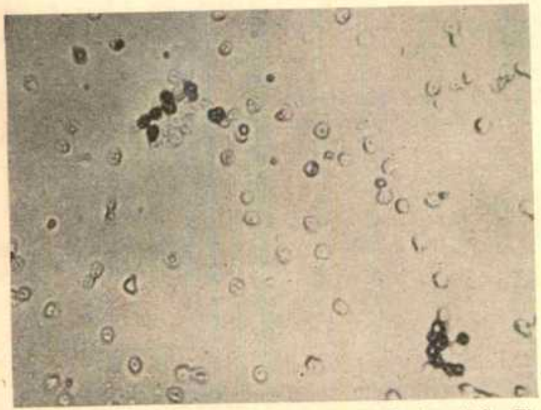

Fig. 2. Differential agglutination with anti-S at + 4° C. The small agglutinates stand out darkly (due to hæmoglobin F), thus confirming their origin from fœtal red cells

The results of the investigation have obvious relevance to the low incidence of iso-immunization in Rh-negative mothers as in the majority of cases the placenta seems to be an effective barrier against the entry of more than 1 ml. of fœtal blood. In Rh-negative patients in whom significant fœtal bleeding is detected immediately after delivery, it may be possible (as judged by the *in vitro* results) to inactivate the circulating fœtal cells by the administration of anti-D and thus prevent iso-immunization.

Using Rh-negative male volunteers, we have already shown that the administration of Rh-positive cells followed half an hour later by anti-D, results in these cells being coated with the antibody. In view of the results of Stern and Berger[7], it is hoped that this coating will prevent Rh-sensitization.

We thank the United Liverpool Hospitals Research Committee, under the chairmanship of Lord Cohen of Birkenhead, and the Nuffield Foundation for supporting this research. We are also grateful to Dr. R. R. Race and to Dr. I. Dunsford for their help and advice.

RADIOBIOLOGY

Proliferative Cycle in the Growing Hair Follicle of the Mouse

THE intermitotic phase has been divided into three segments: the phase of synthesis of deoxyribonucleic acid (DNA) (S phase), preceded and followed by 'gaps' called G_1 and G_2, respectively[1]. The duration of these phases can be accurately measured by pulse-labelling with tritiated thymidine, followed by serial killing, preparation of autoradiographs, and determination of the fraction of mitoses labelled at various intervals between injection and death[2,3]. Several kinds of cells have been so studied; the present communication adds to the list the cells of the growing-hair follicle in the mouse.

Young adult male $CF1$ mice were used. Hair growth was initiated by plucking[4]. Tritiated thymidine (20 μc., sp. act. 1·9 c./mM) was administered intraperitoneally 10–11 days after plucking, at which time hair growth is proceeding at full speed. Animals were killed at times ranging from 10 min. to 42 hr. after labelling. Autoradiographs were prepared; 50–100 ana- and meta-phases on each slide were scored for presence or absence of label. Presence of label indicates that the cell was synthesizing DNA during the period when label was available, that is, the first few minutes following injection[5]. When the interval between injection and death is short, no meta- or ana-phases are found to be labelled, because cells in this stage at the time of death were in G_2 or prophase at the time of labelling. Longer intervals yield labelled mitoses, since the cells in mitosis at the time of death were in S phase at the time of injection. Still longer intervals again result in unlabelled mitoses, since the injection in these cases coincides with the G_1 phase, mitosis, or G_2 phase of the preceding cycle.

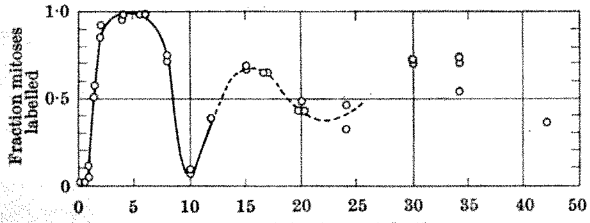

Fig. 1. Fraction of mitoses labelled as a function of the interval between injection of label and death. Each symbol represents one mouse

The results are shown in Fig. 1. The mean duration of the G_2 plus prophase is the interval between the origin and the time when 50 per cent of all meta- and ana-phases are labelled; it is 1·5 hr. The mean duration of the S phase is the width of the wave of labelled mitoses, measured between the two 50 per cent points; it is about 7 hr. The variability in the duration of the S phase can be estimated from the difference between the slopes of the ascending and descending limbs of the wave[2]: the standard deviation is about 0·9 hr. The distance between corresponding points on the first and second waves represents the generation time. However, since the second wave is not well defined, the estimation is equivocal; roughly, the generation time must be near 12 hr. Of this time, 8·5 hr. are taken up by the S and G_2 phases and prophase; allowing about 0·5 hr. for meta- and ana-phase, the remaining 3 hr. represent the mean duration of G_1. The distribution of durations of G_1 in individual cells can be roughly estimated from the shape of the second wave[3]. The data are compatible with an exponential distribution, possibly with some lag; this would imply that soon after the cells enter the G_1 phase there is a constant probability (of about 0·0055 min.$^{-1}$) that DNA synthesis will commence during the following minute.

The results of this work, together with findings in other cell systems, support a general impression that the duration of the S–G_2-mitosis sequence is fairly constant in a given species, while the duration of the G_1 phase varies widely and is chiefly responsible for differences in generation times, both within and between cell populations.

The amount of label in hair follicle cells is much less than in intestinal epithelial cells of the same animals. Maturing cells carry their label into the hair shaft, where it disappears at the same time as the nuclei. An artefact often seen is deposition of a dense layer of silver grains on the surface of hair.

Formation of an Ommatin Pigment from Tyrosine by Ultra-violet Irradiation

In the course of an investigation of the effect of ultra-violet irradiation on the formation of melanin from tyrosine, it was found that a brief period (5 min.) of irradiation had an effect similar to that brought about by the addition of a minute quantity of DOPA; on addition of tyrosinase to the irradiated solution oxygen uptake began immediately without an induction period, and ultimately reached a value approximating that calculated for conversion of the tyrosine to melanin. As the reaction proceeded, typical melanin granules were formed.

Attempts to bring about non-enzymatic melanin formation from tyrosine by irradiation were unsuccessful. Short periods of exposure to ultra-violet light resulted in the development of a golden-yellow product; limited increases in irradiation time had the effect of deepening the golden colour; but at no time was there evidence of melanin formation, even when solutions containing the yellow product were allowed to remain at room temperature for several days. Prolonged exposure to irradiation resulted in almost complete disappearance of this colour, with an accompanying drastic increase in oxygen uptake suggesting oxidative destruction. Changes in absorption spectra brought about by increasing dosages of irradiation indicated the formation of products having greater absorbency at 245–250 mμ and at 290–340 mμ than does unirradiated tyrosine. Analysis of solutions briefly exposed to ultra-violet radiation demonstrated the presence of DOPA quinone and of 5,6-dihydroxyindole.

The yellow pigment responsible for the change in absorbance was extracted by salting out with sodium chloride and shaking with *iso*butyl alcohol; the yellowish-tan muff formed at the interface was dissolved in alkali to give a reddish-brown solution. In Fig. 1, the spectra of the extracts indicate the formation of a product with maximum absorbance in the ultra-violet at 245 mμ, with a second peak at 300–305 mμ. That this product is not a melanin is shown by curve *D*, the absorption spectrum of a melanin obtained by enzyme action on briefly irradiated tyrosine. The pigment was insoluble in *iso*butyl alcohol until brought to *p*H 2; when it was extracted into alcohol at this *p*H, it exhibited a brilliant blue fluorescence with maximum emission in the region 410–430 mμ.

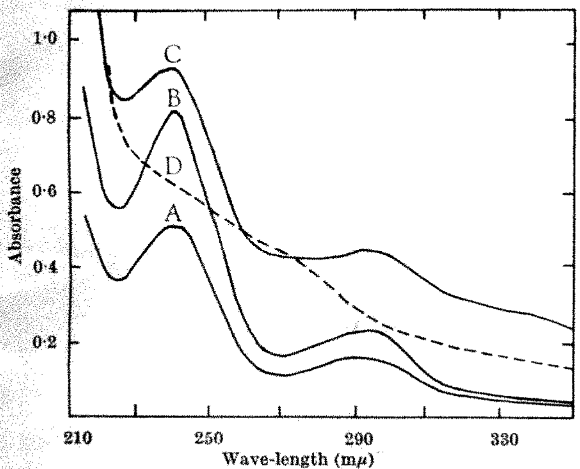

Fig. 1. Absorption spectra of pigment extracts obtained by irradiation of tyrosine for: *A*, 10; *B*, 20; *C*, 120 min.; *D*, purified melanin obtained by enzyme action on an irradiated tyrosine

In these characteristics, colour, relative insolubility, absorption spectrum in the ultra-violet region, and emission spectrum, the pigment, which is not an intermediate in the normal pathway of melanin formation, resembles the fluorescent red-yellow xanthommatin described by Butenandt *et al.*[1]. It is probable that as a result of irradiation, oxidation of the dihydroxyindole with the breaking of the 2 : 3 bond of the pyrrole ring has given rise to an *o*-amino phenol[2] which reacted with the DOPA quinone to form the ommatin pigment. This is of particular interest in relation to Fitzpatrick's[3] work on the production of pheomelanin, and as demonstrating an alternative pathway of pigment formation from tyrosine, one that is non-enzymatic.

HISTOCHEMISTRY

Enzyme Histochemistry of the Cells in Hodgkin's Disease and Allied Disorders

The complex nomenclature applied to cellular components of the reticuloendothelial system, based on their morphological characteristics, has resulted in a variety of controversial classifications of lymphoreticular neoplasia.

Enzyme histochemistry offers valuable assistance in identifying the various cell types and their malignant counterparts.

Braunstein, Freiman and Gall[1], in a preliminary report on the distribution of enzymatic activity in malignant lymphoma, stated that in general the enzymatic activity of cells of the various histiocytic types of malignant lymphoma corresponded to that of their normal counterparts. Of particular interest was the demonstration that the cells of reticulum cell sarcoma (histiocytic lymphoma) manifested enzyme activity identical with that of non-neoplastic histiocytes. They claimed also that large anaplastic cells and Sternberg cells of Hodgkin's 'granuloma' and sarcoma also manifested a similar pattern histochemically.

Methods for the histochemical demonstration of acid phosphatase, alkaline phosphatase and non-specific esterase[2] have been applied to lymph nodes and spleen in these laboratories, as part of a similar investigation.

The results of Braunstein *et al.* were confirmed, in part, in that histiocytes, wherever they were located, showed marked activity of acid phosphatase and non-specific esterase. Cells thought to be derived from histiocytes, for example, 'epithelioid' and 'endothelioid' cells and Langhans giant cells in tuberculous lymph nodes, together with foreign-body giant cells, reacted similarly. Splenic sinus lining cells, however, were consistently negative for these enzymes and are therefore not considered to be true histiocytes[3].

No reactions for these enzymes have been observed in lymphocytes. Alkaline phosphatase was confined to capillary endothelium, to some polymorphonuclear leucocytes and to an occasional mononuclear cell.

Twenty-seven cases of malignant lymphoma and leukæmia have been investigated. These included lymphocytic lymphoma (6), histiocytic lymphoma (reticulum cell sarcoma, 5), mixed lymphocytic-histiocytic lymphoma (1), follicular lymphoma (5), Hodgkin's 'granuloma' (6), Hodgkin's sarcoma (1), lymphocytic leukæmia (2), 'monocytic' leukæmia (1), and 'leukæmic reticuloendotheliosis' (1).

Strong non-specific esterase and acid phosphatase activity was observed in histiocytes (reticulum cells), however atypical and pleomorphic, in all these conditions. Moreover, these reactions demonstrated the abundant atypical histiocytes in five cases of follicular lymphoma, thus confirming the classification of Rappaport *et al.*[4], which includes, among others, mixed lympho-histiocytic and predominantly histiocytic types.

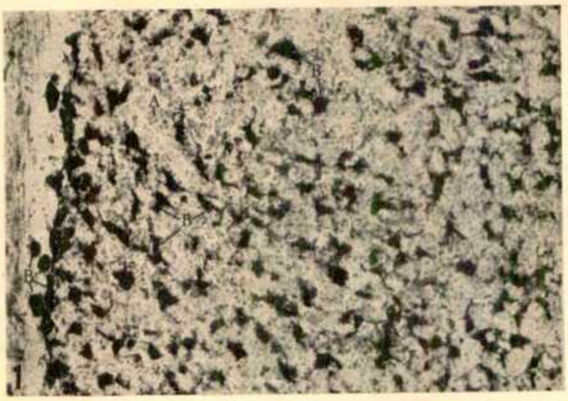
In Hodgkin's 'granuloma', however, mononuclear, binuclear (mirror-image) and multinuclear Reed–Sternberg cells were consistently negative for these enzymes, in striking contrast to the activity in adjacent reticulum cells. In one case of Hodgkin's sarcoma a minimal reaction for non-specific esterase was observed in some of the bizarre multinucleated cells.

No enzymatic activity was elicited from neoplastic lymphocytes.

The strong alkaline phosphatase of capillary endothelium demonstrated widespread proliferation of small blood vessels in all cases of Hodgkin's disease and around some foci of neoplastic tissue in other conditions. This feature is not obvious in routine paraffin sections, stained with hæmatoxylin and eosin.

In a case of 'monocytic' leukæmia, monocytoid cells infiltrating lymph nodes and spleen were also negative for these enzymes, in contrast to strong activity in surrounding histiocytes.

A case with long-standing myelophthisic anæmia, followed by the occurrence of atypical mononuclear and multinuclear cells in the bone-marrow, monocytoid cells in the peripheral blood, lymphadenopathy, hepato-splenomegaly and widespread infiltration into the skin and subcutaneous tissues, was also encountered. This type of case has been designated 'leukæmic reticuloendotheliosis'. The monocytoid cells again showed no evidence of enzymatic activity.



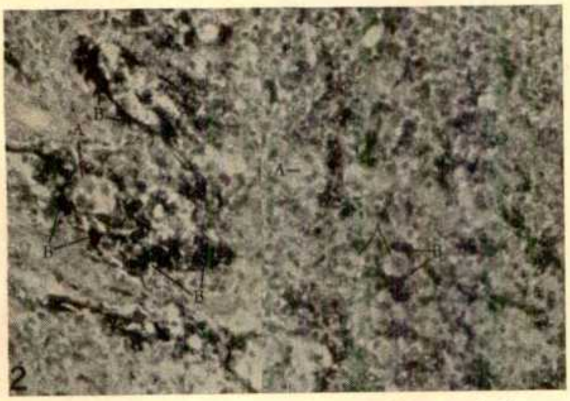


Fig. 1. Histiocytic lymphoma (reticulum cell sarcoma). Frozen section of a lymph node demonstrating non-specific esterase activity in malignant histiocytes (*B*); lymphocytes (*A*) show no activity. α-Naphthyl acetate method. (× *c*. 150)

Fig. 2. Hodgkin's disease. Composite photograph of frozen sections of lymph nodes showing non-specific esterase activity in histiocytes (*B*) but not in Reed–Sternberg cells (*A*). Mononuclear, binuclear and multinuclear cells are shown. α-Naphthyl acetate method. (× *c*. 150)

These findings indicate that, if Reed–Sternberg cells and monocytoid cells are derived from histiocytes (reticulum cells), then there has been a loss of activity of both non-specific esterase and acid phosphatase in the first two cell types. This seems most unlikely since there is no alteration in the reaction of these enzymes in malignant histiocytes. Furthermore, one would expect some cells to show a loss of activity of only one or other of the enzymes, especially in the less malignant form of Hodgkin's disease.

It seems probable, therefore, that both Reed–Sternberg and monocytoid cells are derived from cells other than histiocytes. That they may have a common origin from a primitive mesenchymal cell is not disputed, but, from the results of these enzyme studies, it appears that their relationship to the histiocyte is no closer than that of the lymphocyte to the histiocyte.

Histochemical Analysis of some Dehydrogenase Systems in the Erythrocytes of some Lower Vertebrates

RECENTLY I have studied histochemically three dehydrogenase systems, namely, succinic phosphopyridine nucleotide (DPN) and triphosphopyridine nucleotide (TPN) diaphorases and the DPN-dependent enzymes: lactic, malic, glutamic, β-hydroxybutyric, and ethanolic dehydrogenases, in the renal adenocarcinoma occurring in a laboratory strain of the oviparous toothcarp *Aplocheilus lineatus*[1]. In continuation of this investigation I decided to study the distribution of these enzymes, and also œstradiol-17β-dehydrogenase, in the erythrocytes of some of the lower vertebrates, namely, some teleosts, amphibians and reptilians.

These enzymes, with the exception of œstradiol-17β-dehydrogenase, were determined by the recently developed methods of Seligman, Nachlas and co-workers[2-5], based on the use of 2,2′-di-*p*-nitrophenyl-5,5′-diphenyl-3,3′-(3,3′-dimethoxy-4,4′-biphenylene)-ditetrazolium chloride (nitro-BT)[3] as the chromogenic electron acceptor. The sections were incubated at 37° C. for 15 min. Some sections were also processed with Regaud's stain[6] to demonstrate mitochondria. In general, for morphological orientation parallel sections were stained with hæmatoxylin and eosin, hæmatoxylin and azophloxin or thionin.

For incubation with the œstrogens, the erythrocytes were suspended in isotonic phosphate buffer, *p*H 7·4; and afterwards the suspensions were shaken at 20° C. For the comparative determinations of enzymatic activity, quantities containing the same hæmoglobin content were used. Isolation, and qualitative and quantitative determination, of the steroids were carried out mainly by Repke's methods[7,8]. The œstradiol epimers were separated paper-chromatographically in the system chloroform-formamid.

The succinic dehydrogenase activity was low in the erythrocytes of all species investigated; it was linked to the cell membranes and the mitochondria. The DPN diaphorase activity appeared to be high, however. Also, this enzyme and the DPN-linked dehydrogenases were linked to the mitochondria and some cell membranes. The TPN diaphorase activity was much lower than the DPN diaphorase activity, and exhibited a widely dispersed and more finely intracytoplasmic distribution, which is certainly suggestive of the presence of microsomes and showed a high concentration in the cell membranes. The lactic dehydrogenase activity appeared to be rather high, the malic and β-hydroxybutyric dehydrogenase activities somewhat lower, whereas the glutamic and particularly the ethanolic dehydrogenase activity were generally low. The lactic dehydrogenase was more active than the malic dehydrogenase. As can be seen from Table 1, the enzymatic activities of the erythrocytes of the species investigated are mainly the same, although some minor differences can be established.

The œstradiol-17β-dehydrogenase occurred in the erythrocytes examined. This enzyme is capable of reducing œstrone to œstradiol-17β and of oxidizing œstradiol-17β to œstrone. An œstradiol-17β-dehydrogenase, found in ruminants, in addition to the œstradiol-17β-dehydrogenase[9], is not present in the erythrocytes of the lower vertebrates examined.

In general, the erythrocytes of the species examined correspond as regards œstradiol dehydrogenase

Table 1. Distribution of Succinic Dehydrogenase, DPN and TPN Diaphorase and Several DPN-Linked Dehydrogenases in the Erythrocytes of some Lower Vertebrates

The enzymatic activity was graded microscopically on the basis of colour reaction, 0 to 4, by inspection of the erythrocytes.

Non-specific Esterase Activity in Histiocytes

Histiocytes in subcutaneous connective tissue are characterized by having marked phagocytic activity. We have reported previously that histiocytes increase their enzymatic activities in proportion to the degree of transformation of these cells under various irritations[1].

Recently, we have examined histochemically non-specific esterase activity in a dorsal subcutaneous spread from rabbits intensely stained with trypan blue. The dose of trypan blue was 10 c.c. of a 1 per cent solution injected intravenously once daily for seven days. It was found that histiocytes having trypan blue granules in their cytoplasm exhibited strong non-specific esterase reaction in discrete areas corresponding to the trypan blue granules. In contrast, fixed histiocytes, without phagocytosed particles, in a spread of normal subcutaneous tissue, showed strong diffuse enzymatic activity in their cytoplasm. It is not clear whether this non-specific esterase activity exists inside the trypan blue granules or around them. However, it is unquestionable that, when trypan blue is being ingested by the digestive vacuoles of the histiocyte and concentrated into granules within them, the non-specific esterase distributed in the protoplasm becomes organized and collects in the region of the trypan blue granules.

PATHOLOGY

Evidence for Multiple Cæruloplasmin Components in Human Serum

More than one component of human cæruloplasmin has been reported by several investigators[1]. Morell and Scheinberg[1] have observed 4, possibly 5, components of cæruloplasmin by fractionating a pool composed of 9,109 individual sera. In such a large pool, infrequent unusual components would be easy to lose. Furthermore, the complex fractionation procedure provides opportunity for artefactual alteration of specific proteins. The resolving power of vertical starch-gel electrophoresis[2] combined with direct chemical and enzymic analysis on the gel provides a simple and elegant means of examining the problem in individual sera. Using this technique we have found 5 electrophoretically distinct proteins having one or more characteristic properties of cæruloplasmin.

Sera were obtained from 43 pregnant women (in the third trimester of pregnancy or within a few days *post partum*), 17 patients with various diseases (Table 1) and 5 normal individuals. A voltage gradient of 5 V./cm. was maintained for periods of 16–20 hr. at room temperature. Half of each starch-gel block was stained with amido black 10*B*[2]; the other half was stained with *p*-phenylenediamine dihydrochloride (PPD), employing a modification of the method of Morell and Scheinberg[1]. Filter paper strips were saturated with a 1·0 *M* acetate buffer (*p*H 5·0) which contained 0·5 per cent PPD. These strips were pressed on the cut surface of the block for 5 min. and

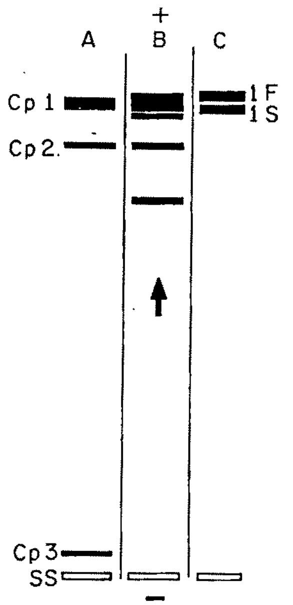

Fig. 1. Schematic diagram of the results of vertical starch-gel electrophoresis of serum of a pregnant human (*A*), cæruloplasmin concentrate, K.A.A.B.I. *DWZ* 71 (*B*) and 2 sera with atypical cæruloplasmins (*C*). *Cp* 1, Principal cæruloplasmin component; *Cp* 2 and *Cp* 3, probable and presumptive minor cæruloplasmin components respectively; 1*F*, major PPD oxidase component with fast mobility in serum of normal pregnant human; 1*S*, major PPD oxidase component with slow mobility in serum of patient with the muco-cutaneous syndrome

then removed. The block was allowed to stand at room temperature for the next 6 hr., during which time a deep purple colour developed in the region of the fast α-2-globulins. This principal component (*Cp* 1 of Table 1 and Fig. 1) was found in all specimens except one from a patient with Wilson's disease. Two other patients with this disorder had markedly diminished but detectable amounts of this material having a mobility exactly like that of the principal component of normal individuals. A principal component having a slightly faster mobility (*Cp* 1*F*) was found in the serum of one normal pregnant woman; one with a slightly slower mobility (*Cp* 1*S*) was found in the serum of a patient with the muco-cutaneous syndrome[3].

In the area associated with the transferrins, a second violet band of products of PPD oxidation (*Cp* 2) was found in specimens from all pregnant subjects, from one normal female, from a patient with carcinoma of the lung and from a patient with prostatic carcinoma who had been receiving stilbœstrol for 5 years. The second band in all cases was considerably less intense than the main component. A second examination was needed to demonstrate its presence in the sera of a few pregnant subjects.

* One specimen had atypical (fast) mobility.
† Atypical; (slow) mobility.

A very faint third component (*Cp* 3) appeared immediately in front of the sample insertion slot in all sera for which it was examined (3 normal and 21 pregnant subjects).

A commercially prepared cæruloplasmin concentrate of human *post-partum* serum (lot *DWZ* 71 from K.A.A.B.I. of Stockholm) showed a very intensely stained principal component covering a broad zone in the fast α-2-region, apparently comparable to *Cp* 1 described above, and a second band with the same mobility as that of *Cp* 2 described above. Two much fainter bands were also found: one between the principal component and the second band and another with considerably slower electrophoretic mobility than the second band.

Several blocks were stained by filter paper strips saturated with 1·0 *M* acetate buffer (*p*H 5·0) which contained 6 m*M* concentrations of serotonin creatinine sulphate, L-adrenaline or L-nor-adrenaline bitartrate. These strips were pressed on the cut surfaces of the starch blocks and left there for 15 min. Coloured products developed during the next 24 hr. in the α-2-globulin region (*Cp* 1) of samples from normal and pregnant individuals and in the K.A.A.B.I. cæruloplasmin concentrate. Staining of *Cp* 2 in the region of the transferrins was visible only in the cæruloplasmin concentrate.

Blocks were stained for copper by placing them in a saturated ethanolic solution of rubeanic acid for 24 hr., after which time greenish-black bands were seen at the sites of *Cp* 1 and *Cp* 2. Visual estimates of the PPD staining intensity suggest that the concentration of *Cp* 3 is of the order of 1/1,000th that of *Cp* 1; its failure to react with rubeanic acid may therefore be due to its low concentration.

The *Cp* 1 component has the principal characteristic properties of cæruloplasmin: it has a natural blue colour, contains copper, and oxidizes PPD, 5-hydroxytryptamine, adrenaline and nor-adrenaline[4,5]. *Cp* 2 contains copper and is visibly capable of oxidizing PPD and the other substrates; this is probable evidence that this protein is a cæruloplasmin. *Cp* 3 oxidizes visibly PPD; this is presumptive evidence that this protein is a cæruloplasmin. *Cp* 1*F* and *Cp* 1*S* have not as yet been examined in detail with respect to properties other than PPD oxidation.

The occurrence of the *Cp* 2 in pregnant women and in a male receiving stilbœstrol suggests that œstrogens influence the appearance of this protein in detectable amounts. In all these cases, *Cp* 1 was visibly increased in concentration as compared with that found in normal sera; this is in accordance with the known ability of œstrogens to influence cæruloplasmin as measured by other techniques[4]. The appearance of *Cp* 2 appears to be determined by some factor other than concentration, since it could not be found in normal sera which had been concentrated five-fold and ten-fold, raising the concentration of the *Cp* 1 component to the equivalent or excess of that seen in the serum of pregnant subjects (serum was placed in a dialysis casing which was suspended in air in front of an electric fan).

The atypical components, *Cp* 1*F* and *Cp* 1*S*, are being investigated further by means of family studies.

This investigation was supported in part by research grant *H*–3174 from the National Heart Institute of the U.S. Public Health Service and by a grant from the State of Washington Fund for Biology and Medicine.

Note added in proof: *Cp* 1*S* has a normal mobility when the haptoglobin (type 1–1) is completely removed from this zone by saturation with hæmoglobin. Blood relatives of this patient all have the normal *Cp* 1. A study of four generations of the family in which *Cp* 1*F* is segregating indicates inheritance of the trait as a dominant character. *Cp* 1*F* is differentiated more readily from *Cp* 1 at *p*H 9·5 (0·0125 *M* borate buffer).

BIOLOGY

Effect of 5-Bromuracil on Crown Gall Tumour Induction

Crown gall tumours in plants are initiated by the action of virulent strains of *Agrobacterium tumefaciens* (Smith and Town) Conn on susceptible plant cells. Once these cells have been altered to tumour cells, the presence of the bacteria is no longer required for their continuing, autonomous growth[1]. The unknown agent or method by which this alteration of properly conditioned cells to tumour cells is accomplished is not known[2]. There have been a number of recent claims that this agent is a nucleic acid, specifically a deoxyribonucleic acid (DNA)[3,4] or that DNA plays some accessory part in tumour induction[5]. Some of these claims have been subject to critical examination and have been shown to rest on inadequate evidence[6]. The most recent claim that the transforming agent may be a DNA rests on the work of Bopp[4], who reported that the pyrimidine analogue 5-bromuracil does not inhibit the growth of *A. tumefaciens*, the wound-healing reaction of the host plant, or the growth of induced tumours, but does inhibit the initiation of tumours. This communication is concerned with an evaluation of these findings.

Four different samples of 5-bromuracil were obtained from commercial laboratories. Sample 1 was purchased from California Biochemicals, Los Angeles, California; sample 2 was purchased from Mann Research Laboratories, New York; sample 3 was a sample used by Dr. Bopp in his experiments and kindly sent to us; it was manufactured by Flüka A. G., Buchs, Switzerland; while sample 4 was purchased from Nutritional Biochemicals Corporation, Cleveland, Ohio.

The effect of these samples at a concentration of 200 μgm./ml. on the generation time of the bacteria is shown in Table 2. In these experiments the bacteria were grown in a defined medium[7] for 24 hr., then diluted 100,000 times into special flasks equipped with tubes for photometry. The medium containing 5-bromuracil and the control medium were both filter-sterilized through *HA* Millipore filters (Millipore Filter Corp., Bedford, Mass.), because it was found that autoclaving destroyed the inhibitory principle in sample 4. Not enough of sample 3 was available to test the effects of autoclaving on its growth-retarding component. The flasks were shaken about 150 times per minute on a motor-driven shaker in an incubator kept at 27° C. Turbidimetric readings were made with a Coleman, Jr., spectrophotometer at 410 mμ.

The effect of 5-bromuracil on tumour induction was tested by inoculating the midrib of young *Kalanchoe daigremontiana* (Hamet and Perrier) leaves with the highly virulent strain *B*6 of *A. tumefaciens* and placing one drop of a solution containing 200 μgm./ml. 5 bromuracil on the inoculation site on the day of inoculation and on 3 successive days. Water was applied to the control inoculations. About two weeks later the infected sites were scored independently by each of us. The average for 32 inoculations is given in Table 1. These results clearly indicate that samples 1, 2, and 3 did not interfere with tumour induction, whereas sample 4 had a definito inhibitory effect.

Table 1. THE EFFECT OF 5-BROMURACIL ON BACTERIAL GROWTH AND TUMOUR INDUCTION

Treatment	Bacterial growth (in terms of generation time)	Average tumour score*
Control (water)	2·5	1·5
Sample 1, 200 μgm./ml.	2·5	1·6
Sample 2, 200 μgm./ml.	2·5	1·6
Sample 3, 200 μgm./ml.	3·0	1·6
Sample 4, 200 μgm./ml.	4·0	0·4

* Scoring: 0 = no reaction, 0·5 = questionable reaction, 1 = definite reaction, and 2 = strong reaction.

Chromatographic analysis of the four samples by ascending paper chromatography on Whatman No. 1 paper was carried out in two separate solvent systems. In an *n*-butanol/water (43 : 7) system, samples 1, 2, and 3 showed an ultra-violet absorbing spot at $R_F \sim$ 0·35; no other spots were detectable. In an *iso*-propanol/hydrochloride (13 : 7) system, samples 1, 2, and 3 showed ultra-violet absorption only at $R_F \sim$ 0·60; sample 2 had a slight 'tail' behind it. Sample 4 did not show any ultra-violet absorbing or other ultra-violet detectable spots at any point past the origin in either of these two solvent systems. Samples 1 and 2 were white, sample 3 was light pink, and sample 4 had a pinkish tinge. Elemental analysis of these samples was carried out by Mr. S. T. Bella of the Rockefeller Institute. The results of these analyses are shown in Table 2 and confirm the chromatographic evidence of the impurity of sample 4.

Table 2. ELEMENTAL ANALYSIS OF FOUR SAMPLES OF 5-BROMURACIL

Sample	Carbon	Hydrogen	Nitrogen
1	25·18	1·64	15·38
2	25·41	1·45	14·89
3	25·50	1·51	*
4	16·39	1·75	15·43
Theoretical	25·14	1·58	14·67

* Insufficient sample available for nitrogen determination.

These results indicate that there is associated with certain commercially available samples of 5-bromuracil a heat-labile impurity which does not absorb in the ultra-violet. This impurity inhibits bacterial growth and thus cannot be considered a specific inhibitor of tumour induction. We suggest that the tumour inhibition observed by Bopp reflects the presence of an impurity in his samples. Such an impurity, although inhibitory to the bacteria, would not have been detected by means of the bacteriological techniques which he employed.

Samples of comparatively pure 5-bromuracil failed to inhibit tumour induction, thus seriously questioning the validity of the data which were interpreted to indicate that 5-bromuracil specifically inhibits the formation of an effective tumour-inducing agent and that such an agent might be a DNA.

We acknowledge the interest and support of Dr. Armin C. Braun during this investigation.

Seasonal Acclimatization of Oxygen Consumption to Temperature in a Tropical Poikilotherm, the Earthworm, *Megascolex mauritii*

SEASONAL acclimatization of oxygen consumption to temperature has been demonstrated in poikilotherms by many authors, and its profound ecological significance is widely recognized[1-5]. But most such investigations are restricted mainly to marine organisms of cold and temperate zones. Comparatively little attention has been paid to such seasonal compensatory changes in oxygen consumption in tropical, freshwater and amphibious animals and much less in the terrestrial forms. Except for the work of Vernberg[6] on intertidal crabs, nothing has been reported of the seasonal fluctuations of respiration in any tropical poikilotherm.

The results of this work show the existence of a homoiostatic mechanism in oxygen consumption, compensating for the seasonal temperature changes in the tropical earthworm, *Megascolex mauritii*.

The oxygen consumption of these worms was measured under water at 15°, 20°, 25°, 30°, 35° and 40° C., by Winkler's method[7]. The determinations were made during the winter (January) and the summer (June) of 1959 and 1960. Measurements at 40° C. in June 1959, and those at 15° C. in June 1960, could not be made. The results for the year 1960 are presented in Fig. 1. The regression lines for 1959 summer samples are also included for comparison.

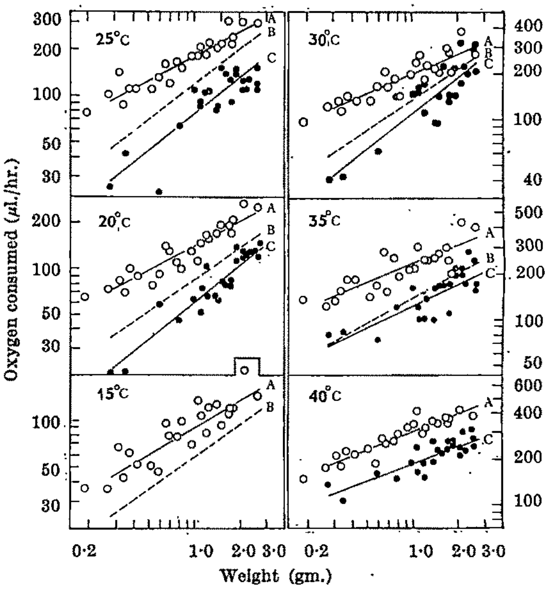

Fig. 1. Oxygen consumption in *Megascolex mauritii* as a function of size and temperature during winter and summer. Each point represents an individual measurement; double logarithmic grid; *A* (open circles), winter animals of January 1960; *B*, summer animals of June 1959; *C* (closed circles), summer animals of June 1960

Acclimatization of oxygen consumption to seasonal change in temperature occurs in the tropical earthworm *Megascolex mauritii*, as may be seen from the fact that, at all the temperatures investigated, the metabolism of the winter animals (lines *A* in Fig. 1) was higher than that of the summer samples (lines *B* and *C*). The difference in the slopes of the regression curves of winter and summer animals indicates that the effect of weight on oxygen consumption changes with season. In other words, the degree of acclimatization to temperature varies with weight. The degree of acclimatization may be greater in smaller worms, which generally consume oxygen at a higher rate than larger worms. This difference, between smaller and larger worms, in the degree of acclimatization to seasonal temperature changes, explains the flat and steep regression curves of oxygen consumption of winter and summer populations, respectively. Another fact that is clear from Fig. 1 is that the June 1959 population (lines *B*) utilized more oxygen than that of the June 1960 (lines *C*).

Roberts[8], working on population samples of *Pachygrapsus crassipes*, could not detect any seasonal thermal acclimatization of respiration. Recently, it was shown by Vernberg[6] that no seasonal variation in oxygen consumption was to be found in the tropical form, *Uca rapax*, whereas a marked seasonal acclimatization was exhibited by the temperate form, *Uca pugnax*. This absence of seasonal acclimatization to temperature in the tropical crab, he thought, might be due to small annual temperature fluctuations. He also felt that the results of Roberts on *P. crassipes* might be due to low annual fluctuations in temperature. But the high and low mean monthly temperatures recorded by Roberts were about 12° C. in January and 22° C. in August. The high and low mean temperatures recorded during my investigation were 35° C. in May 1959, 36·5° C. in May 1960, and 25·5° C. in December 1959. Though the difference in the high and low temperatures is nearly the same in both cases, it is interesting to note that good metabolic acclimatization to seasonal change was observed in this tropical form.

The difference in oxygen consumption between the two summer populations of June 1959 (lines *B*) and June 1960 (lines *C*) can be correlated with the history of temperature during the two summer seasons (Table 1). The temperature during summer 1960 was not only higher (36·5° C.) than in 1959 (35° C.) but also was maintained for a longer duration. It is noteworthy that the degree of thermal acclimatization of oxygen consumption in summer populations depends on the intensity as well as the duration of high temperature during that particular season.

Table 1. STATEMENT OF MEAN MONTHLY TEMPERATURE (IN ° C.) DURING WINTER AND SUMMER OF 1959 AND 1960

Year	Winter		Summer			
	Dec.	Jan.	Mar.	April	May	June
1959	—	—	31·5	33·5	35	35
1960	25·5	26	31·5	35	36·5	36

Similar work, during the same period (January and June 1960), on another tropical earthworm, *Octochætus* sp., also showed a good seasonal acclimatization of respiration to temperature and this acclimatization was more evident in the smaller worms.

A complete report will be published elsewhere.

I wish to express my gratitude to Prof. Kandula Pampapathi-Rao, head of the Department of Zoology, Sri Venkateswara University, Tirupati, for his interest and guidance throughout. Part of this work was carried out during the tenure of a junior research fellowship of the Council of Scientific and Industrial Research, New Delhi.

A Hermit Crab New to Britain

OF recent years the hermit crab *Clibanarius misanthropus* (Risso) has been reported from stations successively farther north along the coast of the Bay of Biscay[1]. It seems probable that this represents a true northerly advance of this example of an essentially tropical genus, for it is unlikely to have been overlooked since its almost exclusively intertidal habit and its brilliant colours attract the attention. By 1957 it had been reported to the north of Brest, but it does not seem yet to have been found along the north French coast: in particular, the collectors of the Station Biologique at Roscoff have not found it. Indeed, Crisp and Fischer-Piette[1] advance reasons for supposing that it is unlikely to spread along this coast. On the other hand, the drift of surface water which occurs in some years from Finistère towards Land's End or towards the Scilly Islands might be expected to carry larvæ to the British shores. Despite regular surveys of the shores of the Scilly Islands, our colleagues have not found this species there; but during the early months of 1960 large numbers were found on the shore at Mousehole on the southern coast of Cornwall (lat. 56° 6′ N., long. 5° 31′ W.), near Land's End. It is significant that the water at the western end of the English Channel in March and April 1959 (when the larvæ of *C. misanthropus* would be planktonic) had an unusually high salinity, suggesting the presence of Biscay water flowing into the Channel.

C. misanthropus is a hermit crab with subequal claws and hence quite unlike any of the native species which have unequal claws. It seems likely that it was not present on this shore before the winter of 1959–60, to judge by the reports of amateur collectors in this region, nor has it been found on any of a number of beaches and shores in the neighbourhood. During the winter it was the commonest hermit crab at about mid-tide level on this one shore, as many as 48 being found in one small rock-pool, together with no more than 2 specimens of other species; in the summer it has been confined mainly to pools lower down on the shore, around low-water neap tide mark, but is still abundant. Most of them inhabit shells of *Littorina* sp., while a few are in shells of *Nucella*. In this they contrast with the French specimens, which were mainly found in *Gibbula* or *Monodonta* shells. During the winter all the animals collected were of nearly the same size; but in September 1960 a number of much smaller crabs were present in the population, suggesting that they had bred successfully. It will be interesting to observe if they succeed in permanently colonizing British shores.

It has been suggested[1] that *Pagurus fasciatus* Bell is identical with this species. Bell[2] described and named *P. fasciatus*, without ever having seen a specimen, from a coloured drawing supplied by a Mr. Cocks of Falmouth, where, presumably, he collected his specimen. We feel that this identification cannot be correct, but the description is too vague for any certainty. There is just a slight possibility, therefore, that *Clibanarius misanthropus* has been taken before on the south coast of Cornwall, more than a hundred years ago.

We wish to thank Dr. A. F. Turk for his interest.

Note added in proof. During spring, 1961, a new year-class has appeared at Mousehole and specimens of this same (new) year class have been collected at Wembury, a similar habitat on the southern coast of Devon, 105 km. east of Mousehole. Since Wembury (lat. 50° 19′ N., long. 4° 5′ W.) is probably the commonest collecting ground of all for workers and students at the Plymouth Laboratory, it seems exceedingly unlikely that *Clibanarius* should have been present in earlier years. It thus seems that it is continuing its northward and westward spread.

A Bathyal-abyssal Hermit Crab with a Calcified Asymmetrical Abdomen

IN the highly productive part of the Pacific Ocean, off Central America, the Danish *Galathea* Deep-Sea Expedition in 1952 made an exceptionally rich haul with a large herring otter trawl at a depth of 3,570 m. This haul yielded *inter alia* the first known species of *Neopilina* and a total of 126 species and about 2,100 specimens of benthic animals.

The 10 species of decapod crustaceans comprised 18 specimens of a pagurid, *Probeebei mirabilis*[1]. This genus and species was described by Boone[2,3] as "a primitive macruran crustacean". First and foremost, because of the calcified abdomen the author did not recognize it as a pagurid, and apart from a reference to it in the *Zoological Record* of 1926 it has since been almost totally neglected, for example, in Bronn, by Melin[4], Gordan[5], and others. Within the Paguridea it belongs to the Pagurinae Latr. (= Eupagurinae Ortm.). Boone's family Probeebeidae[3] is thus invalid.

The holotype was the only specimen collected by the *Arcturus* Expedition in 1925, south of Cocos Island in the Gulf of Panama at 1,145 m. depth. It belongs to the youngest post-larval stage which was represented in the *Galathea* material, and is 20 mm. long.

The largest of the adult specimens measures 65 mm. The carapace is somewhat broadened and furnished with many short spines and a long rostrum. The abdomen is moderately large, completely calcified dorsally, almost entirely symmetrical in the male and somewhat asymmetrical in the female, the left part of each segment being a little longer than the right and with only the left pleopods developed. The telson is symmetrical in both sexes. The right cheliped is slightly larger than the left, and peræopods II and III are very elongated as in *Tylaspis*, the hitherto deepest recorded hermit crab[6]. The male has the first pair of pleopods preserved, the female pleopods 2–5.

Phylogenetically the genus is most closely related to other genera with paired pleopods in the male and with a corresponding number of pairs of gills (eleven): *Parapagurus*, *Sympagurus*, *Tylaspis*, and *Tomopagurus*. Apart from the latter, which occurs at a depth of 132 m. off the Barbados, the remaining genera are bathyal or abyssal.

A number of instances are known of hermit crabs having evolved means other than a gastropod shell for protection of the abdomen, probably first and foremost because of lack of sufficient shell material. Primarily in the deep sea, several species have taken advantage of *Dentalium* shells, pieces of wood or bamboo, polychæte tubes, etc. In *Tylaspis*[6] and especially *Ostraconotus*[7], the abdomen has become reduced and is probably unprotected, although it is soft-skinned and can only, to a lesser degree, be folded under the cephalothorax. In these two genera, in practically all the species with an almost straight protective object, and in the three instances mentioned below, the animals have acquired a secondarily symmetrical or almost symmetrical abdomen; but their origin from asymmetrical forms in gastropod shells is always discernible by the presence of unpaired, left-hand pleopods, at any rate in the females. Furthest advanced along this line are those forms which have regained the calcified abdomen of their ancestors (the primitive, quite symmetrical Pylochelidae and the Thalassinidea), namely: (1) the stone crabs (Lithodidae); (2) the robber crab (*Birgus latro*); (3) *Probeebei*, which all originate from the Paguridae but which have evolved from systematically very differing stocks within the family[8]. The Lithodidae are fully 'carcinized'[9], with the comparatively small abdomen firmly pressed against the cephalothorax, with a very crab-like carapace, and with peræopods IV as long as II and III.

Birgus and *Probeebei* represent parallel lines of evolution in environments—dry land and abyssal depths—both of which are extremes in comparison with the warm shallow water in which the pagurids primarily evolved. In both cases the secondary calcification of the abdomen must be due to lack of sufficient shell material. The calcification is further advanced in *Probeebei*; but in several other respects the evolution to a freely roaming animal has caused a considerably greater change of the adult *Birgus* than of *Probeebei*: peræopod IV is comparatively much larger and can be used for walking; not only the male but also the female abdomen are practically symmetrical (apart from the lack of right pleopods), and the uropods have become almost completely reduced; also in the adaptation to the life on dry land (shape of eye-stalks, antennulæ and antennæ, presence of lungs, behaviour, etc.[10]), *Birgus* is much more advanced than the species of the closely related genus *Coenobita*, which are likewise land-dwelling.

On most islands where *Birgus* occurs it outgrows the available land snails soon after having left the sea, but the metamorphosis into the free-living stage can be considerably postponed experimentally[11]. It is to be hoped that future investigations in the area of distribution of *Probeebei mirabilis* will reveal the early post-larval development of this species, which may prove as interesting as that of *Birgus latro*.

Adaptive Euryhalinity in the Cyprinodont *Lebistes reticulatus* Peters

Lebistes reticulatus has always been considered as a strictly freshwater fish[1] (that is, it can tolerate only a narrow range of salt concentration in the water). In an evacuation canal, which opens in the sea, at Hann (north of Dakar), we were astonished to find numerous individuals of this species, even in spots where the concentration of sea-water was rather high. Experiments in the laboratory led us to the following conclusions:

(1) The upper limit of salinity tolerated by this species, at 20–25° C., when transferred directly from fresh water, is about 50 per cent sea-water. At such a concentration, mortality is very low (7 per cent). At a concentration of 85 per cent sea-water or higher, all fish perished within 2–3 days.

(2) Fish kept in 50 per cent or 75 per cent sea-water, for 1 wk., were transferred to 100 per cent sea-water, without any mortality resulting. During the following two months these fish were regularly observed; they seemed well and healthy, and their behaviour was apparently normal.

(3) Several series of fish were transferred successively to baths containing higher and higher concentrations of sea-water (25, 50, 75 and finally 100 per cent sea-water). They were kept for 1 wk. in each bath; the resulting mortality was nil. This seems to prove that we are dealing with a phenomenon of adaptation rather than selection.

(4) Fish adapted to sea-water were transferred directly to fresh water; no mortality resulted. This means that individuals adapted to sea-water have no need of a new adaptation to fresh water.

(5) The adaptation to sea-water is temporary, since individuals adapted to sea-water all died when transferred to fresh water and returned to sea-water within a week.

(6) A special design permitted us to adapt individuals to more and more concentrated media, by gradually increasing the sea-water content in the aquarium in which the fish were put, in such a manner that the fresh water was replaced by sea-water, within 28 or 36 hr. When fresh-water replacement was accomplished within 28 hr., all fish without exception died during the 24 hr. following. When the replacement was accomplished within 36 hr., only three individuals (out of fifty fish) died. This means that the minimum time for adaptation to sea-water is about 36 hr.

(7) Several series of 25 individuals each were adapted to sea-water during at least 3 wk.; they were transferred to fresh water and then returned again to sea-water, 24, 36, 48 or 72 hr. after. The results obtained were as follows:

Time (hr., in fresh water)	No. dead
24	none
36	4 individuals
46	8 individuals
72	20 individuals

This means that individuals begin to lose their adaptation to sea-water when kept in fresh water for about 36 hr., that is, the minimum time for adaptation to sea-water is approximately equivalent to that during which the fish keep their adaptation to sea-water.

(8) Having noticed during the previous experiments that males usually die before the females, 100 adult individuals of both sexes were transferred directly to pure sea-water. Five and a half hours after, fish began to die (especially males). Six and a half hours after they began to die, all males were already dead, but only 55 females were quite dead. The remaining females died within the following 12 hr.

We are aware of the probable existence of the factor, namely, weight of the individuals in the mortality, since the youngest adult female is usually heavier than the biggest male. However, we think that this factor is not exclusive. For the same sex (male), the histogram has shown that mortality was not a function of the weight, but represented by a Gaussian curve.

Effect of Temperature on *Apis indica* Workers

Recent work on the effect of environmental temperature on the European honeybee, *Apis mellifera*[1-3], has been partially repeated with two colonies of *Apis indica* brought from Ceylon by Mr. L. A. S. Perera.

Groups of 100 *A. indica* were kept in cages for three days with sugar syrup (2 parts sugar : 1 part water) and water at temperatures from 20° to 40° C., three groups being kept at each temperature; the amount of food and water consumed, the temperatures at the centres of the groups, and the number of bees which died, were recorded. The results are given in Table 1. Comparable results for *A. mellifera* are in brackets.

Table 1

Environmental temperature (° C.)	Mean temperature of groups (°C.)	Mean consumption (mm.^{3}) per bee per day		Mean No. dead at end of day 1
		Sugar syrup	Water	
20	24·0 (24·9)	17·1 (31·7)	0·1 (0)	8·9 (4·0)
25	29·3 (29·6)	17·2 (21·3)	0·1 (0·3)	5·5 (1·0)
30	31·4 (30·8)	14·3 (11·5)	0·1 (0·5)	4·0 (4·0)
35	35·7 (35·0)	11·6 (18·6)	1·2 (10·1)	1·0 (3·7)
40	39·6 (39·2)	1·9 (5·5)	21·8 (16·7)	15·0 (13·8)

Groups of *A. indica* at 20° and 25° C. took similar amounts of food and were both about 4 deg. C. above environmental temperature but, in general, the lower the environmental temperature the greater the difference between it and the group temperature, and the greater the food consumption. Thus *A. indica* like *A. mellifera* responds to low temperature by increased food consumption, indicating increased metabolism, and increased production of heat. At 40° C. both species took little food but large quantities of water, reflecting a high rate of losing water. The mortality of both species was similar at the higher temperatures, but was greater for *A. indica* at the lower temperatures.

To find the temperature at which the two species enter chill coma single *A. indica* and *A. mellifera* workers were taken from their hive entrances and placed at low temperatures. Table 2 shows the numbers that moved and were still after exposure for 1 hr. All those that were still, moved again when the temperature was raised.

Table 2

Environmental temperature (° C.)	*A. indica*		*A. mellifera*	
	Moved	Still	Moved	Still
8	0	12	0	12
9	0	17	3	15
10	1	30	20	10
11	22	22	33	10
12	15	12	21	3
13	21	4	26	0
14	6	0	6	0

Unfortunately, the *A. indica* colonies died before much information could be obtained on the effect of previous acclimatization on chill coma temperatures. However, after acclimatization at 35° C. for 24 hr. only 6 out of 21 *A. indica* moved at 11° or 12° C., whereas 12 out of 18 *A. mellifera* moved. Thus the species differed in behaviour ($P < 0 \cdot 05$) even when acclimatized to the same temperature. Both appeared to have a higher chill coma temperature after being kept at temperatures higher than they would have experienced at their hive entrances.

Mellanby[4] found that *Cimex lectularius* (from temperate regions) was more resistant to starvation and desiccation, and could breed more successfully at low temperatures than *C. rotundatus* (from tropical regions) but found no circumstance in which *C. rotundatus* was markedly superior. Our results indicate that *A. mellifera* is more adapted to temperate climates than *A. indica*, but do not show that *A. indica* has any corresponding adaptation to the tropics.

Effect of Ringing Cotton Stems on Content of Reducing Sugars and Insoluble Nitrogen and on Degree of Infection with *Xanthomonas malvacearum* (E.F.S.) Dowson

Hughes and Fowler[1] reported that the glucose-level of the leaves of synthesized varieties containing black-arm resistance genes B_2 or $B_2 + B_3$ was higher than that of the susceptible parent type during the first three months after sowing. Bird and Joham[2] found that girdling the main stem of a susceptible variety caused cotton plants to become more resistant to the same disease. In the present investigation the effect of ringing the main stem of cotton plants on the level of reducing sugars and insoluble nitrogen in the leaves, and its relation to infection with the angular leaf spot disease, were examined.

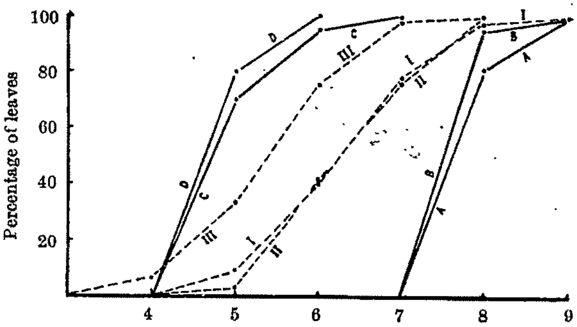

Fig. 2. Cumulative percentage of leaves showing different grades of infection (for explanation of letters and figures, see Table 1). ●——●, 1957 series; ● – – – ●, 1958 series

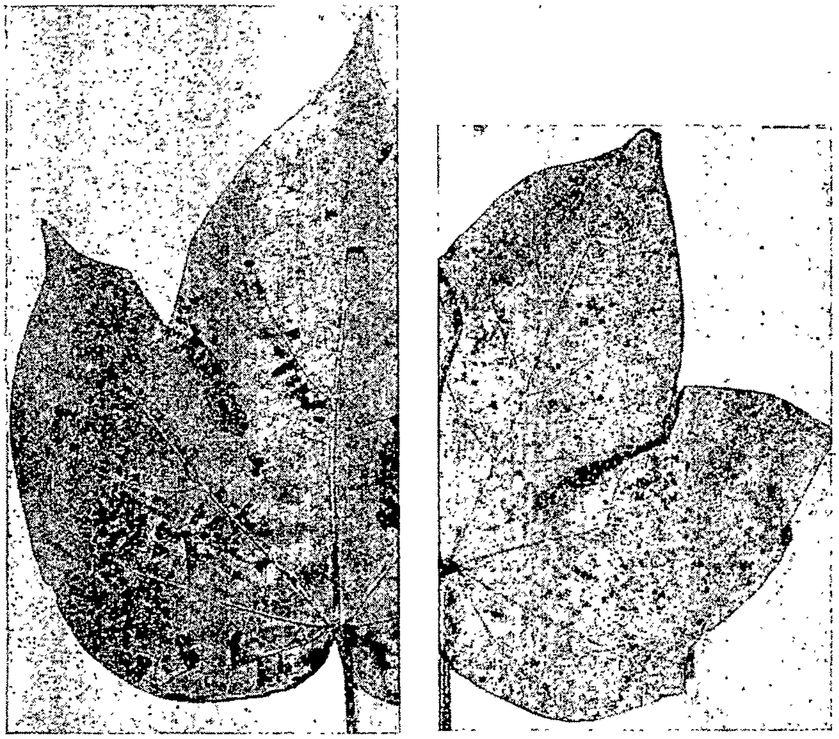
Plants of susceptible Domains Sakel cotton (*Gossypium barbadense* L.) were grown singly in 18-l. tins, topped when about 4 months old to induce thicker foliage, and inoculated about 4 wk. later. Two series of experiments were carried out. In the first, namely, 1957 series, inoculation was by rubbing the under-surface of the leaves with the crude suspension of *Xanthomonas malvacearum* prepared from naturally infected leaves of cotton. Twenty to thirty leaves, borne on four plants, were inoculated for each treatment (Table 1). In the second series (1958 series), inoculation was by spraying a thick water suspension of a recent isolate of *X. malvacearum* on to the leaves of the same variety of cotton. Eight plants were so inoculated in each treatment and 80–100 leaves were used for assessing the degree of infection about 4 wk. later in accordance with the grading system adopted in ref. 3. The grades were based primarily on the size and shape of the spots, with 1 representing full immunity and 12 full susceptibility.



(*a*) (*b*)

Fig. 1. Angular leaf spots on Domains Sakel cotton (1957 series); (*a*) plants not ringed, and (*b*) plants inoculated 10 days after ringing the stem

Representative samples were taken from each plant of the 1958 series for determination of reducing sugars and insoluble nitrogen contents. These samples were chosen of approximately the same size and age, and were cut just before spraying the bacterial suspension at 10–12 a.m. Maskell and Narain's modification (unpublished) of the method in ref. 4 was

adopted for determining reducing sugars. Insoluble nitrogen was determined using a modification by Hassan[5] of the method in ref. 6.

The results of the 1957 series of inoculation experiments showed a marked increase in resistance to angular leaf spot disease 10–15 days after ringing the stems of cotton plants (Fig. 1). Plants ringed and inoculated on the same day showed no appreciable difference in the degree of infection as compared with the control (not ringed). The results of the 1958 series showed a similar trend, but were less marked (Fig. 2), probably due to differences in the method of inoculation adopted in each series. The increase in resistance coincided with a significant rise in the level of reducing sugars in the ringed plants (Table 1). Insoluble nitrogen contents, on the other hand, did not differ significantly in the three treatments. However, there was a tendency toward a lower level of insoluble nitrogen in ringed plants, which was manifested further by a pale green colour of the leaves.

As shown[7], carbohydrates increase in the leaves of stem-ringed plants while the nitrogen-level remains more or less the same. The above results show that this trend causes the plants to become more resistant to angular leaf spot disease. They show, furthermore, that a high level of reducing sugars should prevail at the time of infection. Thus, unless ringed plants are allowed a sufficient time to accumulate sugars in the leaves before inoculation, ringing would exert little or no influence on the degree of infection. The insoluble nitrogen, on the other hand, does not seem to have an effect on the degree of infection. This is in accordance with Hassan's results (unpublished).

ENTOMOLOGY

Use of an Artificial Spermatophore in the Study of Activation of Spermatozoa and Development of Spermatophores in the Cockchafer

I HAVE already described[1] the development of the reproductive organs in the male of the cockchafer (*Melolontha melolontha* L.) and the origin, development, and function of the spermatophore. The spermatophore is formed in the copulatory sac of the male while it is inserted in the bursa copulatrix of the female. The contents of the genital duct (bundles of inactivated spermatozoa, cyst cells) and the secretion of the accessory glands (the hyaline component staining green with Masson's trichrome, a granular component staining red, and basophil droplets staining blue-violet) are expelled into the copulatory sac. Within three hours of copulation, the spermatophore is encased in a protein membrane and deposited in the bursa copulatrix.

The components forming the spermatophore are at first randomly mixed. During copulation and following the deposition of the spermatophore in the bursa copulatrix, characteristic changes take place. The components of the secretion of the accessory glands are differentiated into islands of hyaline and granular substances. The spermatozoa are activated, separate from the bundles, and form clusters. They digest the hyaline substance. By this digestion numerous basophil drops begin to form. The activated spermatozoa, by means of chemotaxis, then enter the receptaculum seminis. The entire course of development has been studied by serial sections.

The suggestion of using an artificial spermatophore originated in the attempt to discover if the mechanism initiating the reactions in the spermatophore was the simple mixing of the spermatophore components or the influence of the ejaculatory duct during copulation or of the bursa copulatrix. The artificial spermatophore is prepared as follows. The contents of the dissected ejaculatory duct and the accessory glands of the male are mixed on a slide approximately in the ratio of 1 : 2 (this ratio corresponds to the ratio in natural conditions). The drop is mixed lightly and covered with a cover-slip. The mixture must be spread without any air bubbles under the entire cover-slip, the edges of which are then sealed with 'Vaseline'. It is necessary to carry out the work quickly. The entire development can then be examined by phase-contrast microscopy.

The components of the artificial spermatophore are distributed randomly when it is first made (Fig. 1). After 30 min. the differentiation of the components of the accessory glands begins. 1–2 hr. later the individual spermatozoa are activated and they move about in the hyaline substance (Fig. 2). After 2–3 hr. the spermatozoa are completely activated and concentrated in large clusters. From 6 to 24 hr. the hyaline substance gradually decreases. After 24 hr. (18° C.) when the hyaline substance is used up, movement of the spermatozoa ceases.

Artificial spermatophores not only clearly show that all the changes are entirely independent of external factors, but also make it possible to observe the entire course of development of the spermatophore *in vitro*.

When the artificial spermatophore was subjected to flowing oxygen, air and nitrogen, development of the spermatophore was found to be quickest and activation most complete in nitrogen ; air was not so

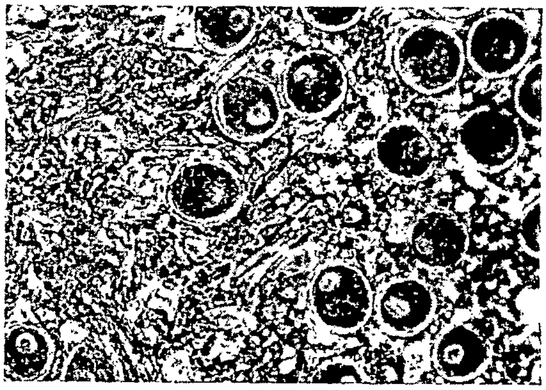

Fig. 1. Artificial spermatophore immediately following its preparation. The components of the secretion of the accessory gland and genital duct are randomly distributed. Phase contrast. (× 210)

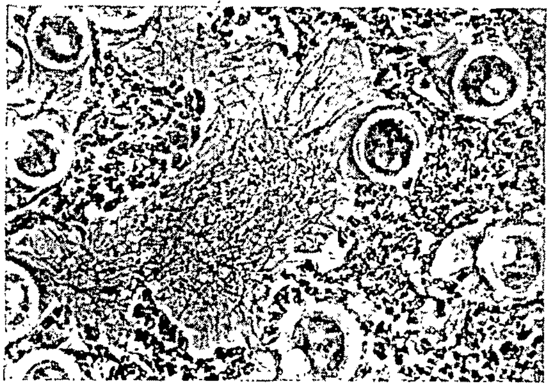

Fig. 2. Artificial spermatophore after 1–2 hr. The components of the secretion of the accessory glands are being differentiated. Individual, activated spermatozoa appear in the hyaline substance. Phase contrast. (× 210)

effective. Although a quick activation of spermatozoa takes place in oxygen, there is, however, no differentiation of the secretions of the accessory glands in oxygen, so that the spermatozoa die in about 1 hr. The mechanism of the development of the spermatophore is, therefore, adapted to the conditions in the bursa copulatrix where there is a lack of oxygen.

Experiments have shown that although oxygen itself may initiate the activation of spermatozoa, it does not do so, however, under natural conditions. Both in the artificial and natural spermatophore, the activation of spermatozoa is initiated by the hyaline substance (in making artificial spermatophores a slight activation often takes place due to contact with air). 10–15 min. after sealing the cover-slip, movement ceases. Complete activation with subsequent clustering may be observed only after differentiation of the secretion of the accessory glands.

The differentiation of the secretion is caused both by the cyst cells and by the bundles of inactivated spermatozoa, evidently due to the change in the surface tension in the spermatophore mass.

The method of making artificial spermatophores, on account of its simplicity, may be used not only in the work on special problems of the development of the spermatophore in insects, but also in some general biological problems, mainly those of activation, inactivation and nutrition of spermatozoa.

Termination of Pupal Diapause in the Cinnabar Moth and the Reproductive Capacity of the Resulting Females

Many thousands of pupæ of the cinnabar moth, *Tyria jacobaeae* L., from southern England, and a smaller consignment from central Italy, were introduced into Australia for the control of the noxious weed, ragwort (*Senecio jacobaea* L.), in southern Victoria. In England this moth has a strictly univoltine life-cycle[1] that includes an obligatory pupal diapause[2] lasting for an average of 270 days. Because of this diapause[3], difficulties were expected in synchronizing emergence of the moths with the Australian summer—for this would require diapause to be terminated in less than 150 days or extended to at least 450 days.

The pupæ were stored at 1–3° C. between layers of moist sphagnum. It was hoped that diapause could be terminated by chilling pupæ and later exposing them to higher temperatures. All pupæ were so treated except one small batch of the Italian consignment which was stored at room temperature (range 5–15° C.).

At the beginning of the Australian summer, most of the pupæ were transferred to an insectary where temperatures ranged from 15° to 35° C., but only 6·1 per cent of the English and none of the Italian pupæ produced moths. Strangely enough, 50 per cent of the Italian pupæ kept at room temperature emerged. However, very few of the progeny of these Italian moths completed the larval stage, whereas those from adults of English origin were reasonably successful. Dissections made at the end of summer showed that most of the English pupæ were still alive. The remainder were returned to a cold room and stored until the following year when, after 500 days in diapause, they were again subjected to temperatures in the range of 15–35° C. This second exposure produced an 8·6 per cent emergence.

Three groups of pupæ were set aside to study the effect of temperature and duration of exposure on emergence of adults (see Table 1). Group *B* was held continuously in the cold room at 1–3° C. for 270 days. Group *A* was similarly chilled for 50 days, and then exposed to temperatures within the range 20–48° C. for 150 days. Group *C* was chilled for 90 days, and then held at 15–35° C. for 150 days. Both *A* and *C* were then returned to the cold room. When the pupæ had been in diapause for 300 days, 2–6 batches, each of 25 pupæ, were exposed to 20° C. Samples were drawn from each experimental group at intervals of three weeks. The emergences that resulted are summarized in Table 1. The results for Group *A* suggest that abnormally high temperatures alternating

Table 2. Reproductive Capacity of the Cinnabar Moth

Stock	No. of females tested	No. of diapause (days)	Time of emergence	Percentage of females ovipositing	No. of eggs laid	No. of eggs hatched per female
English	40	150	Jan. 1955	6·2	75	10
Italian	20	150	Jan. 1955	8·5	94·4	29·9
English	100	270	May 1955	8·6	95·7	60·1
English	100	360	Aug. 1956	7·9	81·5	37·6
English	100	420	Oct. 1956	7·8	60·2	15·8
English	100	500	Jan. 1957	8·0	58·9	8·1
Australian	50	270	Dec. 1957	7·8	155·1	74·7

with cold treatment produce an erratic although tolerably high emergence of adults. Prolonged cold treatment (group *B*) was apparently detrimental to the pupæ, as the gradually decreasing values suggest. This was also reflected in the statistical analysis, where emergence from group *B* was significantly different from that of group *A* or *C*. In group *C*, receiving alternately cold and warm conditions, relatively high emergence (40 per cent) was recorded after 533 days, that is, after the insects had spent almost twice the normal period in diapause. The sharp contrast in the results from the English and Italian consignments suggests that they may have comprised two different strains of insects. The English strain proved itself to be the more suitable for the climate of Gippsland, Victoria.

Three factors influencing the reproductive capacities of the moths that emerged under various treatments are summarized in Table 2. All three factors—percentage females ovipositing, number of eggs laid and number of eggs hatched per female—were optimal or near optimal when pupal diapause extended for the normal period of 270 days. In the case of the English stock, however, this corresponded to emergence during the Australian winter. A diapause period of 150 days (that is, emergence in the first Australian summer) resulted in less-favourable reproductive capacity, as also did such longer diapause periods as 360, 420 or 500 days. Although females of the Italian stock laid more eggs than those of the English stock, and their viability was also appreciably higher, very few of their progeny completed larval development. The differences in fecundity associated with the duration of diapause were found to be significant.

To sum up, although termination of diapause in *T. jacobaeae* was more successful when this stage was prolonged rather than shortened, the fecundity of the moths produced was adversely affected by long periods of diapause.

BACTERIOLOGY

Interspecific Induction of Transformation of Bacteria with Respect to Phage-susceptibility

Several examples of bacterial transformation have been reported since the discovery of the phenomenon by Griffith[1]. Among the properties found to be transformed, besides synthesis of the capsular polysaccharide antigens, are drug-resistance and enzymic capacities[2]. In work concerned with the host-specificity of a phage (*S-a*) attacking an amylase-forming bacterium, *Bacillus subtilis* var. *amyloliquefacus*[3], we have tried to transform a non-susceptible organism into a susceptible one. This communication describes the successful results of such an experiment.

First, a trial was made to obtain a susceptible organism through mutation of non-susceptible strains of the *subtilis* group, but with little success, because of the difficulty of discriminating between the wild form and any mutants which might have been produced. A coloured organism, *Bacillus megaterium roseus*, was used in the next trial, in view of the ease in overcoming this difficulty. In fact, several colourless mutants were obtained by the application of a cell-free extract prepared from the susceptible organism. Then tests were made to examine these mutants for their susceptibility to the phage under investigation, which led to the discovery among them of one susceptible mutant. Experimental results will be described briefly now.

The transforming agent was prepared from the cells of the susceptible organism (*Bacillus subtilis* var. *amyloliquefacus*) in the logarithmic phase of its growth (4–5 hr. after inoculation). The bacterium was incubated in a nutrient broth medium in a reciprocal shaker at 37° C. Bacterial cells were gathered by centrifugation, washed three times in 0·9 per cent physiological saline and resuspended in about 10 ml. of the same saline. The cells were disrupted with a sonic oscillator operating at 9–10 kc./s. for 15 min. at 5° C. Cell fragments were collected by centrifugation (10,000*g* 20 min.), the supernatant filtered through a Seitz filter and used as transforming agent after a test for absolute sterility. On the other hand, the cells of *Bacillus megaterium roseus* in the logarithmic phase of growth were incubated at 37° C. in a broth medium with the addition of the transforming agent (final concentration, about 20 μgm. DNA per ml., as determined by the method of Webb and Levy)[4]. At intervals, platings (broth agar) were made to detect the formation of mutants, using several dilutions of aliquots taken from the culture. After 16–18 hr. of incubation, the occurrence of transformation was actually detected, as revealed by the appearance, on later plating, of discoloured mutant colonies at a frequency of approximately one in 10^3–10^4 genuine, pink-coloured colonies. Some of these mutants were pale-yellow in colour, some colourless. No change in morphological characteristics (size and shape) of the cell was discovered in either of them. Each colony of the mutants, as discerned by the naked eye, was separately tested for its susceptibility to phage *S-a* by plating the cells with the addition of appropriate amounts of the phage. With most of the mutants, the result was negative, but there was a colourless strain which showed evident plaque-formation in the test. Multiplication of the phage afterwards was also confirmed by several successive transplantations of the plaques on the colourless mutant.

No back-mutation has been detected, offspring obtained by subculturing the mutant strain, when tested, always exhibiting the acquired characteristics of the mutant, white colour of the colony and susceptibility to phage.

The formation of mutant, either coloured or colourless, was found to be reproducible, its frequency being augmented to some extent by increasing the concentration of the transforming agent. On adding still larger amounts of the inducing agent, however, a state of saturation was obtained, corresponding to a frequency of one mutant colony per 10^3 normal, pink-coloured colonies.

These results are best accounted for by assuming a transformation of the originally phage-resistant, pink-coloured strain of *Bacillus megaterium roseus*, into a phage-susceptible, colourless mutant.

The role of the bacterial extract in inducing the transformation in question is indicated evidently by the fact that no single example of formation of susceptible mutant has ever been observed without the addition of the extract. The colourless mutants appearing, although far less frequently, as a result of spontaneous mutation (that is, without any addition of transforming agent) were also tested for phage-susceptibility but always with negative results. This transforming agent was also found not to be replaceable with extracts prepared in a similar way but from other phage-resistant strains of bacteria (for example, *Bacillus mesentericus vulgatus* Piorkowisky and *Bacillus subtilis NRRL* 558). As to the actual nature of the transforming principle contained in the effective extract, any decisive account will be premature. In view of the finding, however, that the inducing activity of the extract is abolished by treating it with deoxyribonuclease, there is a possibility that a specific deoxyribonucleate is involved (prolonged treatment with other hydrolysing enzymes, such as ribonuclease and trypsin, had no effect on the activity).

In conclusion, it may be stated that the facts reported above will be of some importance in disclosing the possibility of interspecific induction of transformation in bacteria mediated by a soluble transforming principle.

The present work was initiated by the advice given by Prof. A. Takamiya, University of Tokyo, to whom our thanks are due.

Chitinoclastic Activity in the Luminous Bacteria

There would appear to have been no reports in the literature on luminous bacteria of chitinoclastic activity in this group[1] nor, during attempts to obtain chitinoclastic bacteria from marine environments, have luminous bacteria been isolated[2,3]. Indeed, in a recent publication[4] it is stated that members of the genus *Photobacterium* "do not or are not known to hydrolyse . . . chitin". It is, consequently, of importance to report observations made some time ago on the chitinoclastic activity of a variety of luminous bacteria, all the species available at present having been examined.

Chitin was prepared from crab shells by the method of Benton[5], and following precipitation from sulphuric acid by potassium hydroxide and washing it was added to a basal medium consisting of glucose 0·1 per cent, peptone 0·1 per cent, dipotassium hydrogen phosphate 0·005 per cent and agar 1·5 per cent in sea-water, to give a milky opacity. The cultures were streaked on the surface of this medium, incubated at 20° C. for up to 14 days, and examined for the production of a zone of clearing of the chitin around the bacterial growth.

Ph. phosphoreum	12	Marine animals, Drs. Iijima, Yosaki, Japan	11
Unidentified, similar to *Ph. fischero*	29	Fish intestinal contents, North Sea	21
Unidentified possibly new species	1	Fish intestinal contents, North Sea	1

Table 1 shows the strains examined, their source, and their ability to digest chitin under the experimental conditions used. The cultures recorded as negative were not re-examined nor was incubation continued beyond 14 days. It would appear that chitinoclastic activity is widespread among the luminous bacteria, even the freshwater species, *Vibrio albensis*, exhibiting it, and it is, consequently, perhaps not unreasonable to suggest that chitinoclastic activity, to a greater or lesser degree, may be a constant characteristic of this group of bacteria.

The part that the luminous bacteria may play in the degradation of chitin in Nature is obscure. Certain members have been found to be almost invariably present in and frequently forming a large part of the bacterial flora of the intestines of a variety of fish caught in the Arctic, North Sea and around the British Isles. Crustacea may form a not inconsiderable portion of the diet of such fish, and it has been suggested that symbiotic bacteria may aid animals in the digestion of chitin[2]. It is probable, however, that much of the chitin in the oceans finds its way to the bottom deposits and there is little, if any, information concerning the occurrence of luminous bacteria in this environment.

The work described in this communication was prepared as part of the programme of the Department of Scientific and Industrial Research.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Tuesday, June 6

Operational Research Society, and the British Institute of Management (at the Connaught Rooms, Great Queen Street, London, W.C.2), at 9.30 a.m.—Conference on "Operational Research".

University of London (in the Clinical Lecture Theatre, Middlesex Hospital Medical School, Mortimer Street, London, W.1), at 4.15 p.m.—Sir William Ogg: "Soils, Crop Nutrition and Health"* (Sanderson Wells Lecture).

University College (in the Physiology Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. G. P. Lewis: "Bradykinin, its Chemistry, Pharmacology and Role in Physiological and Pathological Reactions".*

University of London (at the Institute of Archæology, Inner Circle, Regent's Park, London, N.W.1), at 5.45 p.m.—Prof. F. E. Zeuner: "Archæological Problems of the Canary Islands".*

Wednesday, June 7

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. P. Wildy: "Architecture of Viruses".*

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. G. R. Coope: "A Northern Insect Fauna from a Terrace of the River Avon at Fladbury, Worcestershire": Dr. H. J. Sullivan: "Distribution of Miospores through Coals and Shales of the Coal Measures Sequence Exposed in Wernddu Claypit, Caerphilly, South Wales".

Thursday, June 8

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. D. J. Bradley: "The Rapid Measurement of Intensity with an Oscillating Fabry-Perot Spectrometer: Isotope Abundance in Mercury": Mr. A. H. Cook: "Precise Measurements of the Density of Mercury at 20° C. II: Content Method".

Royal Institution of Naval Architects (at 10 Upper Belgrave Street, London, S.W.1), at 4.45 p.m.—Mr. J. Clarkson: "The Behaviour of Deck Stiffening under Concentrated Loads" and "Uniform Pressure Tests on Plates with Edges Free to Slide Inwards".

Mineralogical Society (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers.

Institute of Physics and the Physical Society, Acoustics Group (in the Physics Department, Imperial College of Science and Technology, Prince Consort Road, London, S.W.7), at 5.30 p.m.—Annual General Meeting, followed by Dr. W. L. Nyborg (University of Vermont): "Biophysical Applications of Non-linear Acoustics".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Research Worker in Glaciology—Dr. Hal Lister, Lecturer in Polar Studies, King's College, Newcastle-upon-Tyne 1 (June 8).

Assistant Lecturer in Experimental Physics, to collaborate in research in high energy nuclear physics using the accelerators of C.E.R.N. and the Rutherford Laboratory—The Secretary to Council, Westfield College (University of London), Hampstead, London, N.W.3 (June 9).

Assistant Lecturer and a Lecturer in Physics—The Registrar, The University, Nottingham (June 10).

Lecturer or Assistant in Geology—The Secretary of University Court, The University, Glasgow (June 10).

Research Assistant in Mathematical Statistics in the Department of Applied Mathematics—The Registrar, The University, Liverpool (June 10).

Scientific Officer (graduate with first- or second-class honours in mathematics with statistics, or a diploma in statistics) in the Statistics Section, for duties mainly concerned with the design and analysis of field experiments—The Secretary, Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen (June 10).

Research Assistant (with a degree qualification in physics, and preferably an interest in high vacuum techniques and/or electronics) in the Department of Physics and Mathematics, College of Technology, Liverpool, to participate in a research programme dealing with electron impact and corrosion—The Director of Education, City of Liverpool Education Committee, 14 Sir Thomas Street, Liverpool 1 (June 12).

Demonstrator (with a good honours degree in biology or zoology and preferably with experience in practical genetics) in the Biology Department—The Registrar, University College of North Staffordshire, Keele, Staffs (June 15).

Assistant Lecturer in the Geology Department, to teach mineralogy and encourage research in this field—The Registrar, King's College (University of London), Strand, London, W.C.2 (June 16).

Geochemist (with a special interest in spectrography and preferably previous experience of the geochemistry of sedimentary rocks) in the Department of Geology—The Registrar, The University, Sheffield (June 16).

Lecturer in Biochemistry—The Secretary of University Court, The University, Glasgow (June 16).

Assistant Lecturer (Grade III) in Botany—The Registrar, The University, Bristol 8 (June 17).

Professor of Botany—The Secretary and Bursar, University College, Earlsfort Terrace, Dublin, Republic of Ireland (June 17).

Research Assistant (graduate in chemistry or biochemistry) in Chemistry, to work in the Department of Chemistry of the Faculty of Science under the direction of Dr. G. R. Barker on the chemistry and biochemistry of nucleic acids—The Registrar, The University, Manchester 13 (June 17).

Research Assistant in the Department of Mathematics and Physics, to take part in research work on the microwave properties of certain magnetic oxides and to undertake a certain amount of teaching—The Registrar, College of Technology, Park Road, Portsmouth (June 17).

Research Associate (Applied Mathematician) in the Department of Theoretical Mechanics (Faculty of Engineering)—The Registrar, The University, Bristol 8 (June 17).

Virologist, Experimental Officer (male, with a degree in botany or agriculture and experience of plant virus techniques), to co-operate in research aimed at developing virus resistance in the potato—The Secretary, Scottish Plant Breeding Station, Pentlandfield, Roslin, Midlothian (June 17).

Lecturer (Grade II) in the Department of Mechanical Engineering—The Registrar and Secretary, The University, Bristol (June 19).

Assistant Lecturer in Biochemistry in the Department of Agricultural Biochemistry—The Registrar, University College of Wales, Aberystwyth (June 24).

Lecturer in Pharmacology in the Department of Pharmacology and Therapeutics—Joint Clerk to the University Court, Queen's College (University of St. Andrews), Dundee (June 24).

Research Assistant (man or woman graduate of any university) for freshwater phytoplankton investigations—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey (June 24).

Lecturer (with a knowledge of selection and breeding of Nigerian grasses) in Plant Breeding in the Department of Agriculture, University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (June 25).

Lecturer or Assistant Lecturer in Physiology—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (June 30).

Lecturers (2) in Chemistry at Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, W.C.1 (New Zealand and London, June 30).

Lecturer or Assistant Lecturer in Physical Metallurgy—The Assistant Registrar (Science), The University, Edgbaston, Birmingham 15 (July 1).

Research Students (with the degree of Bachelor or Master of a British University other than Manchester) in Science—The Registrar, The University, Manchester 13 (July 1).

Senior Lecturer (experienced in clinical biochemistry as well as in administration and capable of directing the clinical pathology service of a general hospital of approximately six hundred beds) in Clinical Pathology at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong and London, July 7).

Senior Lecturer or Lecturer in Scientific Thought in the School of Philosophy, University of New South Wales—Agent-General for New South Wales, 56–57 Strand, London, W.C.2 (Australia and London, July 14).

Assistant Professor in Biophysics and an Assistant Professor in Meteorology—G. M. Shrum, Physics Department, University of British Columbia, Vancouver 8, B.C., Canada.

Distillers Company Research Student in the Department of Chemical Engineering, for work leading to a higher degree on the kinetics of the gaseous oxidation of aromatic hydrocarbons—The Secretary, University College, Gower Street, London, W.C.1.

Graduate (with a good first degree in chemistry, physics or chemical engineering) in the Chemical Engineering Department, to undertake research for a higher degree on some aspects of flame propagation—Dr. J. H. Burgoyne, Chemical Engineering Department, Imperial College of Science and Technology, London, S.W.7.

Head of the Department of Parasitology, The Secretary, Animal Diseases Research Association, Moredun Institute, Gilmerton, Edinburgh 9.

Head (with high academic qualifications in mathematics and teaching and research or industrial experience) of the Department of Mathematics—The Principal, Huddersfield College of Technology, Huddersfield.

Lecturer in Mathematics: and an Assistant, Grade B, in Mathematics—The Registrar (Department *F*), Bradford Institute of Technology, Bradford 7.

Low Temperature Physicist (Assistant Professor, Associate Professor or Professor) in the Low Temperature Laboratory—G. M. Shrum, Physics Department, University of British Columbia, Vancouver, B.C., Canada.

Postdoctoral Fellow, for work in the field of photochemical reactions in the alkali halides—Dr. P. W. M. Jacobs, Chemistry Department, Imperial College of Science and Technology, Prince Consort Road, London, S.W.7.

Postdoctoral Research Fellow, for research in gas kinetics—Dr. H. M. Frey, Chemistry Department, The University, Southampton.

Reader (with high academic qualifications and considerable teaching and research experience in any field of botany or zoology) in Biology—The Registrar (Department *F*), Bradford Institute of Technology, Bradford 7.

Scientific Officer or Senior Scientific Officer (honours graduate in chemistry or biochemistry) in the Physiology Department, to study the isolation and properties of various enzymes from the mammary gland and milk—The Secretary, The National Institute for Research in Dairying (University of Reading), Shinfield, near Reading, quoting Ref. 61/16.

CO-OPERATION IN THE EXPANSION OF HIGHER EDUCATION

THE strength of a modern economy depends on its industrial vigour, and this in turn on technology, or the continuous application of scientific knowledge. All are based on the creative capacity of man and on his education. Accordingly, an adequate supply of scientists, engineers and technicians is a major factor in economic growth, and recognition of this led the Organization of European Economic Co-operation to establish in 1958 its Office for Scientific and Technical Personnel, with the main task of assisting member countries to increase their scientific and technical man-power, in quality as well as in quantity. Major aspects of the programme of this Office include forecasting future needs for scientific and technical man-power; determining the investment required in education and training facilities to meet those needs; modernizing methods of teaching and curricula in mathematics and science subjects in the schools; training and re-training teachers; and facilitating international exchange of information and personnel in this field.

When the Office was established in 1958, few member countries had adequate statistics on their position with regard to man-power, and still fewer on future requirements. The statistical procedures for producing such data had no international standard, nor were there standards for academic qualifications or international equivalents. As a first step, therefore, the Office arranged a conference on "Techniques for Forecasting Future Requirements of Scientific and Technical Personnel" at The Hague in November 1959, at which a series of papers was presented on such subjects as economic growth and the man-power factor; educational planning in the light of economic requirements; the role of statistics in forecasting the demand for, and supply of, scientific and technical personnel; and intellectual resources and the growth of higher education.

These papers and brief summaries of the ensuing discussion have now been published under the title *Forecasting Manpower Needs for the Age of Science**. The Office clearly proposes to work on very similar lines to those of the U.S. National Science Foundation, and it needs no more than a glance at such an article as "More Universities" in *The Westminster Bank Review* of February to appreciate how closely the programmes of both bodies bear on current problems in Britain. It is obvious, too, from recent addresses of university authorities, such as that of Sir Charles Morris, vice-chancellor of the University of Leeds, at a meeting of the University Court last November, or that of Dr. B. V. Bowden at the annual meeting of the Court of Governors of the Manchester College of Science and Technology in the same month, how keenly they are aware of the importance of these factors. Dr. Bowden, for example, stressed particularly the importance of adequate expansion in engineering and urged re-consideration of the establishment of a technological university on a large enough scale. At Leeds the questions of numbers. standards and balance of studies, alike in relation to general education and to the demands of the community for particular categories of qualified men and women, are obviously much in mind.

The article in *The Westminster Bank Review* is concerned more especially with the inquiry now being undertaken by the Robbins Committee, and surveys very fairly the situation which confronts Britain in both university and technical education with the growth of secondary education. It indicates very clearly some of the decisions which will have to be made at an early date—decisions which should be based on facts that are ascertainable, not on prejudice or tradition. Apart from the question of how large is the supply of students potentially capable of profiting by higher education, whether or not at a university, and taking account both of the 'bulge' and of the nation's needs for trained man-power, including overseas needs, the article stresses the vital importance of nourishing among as many young people as possible the ability to think for themselves and to question what Galbraith has termed broadly 'the conventional wisdom'. This does not imply that such education should necessarily be given at a university, though it is true that many students who fail to obtain a good degree have benefited from the broadening influence of university education, and that it is wrong that anyone of proved ability should be excluded from a university purely for lack of space.

The difficulties of university expansion are not to be under-estimated, or attributed simply to a reluctance of many university authorities to lower high academic standards, or to existing concepts of the optimum size for a university, any more than it should be assumed that an academic education is the best type of higher education for every promising student. Much more thought could well be given here to the function of the colleges of technology; and the question of balance, particularly in relation to the technical colleges, is extremely important. There are problems of staff, of the siting of new institutions, and of finance, and it is imperative that, so far as possible, these decisions should be based on careful analysis of the facts, and on critical and creative analysis by the Robbins Committee.

Whether, therefore, we agree or not with the view put forward at the conference at The Hague already mentioned by Dr. Alexander King, director of the Office for Scientific and Technical Personnel (Organization for European Economic Co-operation), that education is essentially a long-term process which requires planning on a careful assessment of the broad pattern of needs, and that forecasting of man-power needs is thus an essential pre-requisite to the elaboration of sound educational programmes, some such forecasting must have a place in planning the expansion of higher education of all types. This is just as true in such a country as the United Kingdom as it is in the lesser-developed countries. University expansion must be planned in relation to the potential needs, even although it must be planned in relation to available resources of staff, buildings and equipment and finance. In fact, as Mr. Erik Jb. Schmidt recognizes in his paper on economic growth and the man-power factor, the physical limits to a rapid development of technical education are likely to be greater obstacles than the economic limits, and this is especially true of staff.

---

* Organization for European Economic Co-operation: Office for Scientific and Technical Personnel. *Forecasting Manpower Needs for the Age of Science.* Pp. 141. (Paris: Organization for European Economic Co-operation; London: H.M. Stationery Office, 1960.) 7.50 N.F.; 10*s.* 6*d.*; 2 dollars.

Mr. Schmidt visualizes a definite vertical build-up of the educational system in any country from the elementary to the most-advanced scientific stages, with appropriate balance between the several professional and vocational sectors, varying from country to country. He stresses the need for flexibility, and suggests that even with the present imperfect knowledge of the most appropriate structure, much could be done to improve the effectiveness of existing systems. Better vocational counselling, the differentiation of education and the development of various types of education in a system of graduated steps, shortening the period of education by eliminating obsolete material in courses and using modern methods of instruction and more differentiated use of teachers are all means by which existing teachers could be used more efficiently and the demands made both on them and on students minimized.

Mr. P. H. Coombs in his paper seeks to indicate the assumptions which could form a basis for educational planning, the changes required and the basic steps which should be taken. Obviously the first step is a clear analysis and appraisal of the existing educational system; but there was a wide difference of opinion at the Conference as to the practicability of defining the educational aims and goals most appropriate for the period covering the next ten years. The Danish delegate thought that reliable long-range forecasts were scarcely possible, whereas Prof. M. Vermot Gauchy went much further than Dr. H. Goldstein or Dr. S. Moberg, who merely discussed the role of statistics in forecasting supply and demand or indicated methods and techniques used in Sweden for forecasting specialized man-power requirements, in that he presented an elaborate statistical technique for measuring a myriad of future needs within each individual economic sector. Nevertheless, all three appear by implication to accept the practicability of Mr. Coombs's third and fourth steps: determination of the economic resources and internal changes required to achieve these goals, and of the adequacy of institutional and political mechanisms and processes for educational planning and decision-making, for mobilizing educational resources and for executing agreed plans.

Mr. Coombs lays much stress on the contribution of the economist to the planning of education, and much more work of the type that Mr. Vaizey has undertaken in "The Costs of Education" is certainly needed. Nevertheless, the report does not ignore the inherent conflict between the planning and guidance of man-power on one hand and the freedom of choice in a free society on the other. Moreover, Prof. P. de Wolff's paper on intellectual resources and the growth of higher education, which leads to the general conclusion that available reserves seem to allow for a considerable expansion of participation in higher education,. points also to the importance of international co-operation in improving and unifying the methods for obtaining comparable data in this field. Prof. de Wolff also agrees with Dr. Goldstein that there is a sound basis for identifying talent among comparable social groups but stresses the considerable influence of environmental factors.

Generally, it may be said that the Conference agreed that as yet no established and unique methodology exists for forecasting in respect of scientific and technical personnel, and it would be unwise to regard forecasts as a rigid and infallible guide to policy. Forecasts of demand should indeed be increasingly comprehensive, but long-term forecasts require supplementing by short-term checks, and overall analyses and projections require supplementing by detailed examination, industry by industry, and by type of qualification. Apart from the attention given to the reserves of intellectual potential, stress was laid on the opportunities for increasing the efficiency of educational systems in utilizing talent, and this aspect must become of increasing importance as the cost of education continues to rise. Further, it is interesting to note not only the agreement at the Conference as to the value and opportunity for international co-operation in methodology in this field but also the recognition of the special problems of the under-developed countries in the supply of scientists, engineers and technicians, particularly in respect of special needs for investment in education within the framework of national economic development. As the writer in *The Westminster Bank Review* remarks, more than 6,000 places at British universities are at present taken by Commonwealth students, and a further 4,000 places by other foreign students. Despite the growth of universities in Colonial and Commonwealth territories, the general improvement in educational standards throughout Africa and Asia will lead increasing numbers of Commonwealth students to seek to finish their education at British universities and colleges of technology.

It would be folly to disregard this demand or to fail to provide for it as generously as possible in plans for the expansion of higher education in Britain. The existence of this need, however, only illustrates further the need for close integration of the economic, scientific and technological and the human aspects of the many problems involved, and the danger of taking sectional decisions at almost any stage or level. Again, the report of the Conference of the Office for Scientific and Technical Personnel well emphasizes the need for flexibility and for further inquiry in many directions. The need for experiment is no less urgent and should be remembered at all levels in planning the expansion of existing or the development of new universities, in the field of technological education, and in the inquiries for which the reconstituted Central Advisory Council for Education in England, under Lord Amory's chairmanship, is responsible.

It is perhaps particularly desirable that such considerations should be given due weight at conferences like that on specialization in schools convened early in March by the Education Group and the Manchester Branch of the Institute of Physics and the Physical Society, at which Lord James of Rusholme uttered strong words against forcing the choice between arts and science too early, and again in considering the reconstruction of technical education. Something more than better links between schools and technical colleges is required. The proposals in the White Paper on Technical Education (see *Nature*, March 4, p. 701) aimed at broadening the education received by the students, adapting the system more closely to the needs of industry, increasing the variety of courses offered and reducing the existing wastage should receive unqualified welcome; but these will not remove the need for much more creative and constructive thought about the relations of technical and technological education, and the relations of both to the schools and the universities. Moreover, while the national and economic aspects of these interrelated problems are rightly kept in the forefront, the human aspects are no less important, and it is unfortunate that only too often these tend to receive the least-discriminating treatment, or to be made the play-ball of party political prejudice. One very important reason for welcoming the co-operation between industry and educational institutions and authorities of all types, which the White Paper on Technical Education emphasizes, is the contribution it could make to eliminating this tendency.

A DIVERSITY OF THEOLOGICAL SPECULATIONS

Immortal Longings

By Stephen Findlay. Pp. 192. (London: Victor Gollancz, Ltd., 1961.) 21*s*. net.

The Firmament of Time

By Dr. Loren Eiseley. Pp. viii+183. (London: Victor Gollancz, Ltd., 1961.) 16*s*. net.

WHEN confronted with a good book with which he fundamentally disagrees, the first duty of a reviewer is to direct attention to its merits, and in the case of Mr. Findlay's volume they are considerable. *Immortal Longings* is a very well-written and well-informed study of the case for human immortality and the survival of bodily death. It surveys the familiar ground of metaphysical and theological beliefs, arguments and theories with admirable lucidity and concludes with a brilliant summary of the present situation in psychical research. I can at least cordially agree with Mr. Findlay in his opinion that philosophers and scientists would do well to pay more attention than they are wont to 'parapsychology'. The upshot of Mr. Findlay's critical study is almost completely negative. At the end 'immortal longings' remain no more than longings and personal immortality a faint possibility. To justify a position almost the exact opposite of Mr. Findlay's would need a book as long as his, and here I must note only some objections to his treatment of the subject. He rightly sees that the Christain belief in immortality depends on belief in God and in revelation. It is a pity that his chapter which touches on this basic theme is inadequate. A destructive criticism of the traditional theistic 'proofs' in their traditional form is not enough, and even this meagre ration of argument is imperfect. Can one, for example, fairly state the teleological argument without some reference to the evolution of mind? A process which issues in the capacity to understand itself, the evolution of the theory of evolution, has, one might think, at least some *prima facie* appearance of purpose; and, Can Kant be so far ignored as to omit all reference to the moral argument? Theistic philosophy has survived Hume's scepticism and moved on, just as science has survived his radical scepticism of causation and necessary connexion and moved on.

The negative conclusion about God and revelation vitiates Mr. Findlay's discussion of the resurrection of Christ. Those who first believed it accepted it as a culminating point in a revelatory process, apart from which it would have no significance, and the situation is the same to-day. The long section on empirical evidence for survival, though, as already remarked, excellently done, seems to me to be dominated by the presupposition that any hypothesis, however complex and conjectural, is to be preferred to that of survival, so that sometimes we seem to be invited to explain the incomprehensible by the inconceivable. This is particularly notable in the interesting discussion of the 'cross-correspondence' data. Almost at the end of his book Mr. Findlay introduces a new and disturbing factor—the mind-body relation. "The whole trend of modern neurology", he writes, "is towards regarding mind and brain as the subjective and objective aspects of the same thing." One could wish that he had elaborated this dictum by explaining what possible meaning it can have. What is this 'thing' which has two such different aspects and is itself presumably neither the one nor the other? This late appearance of the 'unknowable' is confusing for it raises the question whether perhaps it may be immortal!

Dr. Eiseley's book is a very different matter, though, in a wide sense, it bears on the same subject —the nature and destiny of man. It does not incite us, however, to argue or criticize but rather to listen to a prophetic word, to enter into the vision of a man of science contemplating the whole range of life and its development. The titles of the chapters are sufficient indication of the scope and trend of the author's thought: "How the World Became Natural"; "How Death Became Natural"; "How Life Became Natural"; "How Man Became Natural"; "How Human is Man?"; "How Natural is 'Natural'?". The book is in fact a prolonged meditation on the meaning of Nature. The dangers and terrors of the present and the future are not concealed; but the conviction emerges that there is that in man which transcends Nature, and, in Kierkegaard's words, "through the eternal we can conquer the future". Anyone who is depressed in spirit by reading Mr. Findlay's account of the prospects of immortality might find through reading Dr. Eiseley's *The Firmament of Time* a renewal of hope. These two books, diverse as they are in spirit and method, have one common character—they are both written with such grace and mastery of English prose that it is a pleasure to read them. W. R. MATTHEWS

ADVANCES IN ANALYTICAL CHEMISTRY

Advances in Analytical Chemistry and Instrumentation

Vol. 1. Edited by Charles N. Reilley. Pp. vii+445. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 90*s*.

THIS is the first of a series of volumes, to be published at annual intervals, the purpose of which is to select new ideas and instrumental techniques in analytical chemistry and subject them to a detailed, critical review by acknowledged practical experts.

The advisory board controlling this publication is composed of eighteen chemists of such eminence that the success of the series could unequivocally be predicted purely from a consideration of the personalities involved. The excellence of this initial volume serves, however, to confirm any such predilection in the mind of a reviewer.

E. H. Swift and F. C. Anson have contributed a welcome and authoritative chapter on the use of Iwanow's thioacetamide as a substitute for the traditional, but toxicologically objectionable, hydrogen sulphide reagent in general analysis. From kinetic hydrolysis studies, the best conditions for the employment of thioacetamide are established for acid and alkaline media. Detailed practical examples are quoted for the separation of many cations using this unique reagent.

C. A. Horton discusses trends in the macro- and micro-determination of fluorine. This is an element of considerable commercial interest, and it also is important in the fields of water treatment (dental caries) and archæological dating. The review is detailed and up to date, and includes discussion of Prof. Belcher's new reagent, cerium 1,2-dehydroxyanthroquinonyl-3-methylamine-N-N-diacetic acid.

W. Schoniger presents a chapter on organic micro-analysis. The oxygen-flask micro-combustion method is discussed side by side with the more classical micro-chemical methods. The chapter begins with some most useful advice on weighing procedures.

Gas chromatography attracts wide interest because of its delicacy and specificity in micro-analysis. R. B. Seligman and F. L. Gager have contributed an excellent paper on modern detector systems, with particular comment on the great sensitivity of the newer ionization devices. R. F. Godda presents a similarly detailed treatment of the successful application of near infra-red spectrometry in the 1–3μ region. This paper provides a series of valuable tabular information on absorption spectra in this unique range, together with useful comment on the application of various commercial infra-red spectrophotometers.

Approximately a quarter of this first volume is devoted to a critical review by H. Flaschka and A. J. Barnard of the analytical usages of the tetraphenylboron reagent, which for almost a decade has been employed extensively for the gravimetric determination of potassium. The authors describe the applications of tetraphenylboron to the other alkali metals in titrimetric determinations both of volumetric and electrometric type, and also its uses in spectrophotometry and turbidimetry. The applications of tetraphenylboron in the identification and estimation of organic compounds are also described. W. Reinmuth contributes a review chapter on the theory of electrode processes, and the charge transfer phenomena associated with reversible and irreversible systems. Problems associated with electrode materials, salt effects, surface active species, etc., are all discussed critically and the article provides an extensive bibliography of papers on this most complex subject.

This series presents in a compact form the authoritative views of acknowledged experts on techniques and theoretical advances in the physical and analytical fields, and will undoubtedly be welcomed by the research worker and the academic student alike.

D. T. LEWIS

FAST-NEUTRON HANDBOOK

Fast Neutron Physics

Edited by J. B. Marion and J. L. Fowler. Part 1: Techniques. (Interscience Monographs and Texts in Physics and Astronomy, Vol. 4.) Pp. xiv+983. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 218*s*.

FAST neutron physics, in the present context, concerns the study of interactions of atomic nuclei with neutrons of energies between a few keV. and about 50 MeV. The past decade has seen a rapid growth of interest in this field. The stimulation is in large part due to the increasing demands of reactor designers. There is also, however, a better appreciation of the value to the theoretician of data from nuclear reactions which involve neutrons, since the interpretation of such data does not require the inclusion of complicating Coulomb effects. In such a rapidly growing field the description of the latest techniques has been confined mostly to research reports, and little effort has been spent on trying to summarize and evaluate developments. A core of basic technology has, however, been built up, and the present book attempts to summarize this and to provide a standard reference work for the field. The book is the first of two volumes; the second, which is still to be published, will deal with the experimental results and their interpretation by present-day nuclear theories.

This first volume is subtitled *Techniques*, and is concerned primarily with the technical problems of the production, detection and shielding of fast neutrons. It consists of twenty-four articles by authorities in their particular field. The scope of the work can be appreciated by considering the four sections under which the articles are grouped. Section 1 concerns neutron sources, both radioactive sources and the most important neutron-producing reactions. Section 2, "Recoil Detection Methods", has articles on detection by photographic plates and by cloud chambers as well as by proportional and scintillation recoil spectrometers. Section 3 considers other neutron detectors, including 'long counters', solid and gaseous scintillators, helium-3 neutron-spectrometers and fission detectors. Finally, Section 4 treats a number of special topics such as time-of-flight techniques, neutron-flux measurements, collimation and shielding of neutrons and health hazards. In many of the articles information is assembled which has previously been scattered through the literature, or merely passed informally between laboratories; notable in this regard are the articles on flat response counters, on neutron collimation and shielding, and on neutron-producing targets. The work is still reasonably up to date in spite of the fact that it was written in 1958—this shows that a clear need existed for a reference book of this type. The usefulness of the book is enhanced by excellent bibliographies, and these, together with the wide range of topics that it covers, will make it of great value to all research workers in the fast-neutron field.

To end with some mild criticism, the book shows evidence of a lack of balance in assembling the material. A particular example of this is that there are no tables of the emitted neutron energy *vs.* the bombarding particle energy for three commonly used neutron-producing reactions, D(d,n)^{3}He, T(p,n)^{3}He and T(d,n)^{4}He, whereas such tables are included for several rather uncommon reactions such as ^{51}V(p,n)^{51}Cr.

Furthermore, I was left with the impression that many of the articles could have been shortened appreciably without affecting their scope. One can understand the problem that the editors must have had in combining so many parts into one comprehensive whole, but it might have been better if they had exerted their authority somewhat more firmly regarding the length of the contributions. The result of their failure to do this has been that the book is priced well beyond the means of most physicists and will be relegated to the library shelf instead of the experimenter's desk.

J. H. Montague

MATHEMATICS FOR THE BIOLOGIST

An Introduction to the Mathematics of Medicine and Biology

By J. G. Defares and I. N. Sneddon. Pp. xii+663+6 plates. (Amsterdam: North-Holland Publishing Company, 1960.) 85*s*.

THIS is a comprehensive introduction to mathematics for the aspiring biologist and clinician. On second thoughts 'perspiring' would be the better word. The authors are painstakingly meticulous in the correctness of their approach, and some pages read almost like a university text-book in analysis. The reader for whom the book is intended is supposed to have ceased the active study of mathematics several years ago, and it is not difficult to imagine his reactions when confronted with the definition of a field on page 4, and what is virtually a Dedekind section on page 5. However, after learning about convergence, permutations, the binomial theorem and partial fractions, on page 47 the reader is being told in elaborate detail how to plot a point on a graph. This unevenness is explained by the interests of the two authors. One is a mathematician, the other a physiologist, and it is usually evident which chapter has been written by which.

The authors guide the readers from limits and derivatives, through the standard techniques of integration and partial differentiation to differential equations, partial as well as ordinary. On the way, he will learn about logarithms, gamma functions, Laplace transforms and Fourier series, so it will be seen that the scope is indeed comprehensive.

Throughout, the theory is illustrated by a wealth of practical examples. They tend to be mainly drawn from physiology, but one excellent feature of them is the emphasis placed on the construction of a suitable model. Throughout these examples, however, all points found from practical experiments lie exactly on a straight line or other appropriate curve. No indication is given as to what the biologist is to do when this is not the case, as will so often happen.

The authors deliberately exclude the theory of statistics from their scope; but one would have hoped for a little guidance in dealing with this situation in a book intended for biologists, whose results are usually so very variable.

There are one or two mistakes in the examples and in the solutions of the problems. Example 13 in Chapter 4 has a bad slip, and in example 4 of Chapter 6, x should tend to zero. I could make no sense out of paragraph 10 in Chapter 10, and there are some serious misprints in equation 2 on p. 290. The six plates seem useless and their exclusion might possibly reduce the rather high cost. The printing and lay-out are excellent throughout.

To sum up, then, this book is not likely to convince the biologist that mathematics is easy or exciting. As a reference book, it may be extremely useful, but as a text-book, it is much too difficult and laborious for the reader for whom it is intended.

J. F. Scott

RECENT ADVANCES IN ENTOMOLOGY

Annual Review of Entomology, Vol. 6

Edited by Edward A. Steinhaus and Ray F. Smith. Pp. vii+470. (Palo Alto, Calif.: Annual Reviews, Inc., 1961. Published in Co-operation with the Entomological Society of America.) 7 dollars.

IN the six years since this *Review* was started it has already made itself indispensable. It fulfils its declared object exactly, which was to invite specialists to provide authoritative and scholarly reviews of the literature in their particular specialties. In each volume, the editors have presented a list of titles that ranges over every aspect of entomology. The papers are all of a high level of authority, and are supported by very complete bibliographies, so that each takes the reader at once into the heart of the subject.

Volume 6 contains the following articles: "Darwin's Contributions to Entomology", by J. E. and C. L. Remington; "Insect Nutrition", by H. L. House; "Nutritional Factors in Insect Resistance to Chemicals", by H. T. Gordon; "Principles of Insect Cold-hardiness", by R. W. Salt; "The Biochemistry of Insect Hemolymph", by G. R. Wyatt; "The Role of Mitochondria in Respiratory Metabolism of Flight Muscle", by B. Sacktor; "Diurnal Rhythms", by Janet Harker; "The Theoretical and Practical Study of Natural Insect Populations", by O. W. Richards; "Principles of Insect Predation", by C. S. Holling; "Biological Control of Pest Insects in Europe", by J. M. Franz; "Sampling Crop Pests and their Hosts", by A. H. Strickland; "Biology of Chiggers", by Manabu Sasa; "The Phenomenon of Industrial Melanism in Lepidoptera", by H. B. D. Kettlewell; "A Review of the Phylogeny of Mites", by T. A. Woolley; "Palæoentomology", by O. Martynova; "The Analysis of Insect Embryogenesis", by S. J. Counce; "The Chemistry of Organic Insecticides", by T. R. Fukuto; "Mode of Action of Insecticides", by C. C. Roan and T. L. Hopkins; "Ecological Aspects of Plant Virus Transmissions", by W. Carter; "Mechanism of Transmission of Viruses by Mosquitoes", by R. W. Chamberlain and W. D. Sudia; "Arthropod Vectors as Reservoirs of Microbial Disease Agents", by C. B. Philip and W. Burgdorfer; and "Transmission of Filarioid Nematodes", by F. Hawking and M. Worms. In addition there are cumulative indexes to the volumes 2–6 (Why not 1–5 ?).

Not all, however, are equally rewarding to the non-specialist. While most authors interpret the word 'review' to mean a general survey of a field of study, which any interested person might use as a starting point, a few, including one or two in this volume, have moved to the extreme that the editors originally said they wished to avoid: ". . . a mere concatenation of bibliographical summaries or abstracts. . .". An article that can be understood only by people already working in that field would be better placed in a specialized journal.

Apart from these that are a breathless catalogue of new facts, a few others are spoiled by being written in a language that purports to be English, but has to be mentally translated before it can be understood. "Furthermore, lifelong infection of true hibernating mosquitoes may explain, at least in part, the overwintering of virus in colder temperate regions where continuous transmission is interrupted." Why not say: "In colder temperate regions mosquitoes stop biting during the winter, but those that hibernate may act as a winter reservoir for the virus" ? H. B. D. Kettlewell on "Industrial Melanism in Lepidoptera" is a model of clarity: "The canopy of all trees is washed by rain and the pollution is carried down the branches, and finally the trunk".

HAROLD OLDROYD

IN SEARCH OF RACE RELATIONS

White Man

A Study of the Attitudes of Africans to Europeans in Ghana before Independence. By Dr. Gustav Jahoda. Pp. xii + 144. (London and New York: Oxford University Press, 1961. Issued under the auspices of the Institute of Race Relations.) 21*s*. net.

IN the confused and confusing field of studies called 'race relations', the general reader and the research student will welcome a book such as this one. Dr. Jahoda has succeeded in making clear the limits of his study pursued in Ghana just before independence, the methods by which he carried it out, and the conclusions he drew from it. This is a notably difficult type of study, by a European, of African attitudes to the white races. Its scientific basis is that of a psychologist who is willing to use not one but several techniques, and to discuss how far they are applicable and wherein lie their limitations.

The chapters can be arranged in three main groups: the history of White contacts with Ghana (chapter 1); the main groups of informants, school-children and adults, and the methods used to ascertain and record their views (chapters 2–6); and the final two chapters (7 and 8) in which Dr. Jahoda makes an analysis of the results of the study. He says more than once that he felt himself cramped by the limitations of the space allowed, and this is particularly evident in the final two chapters, where a fuller discussion, both of the methods of study and the results, would have been advantageous.

Among the many studies of political and economic development now being made in Africa, this field of 'attitudes' is new, neglected and important. There are two distinct yet related aspects of this problem: the attitudes of Africans to Europeans, and that of Europeans to Africans. Studies have been going on at the University College of Central Africa in both these aspects. There is obviously room in all the African countries for a development of these 'attitudes' studies on a scientific basis, which will be recognized by Africans and Europeans as being valid, objective and yielding results which can be applied to contemporary situations. It is therefore imperative to speed up the process by which African research students can receive the kind of advanced training which will enable them to work as fully equipped colleagues with Europeans. These are not studies to be rushed into in order to provide quick solutions for political and economic relationships. They require the detached, unemotional research which can validate its own methods and justify and explain its results, however unexpected or unpalatable they may appear to Africans or to Europeans.

Dr. Jahoda has provided us in this book with several ideas which form the main theoretical leads in his own work and provide suggestions for further development in subsequent studies. One of these concepts is that of the stereotype held by the members of one race about the members of another, and he emphasizes that this stereotype when acquired is "notoriously resistant to change". This complex of attitudes towards the members of another race is the result of a historical time process, and hence there is an element of "time lag" in the formation and expression of attitudes. This is probably the most outstanding contribution in the present study, and is well worth searching out in all the chapters of the book.

Another factor, illustrated in Chapters 2–5, is the difference in the attitudes of Africans with varying degrees of Western education or none at all. Hence there is no one 'African attitude', and these educationally differentiated attitudes also vary in relation to the stages of political and economic development.

Thirdly, and this concept calls for anthropological as well as psychological investigation, the Africans in this Ghana study distinguished between the British expatriates with whom they had personal contacts in the country, and the British institutions and culture which had been brought to Ghana over a long historical period. This raises in the field of race-relations studies the fundamental question of how far stereotypes and attitudes depend on personal contacts, and how far on identification with or revolt against an imported culture.

There is no index, but there is a detailed synopsis of all the chapters and a useful selected bibliography.

MARGARET READ

Lectures on Ergodic Theory

By Prof. Paul R. Halmos. Pp. vii+100. (New York: Chelsea Publishing Company.) 2.95 dollars.

THIS book is a re-issue of one previously available under the imprint of the Mathematical Society of Japan. It consists of the notes on which Prof. Halmos based a series of lectures given at the University of Chicago in 1955, and, although it makes no claim to being an exhaustive survey, it is yet rich in content.

The lectures are, of course, addressed to pure mathematicians. Although ergodic theory had its origin in Boltzmann's development of the kinetic theory of gases, the subject, as extended by mathematicians, now encompasses a much wider field. Thus only the first few chapters, which deal with recurrence, mean and pointwise convergence, ergodicity (in the sense of metrical transitivity) and mixing theorems, have relevance to the problem of irreversibility as it appears in physics.

The discussion in these initial chapters is in terms of transformations on a measure space; afterwards, algebraic concepts are introduced and topics then considered include conjugacy and equivalence with particular reference to transformations which possess a discrete spectrum, weak and uniform topologies for automorphisms, the topological size of sets of strongly mixing, weakly mixing and ergodic transformations, and the existence of a sigma-finite invariant measure equivalent to a given measure. A list of unsolved problems is appended.

The author's style displays its customary clarity, and the lucid presentation, enhanced by informal asides, augurs well for the author's declared aim of rekindling interest in this branch of mathematics.

I. E. FARQUHAR

Impact

The Theory and Physical Behaviour of Colliding Solids. By Prof. Werner Goldsmith. Pp. xv+379. (London: Edward Arnold (Publishers), Ltd., 1960.) 90*s*. net.

PROF. GOLDSMITH has produced a reference book which will be welcomed by those working on problems of the impact of solids, since much of the subject-matter has hitherto been available only in published papers. The book embraces a wide range of topics, and contains much factual information in the form of tables and graphs. The treatment is concise, and in many of the theoretical solutions only an outline of the main steps is given, with appropriate references to published papers.

After a survey of the classical theory of the impact of rigid bodies, the author considers vibration and wave motion in elastic bodies, and discusses problems involving the collision of elastic rods, and the impact of a rigid mass on a rod or beam. The book continues with a discussion of contact phenomena, and the effect of these phenomena in elastic problems is investigated. Impact problems involving plastic flow are considered, with a brief discussion of the hydrodynamic theory, and a more extended treatment of theories of plastic wave-propagation in rods, beams, and plates. A chapter on impact experiments includes a description of experimental techniques, together with results of many experiments involving elastic and plastic deformations. The book concludes with a chapter on the dynamic properties of materials, and the techniques used in their measurement. There is also an extensive bibliography of nearly six hundred titles.

R. P. N. JONES

Analytical Techniques for Non-Linear Control Systems

By Prof. John C. West. (Electrical Engineering Series.) Pp. 223. (London: English Universities Press, Ltd., 1960.) 25*s*. net.

THIS book describes successively the application of three techniques, namely the phase-plane and describing function techniques, and the use of random inputs, to the analysis of non-linear control systems.

In an approach basically similar to that used in a previous book by the same author on linear servomechanisms, the application to specific simple systems is introduced at an early stage in the description of each technique. Application to more complex systems is then described and the analysis developed from these examples to more general considerations concerning the technique. The same non-linear systems are analysed by each technique and a comparison of results made which forms a particularly interesting connecting link between the three separate groups of chapters.

The style is clear and concise, and the author does not allow mathematical complication to obscure the fundamental principles he describes. This, together with the basic approach of progressing from the particular to the general at each stage, leads to a text which may be easily read as an introduction to the subject, but which at the same time takes the reader further than would an introductory work. Indeed, the material in parts reaches, albeit briefly, almost as far as the present development of the subject permits.

This book fills a definite gap in the existing literature in the field of control mechanisms and is a useful addition to it.

E. M. DEELEY

Physics of Semiconductors

By A. F. Ioffe. Pp. xi+436. (London: Infosearch, Ltd., 1960. Distributed by Cleaver-Hume Press, Ltd., 1960.) 84*s*.

THIS is an English translation of the Russian book published in 1957 which was reviewed in *Nature* (Dec. 7, 1957). Some amendments and additions have been made in the preparation of the translation; the bibliography has been extended and a subject index has been added. A twenty-page section has been added on materials for thermoelements which provides an excellent discussion of impurity effects and solid solutions, and of the attainment of the required high electrical conductivity, high thermoelectric power and low thermal conductivity. The ten pages of "Conclusions" reflect the late author's particular interest in the phenomenon of low carrier mobility in certain materials and the dilemma posed by apparently very short mean free paths.

The book indicates the state of semiconductor physics up to 1957, and the treatment throughout is aimed at giving physical insight into fundamental processes without excessively detailed analytical discussion. It is felt that the book is successful in attaining its intended objectives and can prove stimulating in certain areas of contemporary semiconductor research.

R. E. BURGESS

CENTENARY OF THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY

By DR. JAMES R. KILLIAN, jun.

Chairman of the Corporation, Massachusetts Institute of Technology,
formerly Special Assistant for Science and Technology to the
President of the United States

ONE cannot live in the atmosphere of a great research and educational institution, renewed year after year by youth, with its hopes and energies, and by students, old and young, with their dreams and discoveries, without acquiring a faith in the power of intelligence to achieve a future of peace and order among all peoples.

This faith was strengthened during the recent celebration of the centenary of the Massachusetts Institute of Technology, when some of the world's most eminent intellectual leaders met at the Institute to exchange ideas on how greater good may be sought through greater knowledge. The Institute was honoured by their presence, and we believe the occasion proved a fruitful one for them.

More than 150 men and women from many professional fields in 35 countries participated in a conference on the prospects and implications of scientific and engineering education for the world. Later there were provocative discussions by such thinkers as Aldous Huxley, Prof. J. Robert Oppenheimer, Sir John Cockcroft, Prof. Chen Ning Yang, the Right Hon. Philip J. Noel-Baker, Prof. George W. Beadle and Prof. Peter B. Medawar, on what the future holds in science, the arts, industry and arms control. The Right Hon. Harold Macmillan and Mr. Dean Rusk, Secretary of State, gave notable addresses which cast new light on the complexities of international affairs.

No attempt will be made here to summarize the many points of view that were expressed in the discus-

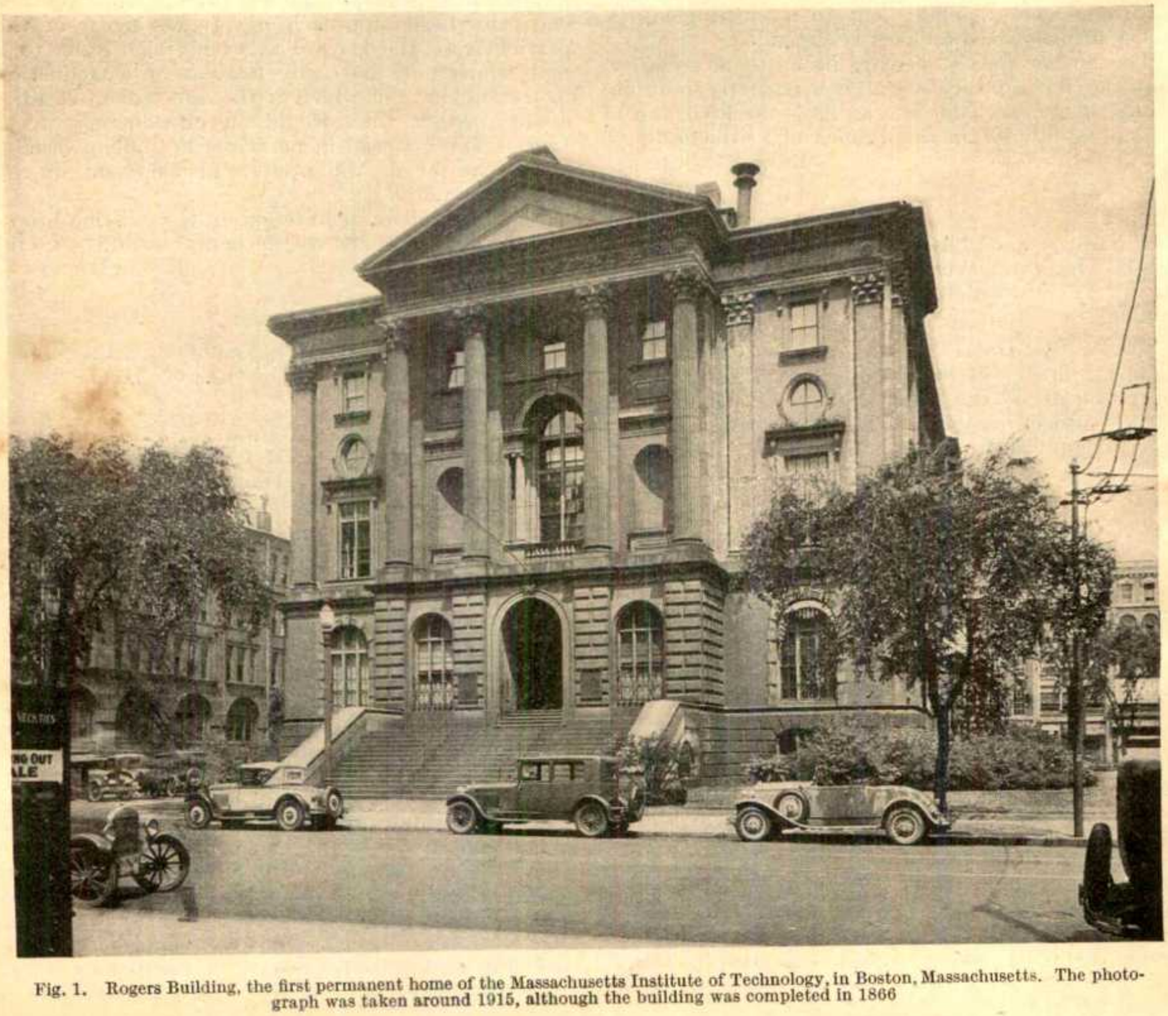

Fig. 1. Rogers Building, the first permanent home of the Massachusetts Institute of Technology, in Boston, Massachusetts. The photograph was taken around 1915, although the building was completed in 1866

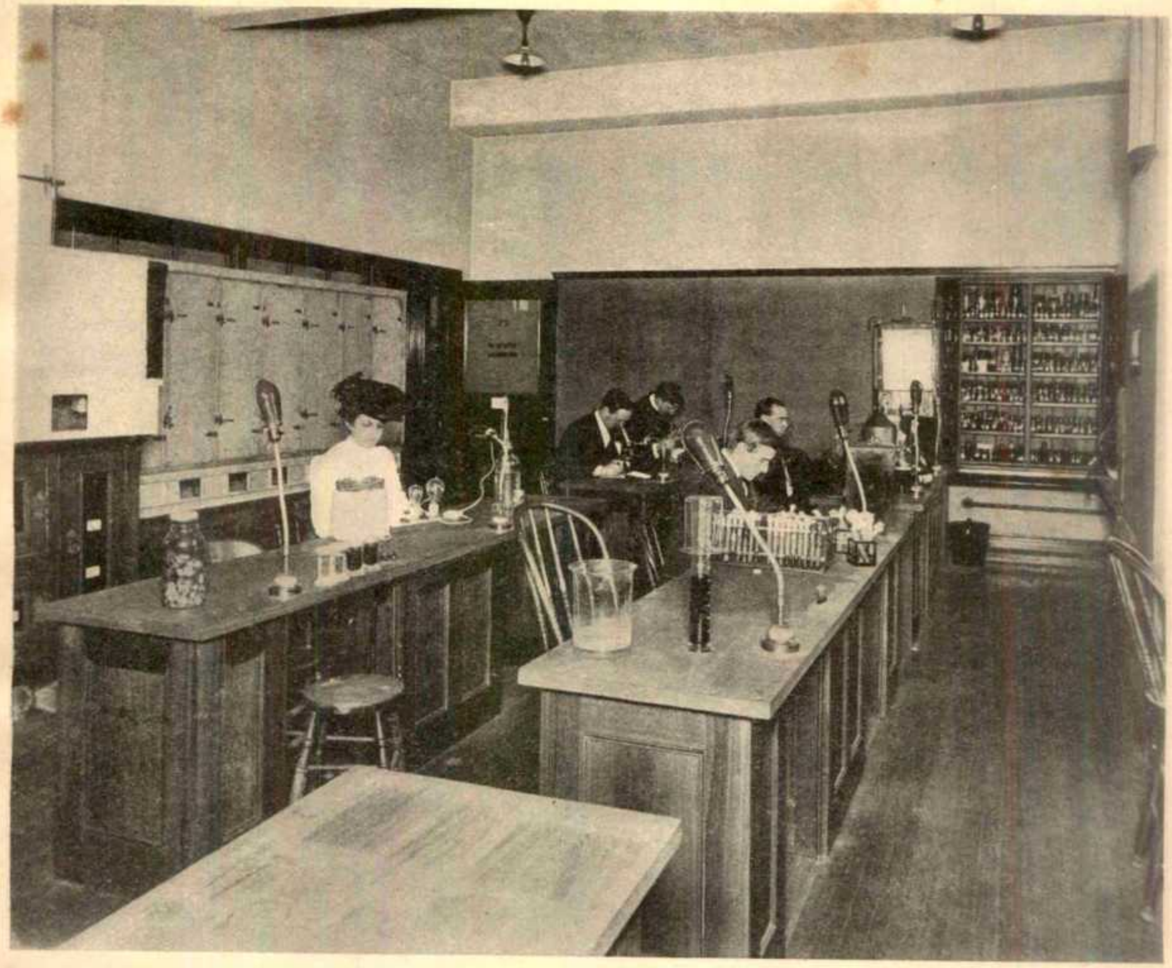

Fig. 2. Photograph of a research laboratory taken when the Institute was in Boston (1895). The students are of graduate-level and are performing experiments in electrolysis and the study of cultures in chemistry

sions. There was no intention that clear-cut conclusions should be sought, and no final solutions of the problems which press on the world from every side were offered. Yet, there was an atmosphere of hope, of awareness of our magnificent opportunity to imagine a better human community, and, through a new blending of the sciences, the social sciences and the humanities, to devise the new strategies required to move toward a better human community.

The expectations and intentions of to-day are closer than one might suppose to those which a hundred years ago led to the founding of the Institute. By the end of the second decade of the nineteenth century, the economic expansion of the United States, with the growth of industry and agriculture, was calling forth new public attitudes toward education and toward science and technology. There were strong forces leading to the popularization of knowledge, including a growing awareness by people from all walks of life that science could provide a better life.

This understanding brought into being lyceums and mechanics' institutes, the forerunners of a new pattern of education, the means for the application of scientific principles to the practical arts, and the development of a new and closer relationship between the scholar and the citizen.

Concurrently, there was a growing demand for universal, free, public education. It was in 1837 that Horace Mann, the eloquent apostle of "well-appointed and efficient means for the universal education of the people", became the first full-time secretary of Massachusetts' new State Board of Education, and in this post led a transformation of the State's schools and set a new pattern of public education for the nation.

In the midst of this national ferment a Virginian, William Barton Rogers, who was to found the Massachusetts Institute of Technology, began to form ideas for a new kind of educational institution to respond to the needs of a growing industrial society.

Rogers had held the chairs of natural philosophy and chemistry in William and Mary College, and of natural philosophy in the University of Virginia. He had served as head of the Virginia State Geological Survey, an experience that broadened his understanding of the social and economic importance of science.

He recognized that science should no longer remain the esoteric concern of a few learned and cultivated men. It was in the public interest that it be the concern of all. The economic expansion of the country, the gradual opening of the West, the growth

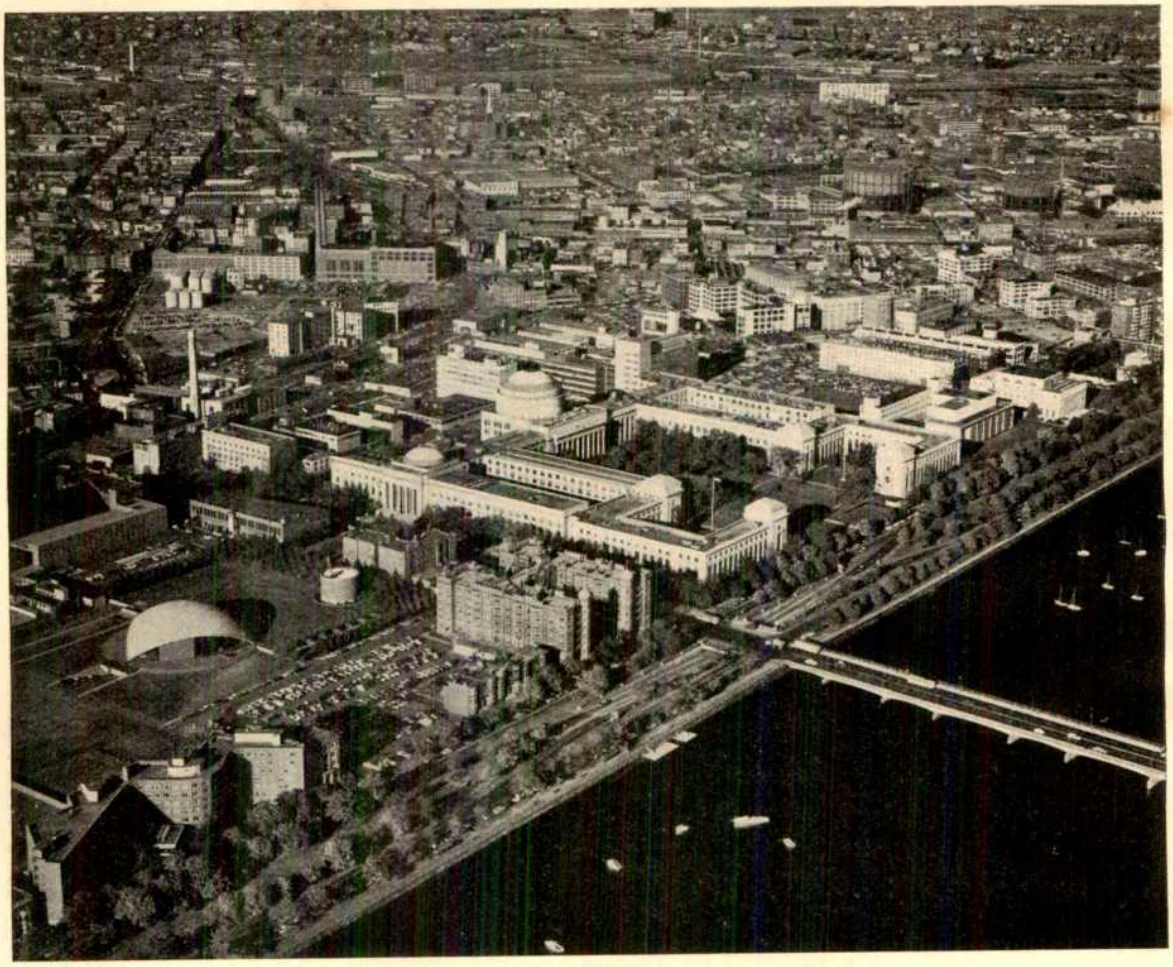

Fig. 3. Aerial view of the Massachusetts Institute of Technology. Kresge Auditorium and the Institute Chapel (the triangular and cylindrical shaped buildings) are on the left. (*Photo: Lawrence Lowry*)

of industries, navigation, transportation, mining, and agriculture, increased the need for a deeper knowledge of the resources of the nation.

What treasures were buried in its rocks, hidden in its forests, lying beneath its waters? How could Nature be controlled to offer better opportunities for manufacturing, transportation, agriculture, and, most important, men? The existing educational institutions were inadequate in attitude, facilities and personnel to meet these demands.

College education was still centred on the study of the classics. Natural science was considered of relatively little importance in comparison. The colleges, as a rule, still believed in 'training the mind', for which purpose Cæsar, Plutarch and Euclid were considered unsurpassed. Engineering as a professional study was almost non-existent in the university system.

A few schools, notably Yale and Williams, had hesitantly and half-heartedly attempted to teach the application of scientific principles to the productive arts. Rensselaer Institute under Amos Eaton and the United States Military Academy under Sylvester Thayer had already pioneered in the training of science teachers and civil engineers, respectively.

Even so, the United States was definitely lagging in technological education relative to Europe, where engineering had long been recognized as a profession. The École Polytechnique in Paris, the Bergakademie at Freiburg, the Technische Hochschule in Zurich—all emphasized a highly intellectual, scientific and analytical approach to education for the technological services demanded by State and industry.

Since his move to the University of Virginia, Rogers had become immersed in college administration. In 1844 he was chosen chairman of the Faculty, a post equivalent to that of the university's chief executive. This position strengthened Rogers's administrative and organizational skills, while affording him full opportunity to ponder Jefferson's educational ideas stressing the use of science and technology for the betterment of society.

His experience led Rogers to question seriously the future of science in the current curricula of existing colleges. Dearth of facilities, improperly trained personnel, and above all the lack of understanding by educators seemed to foretell a dim future for education in science and engineering. It became apparent to Rogers that only through the formation of a new school, free from the vested interests of traditional education, devoted specifically to polytechnic education, could science and its practical application be placed in its proper perspective in the general system of American education. Such circumstances led Rogers in 1846 to prepare this famous "Plan of a Polytechnic School".

Virginia, he concluded, was not then the place to start such innovations. Rogers turned to Boston as the site for consummation of his ideas on polytechnic education. This city, with its flourishing arts and sciences, the centre of factory- and machine-conscious New England, and philanthropically minded families, was a logical place to promote and establish a school devoted to technology.

The proposal attracted nation-wide interest, although it was not until 1861 that Rogers saw its culmination when the "Act to Incorporate the Massachusetts Institute of Technology" was passed by the Massachusetts Legislature "for the purpose of instituting and maintaining a society of arts, a museum of arts, and a school of industrial science, and aiding generally by suitable means the advancement, development and practical application of science in connexion with the arts, agriculture, manufacture, and commerce".

The forerunner of a new type of educational institution, this was fully tuned to the changing technological character of the nation. It was to serve as the model for many other schools throughout the world. The work of Rogers undoubtedly did much to pave the way for the Morrill Act of 1862, which led to the establishment of America's unique system of land-grant colleges.

In his plan for a new kind of university, Rogers stressed four fundamental principles:

First, he emphasized the importance of being useful. He had no sympathy with the prevailing view that the practical professions lacked dignity, or that utility corrupted liberal education. He was one of the earliest advocates of what J. B. Conant has described as the philosophy of the modern American university, "a philosophy hostile to the supremacy of a few traditional vocations, a philosophy moving toward the social equality of all useful labor".

Next Rogers stressed the educational gain derived from building a college programme around a professional objective. He recognized that the discipline, the thoroughness, and the motivation inherent in a professional programme have educational values. He refused to admit of any inevitable conflict between specialism and liberal education.

Rogers's next principle, that of learning by doing, he expressed through the laboratory method of instruction. While this idea was not original with him, he gave it its first systematic application in the

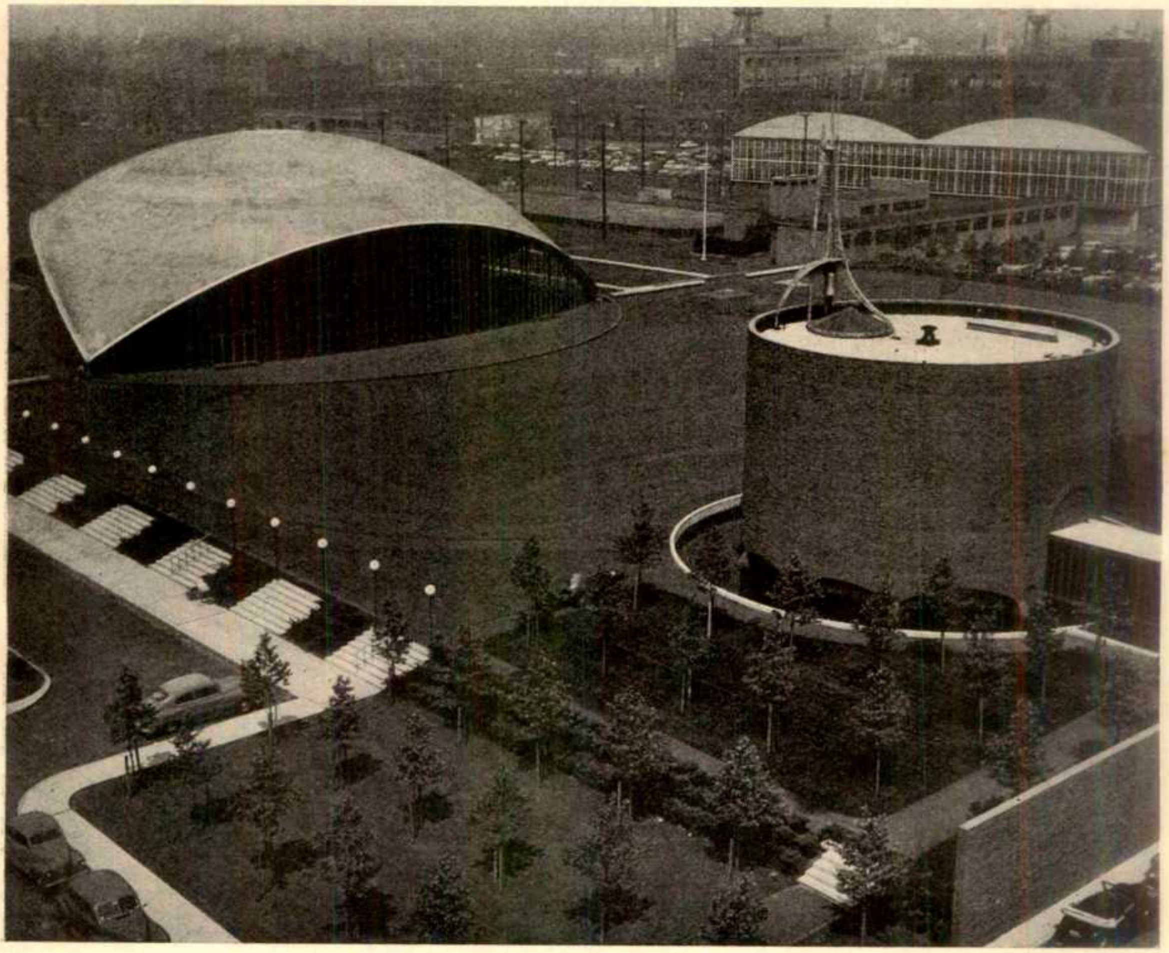

Fig. 4. Kresge Auditorium (left) and the Institute Chapel (right) were designed by Eero Saarinen and are focal points of the Massachusetts Institute of Technology community

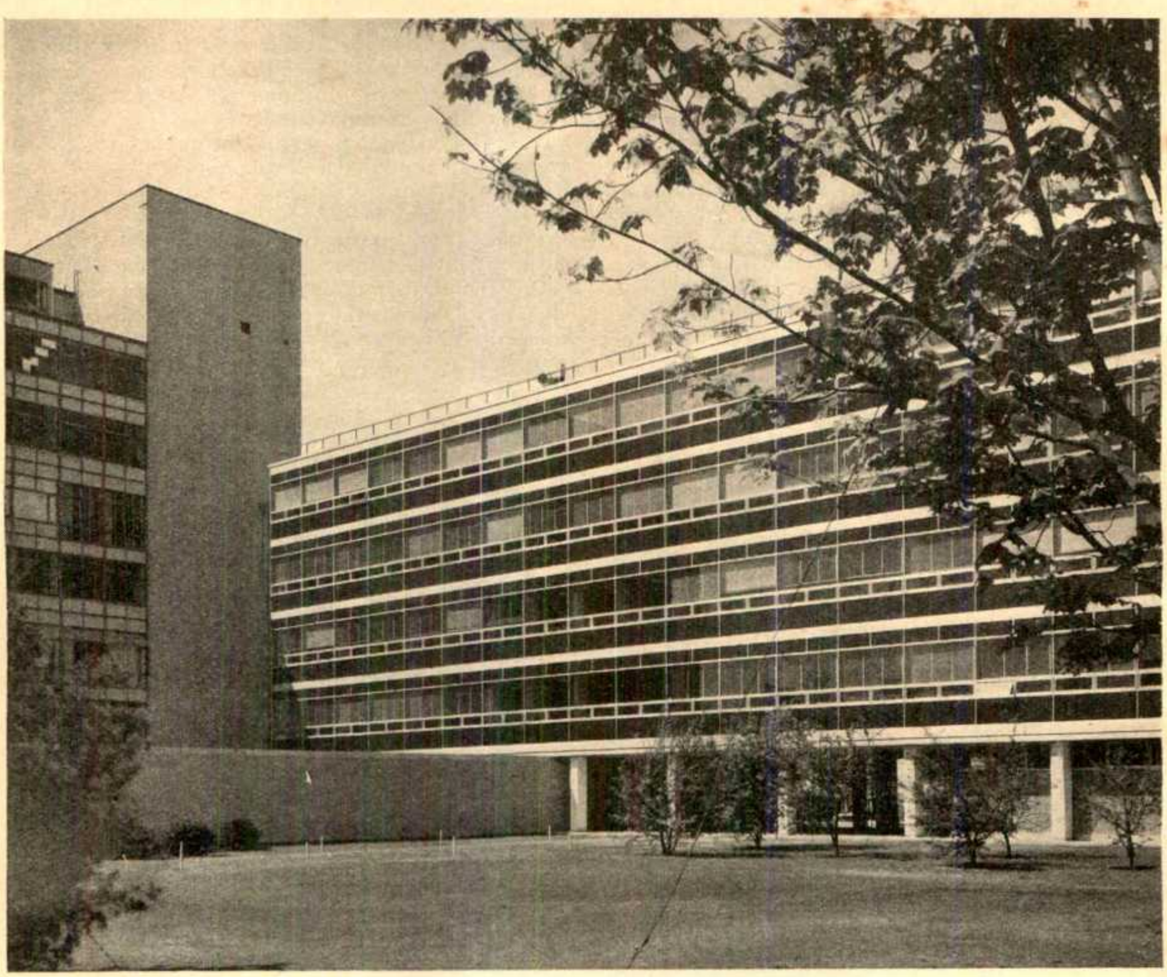

Fig. 5. The Karl T. Compton Memorial Laboratories, which house the Computation Center and the Research Laboratory of Electronics at the Massachusetts Institute of Technology

United States. In his educational thinking, Rogers always stressed method; in a time of scepticism, he had faith in the scientific method. He foresaw the far-reaching effects on higher education of the spirit and method of research, the concept which holds that learning thrives best in an atmosphere of creativeness and not in one limited to imitativeness and antiquarianism. American universities were later to assimilate this idea from the German universities; but Rogers's idea was indigenous.

Next, Rogers was emphatic in his belief that learning principles is more important than learning facts. "We believe", he said, "that the most truly practical education, even in an industrial point of view, is one founded on a thorough knowledge of scientific laws and principles, and which unites with close observation and exact reasoning", and, note this, "a large general cultivation".

He wanted the humanities taught along with engineering and science. He anticipated the need, met by only a few institutions even to-day, of a new kind of institution with its centre of gravity in the sciences instead of the classical studies, but with the humanities and social sciences fully represented and enthusiastically supported as full partners.

In his original prospectus of 1846 Rogers had the boldness and foresight to dream of a destiny for his institution. "I doubt not", Rogers wrote, "that such a . . . school would finally expand into a great institution . . ."!

Rogers laid down the grand design, and successive presidents carried the institution steadily forward toward the quality of institution Rogers had doubted not would be achieved. Francis Amasa Walker, distinguished economist and Civil War general, gave validity to the design and brought the Institute to national prominence.

Richard Cockburn Maclaurin, a Scotsman from New Zealand, who was educated as both lawyer and physicist at the University of Cambridge, attracted to the Massachusetts Institute of Technology financial resources that for the first time began to be commensurate with the Institute's responsibilities and moved the Institute to its present more ample home in Cambridge, Mass. Karl Taylor Compton provided a new thrust by strengthening the sciences and expanding graduate study and research.

Where does the Institute stand at the end of its first hundred years in relation to the aims and hopes of its founder ? How has the innovation served the nation ? What is the record ?

The Massachusetts Institute of Technology has been an educational pioneer since its founding. It virtually created the modern profession of chemical engineering and was the first technological institution to recognize and provide for economics as an important element in the education of the engineer. The Institute was the first school to establish courses in aeronautical engineering, architectural engineering, chemical engineering, food technology, industrial biology, marine engineering, and naval architecture. It established the first collegiate programme in architecture.

The Institute's contributions to education continue to-day to find new expression over a wide range. One striking current example is the work of the Physical Science Study Committee, devoted to creating a new, complete physics course for secondary schools.

The Institute is at present taking the leadership in upgrading and modernizing the education of engineers. Its Electrical Engineering Department has led the way with a drastic overhaul of its curriculum, which embodies a more fundamental approach to electrical engineering—an approach which has prompted acclaim in industry as well as in education. This spirit is now finding rapid acceptance through the School of Engineering.

The Massachusetts Institute of Technology awards 13·6 per cent of the nation's total output of doctorates in engineering and 9·5 per cent of all Master's degrees in engineering. The number of engineering doctorates awarded by the Institute is more than double the number awarded by the second-ranking institution. In this critical area of education (only about 700 engineering doctorates per annum are at present awarded in the entire nation), the Institute has led the country in the number of doctorates awarded in almost all the professional fields of engineering.

The Institute now awards approximately 7 per cent of all the U.S. doctorates in physics. On no other single campus in the United States have so many doctorates in physics been awarded.

The Institute has gained exceptional strength from the quality and cosmopolitan character of its student body. Its 3,600 undergraduates and 2,700 graduate students are a highly select group, and in their origins they probably represent a wider geographical spread than any other student body in America. Typically, Massachusetts Institute of Technology freshmen rank in the top 10 per cent of their high-school graduating classes; the first-year class of 899 students in 1960 was drawn from 677 secondary schools distributed through almost every State and in many foreign countries.

In the graduate school more than 500 American and foreign universities are represented among the student body.

Harvard and Massachusetts Institute of Technology stand first and second respectively, and far ahead of most other institutions, in the number of National Merit Scholarship recipients enrolled. They also lead the country in the number of students receiving General Motors Scholarships and National Science Foundation Fellowships who elect to study in these two institutions.

In its service to the nation, the Institute has played a part that has demonstrated it to be one of the most significant sources of national security and strength in the United States. In recent years it has created and managed the Lincoln Laboratory, out of which has come the *SAGE* system of Air Defense and the concept and design of the *DEW* Line, the early warning line which has been vital to the deterrent power of our strategic striking force.

The Instrumentation Laboratory has pioneered in the development of inertial guidance for missiles, space-vehicles, aircraft, and submarines. Out of this Laboratory have come designs, components and systems which have resulted in industrial production running into hundreds of millions of dollars: for example, the guidance systems used in the *Polaris*, *Thor* and *Titan* missiles. *Thor*, with its 1,500-mile range, was the nation's first operational intermediate-range ballistic missile.

The Research Laboratory of Electronics, with its wide-ranging programme of basic research, has been a well-spring for new concepts and new technology important both to advancement of defence and industrial technology.

From its beginning a hundred years ago, the Institute's resources have thus been brought powerfully to bear on the development of America's industrial strength. The development of every technically based industry has been quickened by research done at the Institute or by its graduates serving in industrial research, engineering, or management capacities.

Massachusetts Institute of Technology graduates have helped to create our modern urban environment and its unequalled array of transport systems and public work. They have brought a command of the methods of science, engineering and management to the defence of the nation, to the achievement of a higher standard of living, and to the advancement of public and private health.

In addition to its contributions to science and engineering, the Institute has been, from the beginning, a centre of management education, a contribution that now finds formal expression in its young and vigorous School of Industrial Management. Industry's growing dependence on engineers in management is confirmed by a recent study which revealed that almost half the Institute's graduates in engineering eventually occupied positions in management, many within five years of their graduation.

Through leadership positions in American industry, the Institute's graduates have contributed to the strength and prosperity of the nation. Some 1,500 alumni of the Institute are presidents of private companies and institutions in the United States; about 1,200 are vice-presidents. The Institute heads the list of educational institutions the graduates of which (more than 1,400) appear in *Who's Who in Engineering*—a number almost double that of the next ranking institution.

At present the Massachusetts Institute of Technology probably has the most comprehensive and varied research programme in the physical sciences and technology to be found in any one place in the world. It has at present under way 900 separate research projects. There is scarcely any aspect of American science and technology that is not touched—and advanced—by its creative activity. Thus, the Institute stands to-day as a generative force, with the opportunity before it to achieve a new order of service to America, through both research and education.

Major among the developments of the past two decades has been the strengthening of the humanities and social studies. The Center for International Studies has been established, the School of Humanities and Social Science has been formed to give formal focus and recognition to programmes in these fields. Political science has been added as a degree-granting programme.

The Massachusetts Institute of Technology has moved steadily, as Rogers clearly hoped it would, toward becoming a university polarized around science.

RECENT ADVANCES IN THE BIOCHEMISTRY OF GLYCOGEN AND STARCH*

By Dr. W. J. WHELAN
The Lister Institute, London

GLYCOGEN, and the components of starch, the largely unbranched amylose and the highly branched, glycogen-like amylopectin, were the first polysaccharides to be synthesized enzymically *in vitro*. Several factors helped in this achievement and in the subsequent rapid progress in the nineteen-forties. The substrate, α-D-glucose 1-phosphate, can be readily obtained in large quantity; the progress of synthesis of the chain-forming α-1,4-linkage is very easy to measure; and the enzymic synthesis of the branch points is accompanied by characteristic changes in the iodine-staining properties of the polysaccharides and their susceptibility to degradation by exo-enzymes. Ten years ago the enzymic synthesis and degradation of these polysaccharides could be reviewed with the feeling that further progress would consist only in adding detail to the already firm outlines.

However, the nineteen-fifties saw the widespread discoveries of the sugar nucleotides and their involvement in carbohydrate biosynthesis. Glycogen and starch have been caught up in these discoveries and the whole conception of their biosynthesis *in vivo* from glucose 1-phosphate is now held to be incorrect. The new evidence points to both polymers originating from uridine diphosphate glucose, polymerized by 'glycogen synthetase'[1] or a corresponding plant enzyme, referred to here as 'amylose synthetase', first reported last September[2]. Phosphorylase is thought to be an agent only of degradation. Other discoveries have been scarcely less disturbing to the older hypotheses. For example, rabbit muscle-phosphorylase *a*, the first glycogen-metabolizing enzyme to be crystallized, is not the predominant form in resting muscle[3]. Instead it is phosphorylase *b*, which dimerizes to the *a* form by an adenosine triphosphate-dependent reaction during the *in vitro* manipulations of isolation[4]. Because phosphorylase *b* requires adenosine monophosphate for activity while *a* does not, a reconsideration of the interrelation of *in vivo* processes must follow. The reverse conversion of phosphorylase *a* into *b* by *PR*-enzyme has also been re-examined. *PR*-enzyme had been thought to be a factor removing a prosthetic group (hence the initials), but after the discovery of the halving in molecular weight when rabbit-muscle *a* enzyme turns into *b* (ref. 5), the initials could be held to apply to phosphorylase rupture. We now know that they stand equally for phosphate removal[6]:

$$\text{phosphorylase } a \xrightarrow{PR\text{-enzyme}} 2 \text{ phosphorylase } b + 4PO_4^{3-}$$

Other enzymes which have been re-scrutinized are those splitting the branch linkages of glycogen and amylopectin. The plant enzyme (*R*-enzyme), attacking amylopectin, has proved to be two enzymes, one specific for the natural macromolecule and the other attacking only the small branched oligosaccharides formed during α-amylolysis of amylopectin[7]. Correspondingly, the activity of the animal enzyme, amylo-1,6-glucosidase, is due to two components[8], but in this case both activities, those of a hydrolase and of a transglycosylase, are necessary to complete the debranching process.

The transglycosylase is one of a vast group of enzymes discovered in the past ten years, the existence of which went unsuspected for lack of suitable means of detection. Paper chromatography provided that means and was instrumental in the discovery in potato juice of an enzyme the specificity of which has not yet been matched by that of any mammalian enzyme. This catalyst, *D*-enzyme[9], redistributes α-1,4-bonds in starch-type polymers. Maltotriose is the smallest molecule on which it exerts any rapid action. It is first converted into maltopentaose and glucose, for the enzyme prefers to transfer glucose residues severally rather than singly. There is no hydrolysis and therefore no change in the average size of the molecules. The enzyme represents a major activity in potato juice and is presumably implicated in starch metabolism. When the action is coupled with that of hexokinase and adenosine triphosphate, to convert glucose into the 6-phosphate, the enzyme is driven to form long, amylose-like chains from maltodextrins and merits consideration as yet another rival to phosphorylase for starch synthesis[10]. Enzymes which likewise redistribute α-1,4-glucosidic bonds but appear to act readily on maltose are also known now in plants[11] and animals[12,14]. Separate but similar catalysts have been discovered in potato (*T*-enzyme)[13] and rabbit muscle[14]. These also transfer α-glucose from maltose but reposition the sugar at C-6, not at C-4, forming the trisaccharide panose. The chemistry of this action is identical with that of the polysaccharide-branching enzymes, *Q*-enzyme in plants, amylo-1,4→1,6-transglycosylase in animals. *T*-enzyme is separable from *Q*-enzyme, so just as with *R*-enzyme (see above) it seems that separate systems are necessary for the same reaction according as to whether the substrate is an oligosaccharide or a polysaccharide. In fact, of the enzymes which it has been customary to involve in the cycle of glycogen–starch synthesis and degradation, only the branching enzymes seem to have retained their places unchallenged. This situation may, however, simply reflect the comparatively scant attention these enzymes have received.

Biosynthesis of Glycogen and Starch

The chain-forming process. The synthetic pathway to glycogen based on uridine diphosphate glucose (Fig. 1) was first reported in 1957, by Leloir and Cardini[1], as taking place in rat liver. Since then, the enzyme has been found in muscle tissue of pigeons[15], humans[16], rabbits[17] and rats[18], in rabbit brain[19], yeast[20] and in beans[2,20a], potatoes and sweet corn[20a]. The early observations of the insolubility of the animal enzyme are probably the result of adsorption on glycogen in the microsomes, and this finding led Leloir *et al.*[2,20a] successfully to search for the enzyme in starch grains. The enzyme preparation reported is in fact a suspension of starch.

---

* Substance of two lectures given in the Department of Biochemistry, University College, London, on February 25 and March 2.

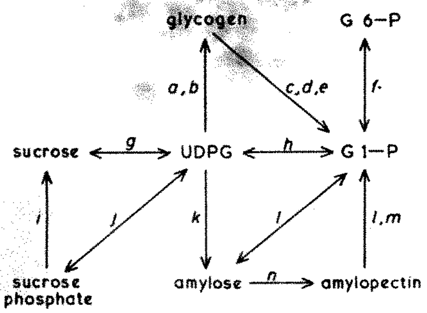

Fig. 1. Synthesis and degradation of glycogen, starch and sucrose. G 6-P, glucose 6-phosphate; UDPG, uridine diphosphate glucose; G 1-P, α-glucose 1-phosphate; *a*, glycogen synthetase; *b*, amylo-1,4 → 1,6-transglucosylase; *c*, phosphorylase; *d*, amylo-1,6-glucosidase; *e*, amylo-1,4 → 1,4-transglucosylase; *f*, phosphoglucomutase; *g*, sucrose synthetase; *h*, UDPG pyrophosphorylase; *i*, sucrose phosphatase; *j*, sucrose phosphate synthetase; *k*, amylose synthetase; *l*, phosphorylase; *m*, *R*-enzyme; *n*, *Q*-enzyme

The finding recalls Stacey's[21] suggestion that the starch grain might contain the enzymes of synthesis.

The discovery of the nucleotide pathway to glycogen explained several observations inconsistent with the idea of phosphorylase as the provider of glycogen[22]. For example, when epinephrine or glucagon are used to stimulate phosphorylase, glycogen disappears. Also the ratio of inorganic phosphate: glucose 1-phosphate in animal tissue is totally unfavourable for glycogen synthesis by phosphorylase. Glycogen synthetase action does not depend on the level of inorganic phosphate, and the conversion of uridine diphosphate glucose is essentially complete[1,15,18].

Glycogen synthetase needs a primer, and its specific requirements are similar to those of muscle phosphorylase. Thus glycogen is the most efficient primer but loses its activity after degradation by α-amylase. Polysaccharides with lower degrees of branching than glycogen are less effective and linear material does not prime[17,18,20]. The problem is therefore posed with glycogen synthetase, as with muscle phosphorylase[23], of the reason why, in order to synthesize α-1,4-bonds, the enzymes require a primer containing α-1,6-bonds and of high molecular weight. Potato phosphorylase[24] and amylose synthetase[20a] have no such scruples. Work with glycogen synthetase presents experimental problems due to the instability of the enzyme and the exotic nature of the glucose-donating substrate. So far the records of 'glycogen' synthesis in fact amount to lengthening of the unit chains of the added primer by only a few glucose residues. A very curious feature of glycogen synthetase is the dependence of the activity of the animal and yeast enzymes on glucose 6-phosphate. The rat-liver enzyme[1], for example, is activated up to 15-fold by the ester, and the 6-phosphates of fructose, glucosamine and galactose can replace the glucose phosphate. The glucose moiety of the phosphate is not, however, incorporated into the synthetic polysaccharide[18], and it remains uncertain whether the effect of sugar phosphate is simply a protection of enzymic activity or something more intimate[1]. The effect has not been mentioned for the bean enzyme[2,20a], but one wonders whether there is any connexion with the still unexplained occurrence of 6-phosphate residues in starch, mainly in the amylopectin component.

Branching enzymes. There is a very close correspondence between glycogen metabolism in animals and starch synthesis in plants. In fact every enzyme implicated in glycogen metabolism has its plant counterpart. Such differences as are found concern specificity, as between *D*-enzyme and its animal analogue, mentioned earlier. These differences are of two types, one concerned with group transfer and the other with the differing shapes of the plant and animal macromolecules. Thus, in regard to the latter, glycogens having 'normal' values of average unit chain-length are not attacked by potato phosphorylase, *D*-enzyme or *R*-enzyme[25]. Only when the glycogen has been fragmented, thereby opening the compact structure, do these enzymes attack it. Yet potato phosphorylase[26] has a molecular weight only 40 per cent of that of rabbit-muscle phosphorylase *a* (ref. 5). A similar comparison can be made between the plant and animal branching enzymes. Potato *Q*-enzyme synthesizes amylopectin from amylose, and will not introduce further branches into amylopectin[27]. The branching enzyme from yeast, which stores glycogen, acts on amylose to produce amylopectin but continues the branching process until the degree of branching is that of glycogen[28], about twice that in amylopectin.

Degradative Enzymes

Phosphorolysis and debranching. The plant and animal phosphorylases are exo-enzymes and in the presence of inorganic phosphate they phosphorolyse amylopectin and glycogen, respectively, until the points of branching are approached. The limits of approach by potato phosphorylase have not been measured, but Cori and Larner[29] defined those of muscle phosphorylase after finding that the residual glycogen dextrin (φ-dextrin) yielded glucose on treatment with amylo-1,6-glucosidase. This suggested a structure in which side-chains (*A* chains) had been degraded to a single 1,6-linked α-glucose residue. The outer length of each chain carrying this residue (*B* chains) was thought to be 5–7 glucose units. Walker and Whelan[8], however, found no such 1,6-bonded single glucose residues in the φ-dextrins of glycogen or amylopectin. They concluded that both the attenuated *A* chain and the outer portion of the *B* chain were each four units long. Their explanation of the appearance of free glucose during debranching is that a transglycosylase repositions glucose residues in the φ-dextrin to form the Cori–Larner-type molecule, then attacked by the glucosidase. A preparation of the glucosidase was in fact found to contain a transglycosylase which repositioned the α-1,4-bonds of maltose and maltotriose, but Illingworth *et al.*[29a] report the lack of this enzyme in a purified preparation. Differences of group transfer also occur between the plant and animal debranching enzymes in that the latter seems capable only of detaching single 1,6-linked glucose residues[29] whereas *R*-enzyme only removes such side-chains when they are two units or longer[30].

α- and β-Amylases. The actions of the α- and β-amylases, endo- and exo-enzymes respectively, are now well understood. The enzymes are generally considered to be entirely specific for the hydrolysis of the α-1,4-glucosidic linkage. Certainly they do not hydrolyse the α-1,6-branch linkages but caution in rigidly defining the specificity is prompted by the recent report[31] that a 'specific' β-1,3-glucosidase also hydrolyses β-1,4-glucosidic bonds when these are proximate to a β-1,3-bond. Also β-amylase liberates both nigerose (α-1,3-diglucose) and maltose from Floridean starch[32].

The limits of action of the amylases on linear and branched amylaceous polysaccharides have been defined. The smallest natural substrate for either enzyme is maltotriose[33,34], hydrolysed to glucose and maltose, but it is maltotetraose which is hydrolysed at rates comparable with those of polysaccharides. The branch linkages offer partial and absolute protection to adjacent 1,4-bonds. In its endwise progression from the non-reducing chain ends of amylopectin and glycogen, β-amylase is unable to hydrolyse the last α-1,4-bond before a 6-substituted glucose unit[35,36]. The fragmenting α-amylases can carve the 6-substituted glucoses away from the polysaccharide, but not in the form of the 1,6-linked disaccharide isomaltose. One or more 4-substituted glucose residues remain in the fragments (α-limit dextrins). Thus the smallest α-limit dextrin formed by malt α-amylase is panose (4-α-isomaltosylglucose), by human-salivary, pig-pancreatic and *Aspergillus oryzae* α-amylases it is the tetrasaccharide 4-α-panosylglucose, whereas *Bacillus subtilis* α-amylase yields a pentasaccharide, tentatively assigned a structure in which α-maltose is joined to C-6 of the central glucose residue in maltotriose[34].

Glycogen-Storage Diseases

A practical outcome of work in a largely academic field of research has been the explanation of the inherited disorders characterized by abnormal deposits of glycogen in the storage organs. The subject has been reviewed very recently[22] and will be mentioned here only briefly. Of the six types of disease listed by Stetten and Stetten[22], four are associated specifically with the impairment of a particular enzyme of the glycogen cycle. In the two other types no specific enzymic lesion has yet been detected. When the deficiency resides in glucose 6-phosphatase (Von Gierke's disease) or phosphorylase (type VI) the glycogen in the diseased tissue has a normal structure, but has undersized outer chains; when the debranching enzyme is deficient (type III) or a low degree of branching in the type IV disease, assumed to be due to lack of branching enzyme.

If glycogen synthetase and phosphorylase are to be thought of as opposing forces then a lack of the latter should lead to excessive amounts of glycogen. This indeed happens in type VI disease, known in human muscle and liver. The normal structure of the resulting glycogen implies that the branching enzyme is in a concentration sufficient to cope with the extra glucose polymerized. It was observed very early in work with phosphorylase that synthesis from glucose 1-phosphate with crude rabbit-muscle extracts led to amylose-like material[23], that is, the chain-lengthening and chain-branching enzymes were in an entirely unfavourable ratio for glycogen formation. Glycogen synthetase activity in rabbit muscle is, however, less than 1 per cent of that of phosphorylase and the balance of synthetase with branching enzyme must therefore be more favourable for glycogen synthesis. The activity of synthetase in rat muscle is known to be sufficient to account for the amounts of glycogen being synthesized[18,37], but the level of glucose 6-phosphate in rat liver, necessary to activate the enzyme (see above), is so low as to limit the rate of synthetase action[1]. The excessive relative activity of muscle phosphorylase can be seen as yet another reason for relegating the enzyme to a place in the catabolism of glycogen, saving only that the supply of adenylic acid could regulate the action of phosphorylase *b*.

Tests of activity of enzymes in heart and liver from cases of type II disease failed to reveal an enzyme deficiency which could account for the excess of glycogen[38]. The results are, however, disturbing in revealing a total absence of glycogen synthetase in four, and a marked deficiency in two, of the six organs examined. The results are obviously incompatible with the excess of glycogen found in the tissues and at face value point to the existence of yet another pathway to glycogen.

Enzyme Structure

Many of the different amylases and phosphorylases have been crystallized and some facets of their structures are emerging. The most significant recent advance in the α-amylase field has been their recognition as metallo-enzymes[39]. All contain at least one atomic proportion of calcium, essential both for the activity of the enzyme and to preserve its integrity against the depredations of proteases. Possibly the calcium maintains the amylase molecule in a configuration unfavourable for proteolysis. *B. subtilis* α-amylase also contains an atom of zinc, uniting two protein moieties, both of which are active in the presence and absence of zinc. End groups of some α-amylases have also been identified.

Human-[40], rabbit-[41], lobster-muscle[42] and potato[26] phosphorylases contain pyridoxal phosphate. Although the rabbit- and lobster-muscle enzymes are reversibly inactivated on removal and re-addition of pyridoxal phosphate, removal being effected by acid, reduction with sodium borohydride renders the pyridoxal acid stable yet does not destroy enzymic activity[43]. The reduced *a* and *b* enzymes are, moreover, still interconvertible. Rabbit and human *a* enzymes contain 4 molecular proportions of pyridoxal phosphate, the *b* forms and potato phosphorylase 2 proportions. Although lobster- and rabbit-muscle phosphorylases *a* are converted into the *b* forms by lobster- or rabbit-muscle phosphorylase phosphatases[42] (this interchange of enzymes does not apply in the $b \rightarrow a$ reaction), the lobster enzyme does not alter in molecular weight[42] but the muscle enzyme is halved in weight[5]. Likewise dog-liver phosphorylases *a* and *b* are equal in weight[44]. Human-[40], rabbit-[23] and lobster-muscle[42] *b* enzymes require adenylic acid for activity, but dog-liver phosphorylase *b* is enzymically inactive[45]. Human- and rabbit-muscle phosphorylases are immunologically identical[40], but dog-liver and -heart phosphorylases are immunologically different[46]. The phosphate removed by phosphatase from rabbit-muscle phosphorylase *a* is attached to serine[6]. Digestion of *a* enzyme with trypsin removes both serine and phosphate as a hexapeptide, Lys. Glu(NH_2).Ileu.Ser(PO_4).Val.Arg, leaving a phosphorylase *b'*, active in presence of adenylic acid, but no longer convertible into the *a* form. Therefore serine phosphate is not concerned with phosphorylase activity.

Outstanding Problems

Of the enzymes listed in Fig. 1, only the phosphorylases[47,48] and *Q*-enzyme[49] have been crystallized. Purification of enzymes has so often led to the discovery of new catalysts and such experiments are essential preliminaries to studies of specificity. Some unsolved problems of specificity have been touched on, for example, the requirements of animal phosphorylase and glycogen synthetase for branched primers of high molecular weight. The suggestion is prompted that they may need to form an alliance between pairs of chains before adding a glucose unit. Such an alliance is the present accepted idea of the action of the branching enzymes[50]. Searching inquiries into substrate specificities require a wider range of substrate than is provided by Nature and specific chemical modifications of amylose are being made, to provide such materials[51]. It is now known, for example, that removal of the oxygen atom of the primary hydroxyl groups in amylose renders the polymer resistant to β-amylolysis and phosphorolysis, but not α-amylolysis[52].

Phosphorylase has been cited as an example of an enzyme capable of performing a transformation *in vitro* which it is not called on to do *in vivo*. Another such example is provided by the enzyme capable of the direct biosynthesis of sucrose from uridine diphosphate glucose (Fig. 1). This enzyme has now been assigned the reverse role *in vivo*, synthesis of sucrose being believed to take place via sucrose phosphate[53]. Another case where reconsideration may be necessary is with the hydrolases. Many of these are now found to transfer to sugar hydroxyls as well as to water. Calculations show that the affinity of the enzyme for hydroxyls in the alternative receptors must be far greater than for water[54] and the possibility thus emerges that the *in vivo* function of such an enzyme may have nothing to do with hydrolysis.

There are some carbohydrases the function *in vivo* of which is still a matter for conjecture. Prominent among these are the amylases. β-Amylase occurs in plants in large amounts—animals seem not to require it—but no enzyme of comparable activity occurs along with the amylase to cope with its product of action, maltose. The enzyme occurs both where starch is abundant, in cereals, or absent, as in the soya bean. α-Amylases in the digestive tract are easily accounted for but what is the function of the small amounts of α-amylase that pervade most living tissue? Fig. 1 is a conventional representation of glycogen and starch metabolism and is incomplete, in that it offers no means of increasing or decreasing the total number of polysaccharide molecules. Possibly α-amylase functions in the glycogen-storage organs by multiplying the number of priming nuclei by hydrolysis. Given a supply of glucose, *D*-enzyme can do the same thing and can also assist in removing primer, as explained elsewhere[55]. It is worth noting also that Fig. 1 contains no means of creating primers where none existed. α-Amylase decreases the number of α-1,4-bonds, *D*-enzyme functions without changing their number and whereas phosphorylase and glycogen synthetase synthesize such bonds, they can only do so if preformed α-1,4-polymers are present. Is there perhaps in plants and animals a system to create the essential primer? Such systems are known in other organisms. Honey invertase acting on sucrose forms maltosylfructose and higher homologues[56], and *Neisseria meningitidis*[57] and beer lactobacilli[58] synthesize maltose from β-glucose 1-phosphate and glucose. Such a system, coupled with a transglycosylase like *D*-enzyme, could provide the necessary primer.

Beyond these studies of isolated enzymes must come attempts to integrate the enzymes into self-sufficient cycles operating *in vitro*. Though the advances in the glycogen and starch field have far outstripped those in any other field of polysaccharide biosynthesis, the goal of the multi-enzyme system may well become a practical objective only in the decade beyond this.

OBITUARIES

Sir David Rivett, K.C.M.G., F.R.S.

With the death of Sir (Albert Cherbury) David Rivett in Sydney on April 1, there passed from the Australian scene a man who had contributed perhaps more than any other to the present healthy state of Australian science. Entrusted as Chief Executive Officer in 1927 with the management of the Council for Scientific and Industrial Research, Rivett and his colleagues contrived, in a country woefully weak in research, to create an atmosphere in which it could flourish.

The men they appointed and supported wholeheartedly did much to inspire the confidence of the people of Australia in the economic value of research. Rivett saw clearly from the outset that his scientists had to be free to tackle their problems on as fundamental a basis as was necessary for their solution. So the men who solved some of the outstanding problems of the farmer and the pastoralist also contributed to the development of science. Nowadays, basic research is a recognized prerogative of the Commonwealth Scientific and Industrial Research Organization, which continues to be known almost as well overseas through its contributions to science as it is within Australia for its long run of outstanding practical successes. To Rivett, first and foremost, should go the credit for this.

Rivett, while chairman of the Council for Scientific and Industrial Research during 1946–49, saw more clearly, and at an earlier date than most scientific leaders throughout the world, the troubles that come to a scientific research body from secrecy. He was persecuted by minor politicians for his belief that security and secrecy are not synonymous terms. But he never ceased to fight for the principle that scientific research needs freedom, and I believe that he thereby saved his beloved Council for Scientific and Industrial Research from lethal restrictive controls.

What sort of background produced this man for whom Australia had so great a need ? David Rivett was born in Tasmania in 1885, the son of a Congregationalist minister of large family and slender means. His secondary and tertiary education, mainly in the State of Victoria, had to be self-supporting. It culminated in a Rhodes scholarship which took him to Oxford for work under Sidgwick. In Stockholm, with Arrhenius, he became recognized as a physical chemist of great talent; his own notable contributions were mainly in phase rule studies and heterogeneous equilibria.

After munitions work in England he returned as a lecturer to the University of Melbourne. There he rejoined Sir David Orme Masson, who from their first meeting had had a boundless admiration for his abilities. It was inevitable that when Orme Masson resigned in 1924 Rivett should be invited to succeed his mentor. He filled the chair with distinction, but after only three years the call came to wider responsibilities with the Council of Scientific and Industrial Research; this he accepted.

Rivett was acknowledged a leader wherever he went. He was general president of the Royal Australian Chemical Institute in 1940 and 1949, president of the Australian and New Zealand Association for the Advancement of Science 1937–39, and president of the Society of Chemical Industry of Victoria in 1930 and 1931. A foundation member of the Australian Academy of Science, he was one of its first vice-presidents. The Australasian Institute of Mining and Metallurgy made him an honorary member in December 1943 for his services to the mining industry of Australia.

Well known abroad, he was president of the Society of Chemical Industry of London in 1949, and was a Fellow of the Royal Society from 1941. He was created K.C.M.G. in 1935, and held the honorary degrees of D.Sc.(Oxon.), D.Sc.(Manchester), and LL.D.(Australian National University).

Despite all his honours and distinctions, Rivett's greatest love was to visit one of his laboratories and to hear at first hand what the young research officers were doing. He was proud of the staff he had gathered, trusted its scientific ability implicitly, and fought for its freedom. No believer in the planning of science, he had the acumen to sense and oppose any impending restraint before it was openly formulated. Once one had gained his confidence he was a magnificent friend and backer; he believed in delegating responsibility and with it any credit that accrued, but in times of adversity he it was who wished to shoulder the blame.

Rivett married, in 1911, Stella Deakin, the daughter of a distinguished Australian statesman. She and their two sons survive him.

His friends throughout the world will deeply mourn his death. Their final thought of David Rivett will be of a man who gave magnificent service to the joint causes of science and humanity.

I. W. Wark

Prof. K. Koshtoyants

Prof. Kachatur Koshtoyants, whose death occurred on April 2, was a well-known figure among the physiologists of Moscow, the director of an active research institute and a stimulating and popular teacher in the University. Kachatur Sergeyevitsh Koshtoyants graduated in medicine in 1926, but his interests always lay in the field of comparative physiology, particularly that of the nervous system. During 1930–31 he had been to Holland to work in Prof. Jordan's laboratory, and five years later he was made head of the Department of Evolutionary Physiology in the Institute of Animal Morphology of the Academy of Sciences in Moscow. From 1943 onwards he was also professor of animal physiology in the University of Moscow. His more recent research dealt with neuro-muscular transmission from a comparative biochemical point of view, and he was the author of a comprehensive treatise on comparative physiology as well as of several monographs on the history of physiology in Russia. Physiologists who have visited his laboratory in Moscow will recall his kind hospitality as well as the range of his research interests, and will wish to express their sympathy to his colleagues in the University and the Academy.

Adrian

NEWS and VIEWS

Prof. Olaf Holtedahl, For.Mem.R.S.

Prof. Olaf Holtedahl, of the University of Oslo, recently elected a foreign member of the Royal Society, is best known for his geological researches on the Caledonian mountain chains of Norway, but he has also distinguished himself as an arctic and antarctic explorer, as a physiographer, and as a palæontologist. Born in 1885, he published his first paper while a student at Oslo in 1909, on Lower Palæozoic rocks of the classical Lake Mjøsa region nearby. Few cities in the world have the natural advantages of Oslo as a centre for studying geology, and no doubt inspired by the unusually fine sequence of Eocambrian–Palæozoic strata here exposed, he soon extended his researches to similar rocks in the northern district of Finnmark, much of which he mapped as a State geologist. A long list of publications during this period includes an outstanding palæontological monograph on the Strophomenidæ. In 1920 he was appointed professor of historical geology in Oslo, where he worked up the geological results of an earlier expedition to Novaya Zemlya, and a few years later he led the Lars Christensen expedition to Antarctica, afterwards editing two large volumes of reports. Attempts to correlate the geological structures of Norway and Britain gave rise to close contacts with British geologists, cemented during a Norwegian excursion which he conducted for the Geologists' Association in 1934 and resulting in his William Smith Lecture to the Geological Society of London, in 1951, on "The Structural History of Norway and its Relation to Great Britain". His two-volume survey of the geology of Norway, published in Norwegian in 1953, was written in simple form to encourage a local revival of geological studies, particularly in schools. A Russian translation appeared during 1957–58, and an abridged, re-written, version in English, with contributions from colleagues, was produced for the International Geological Congress last year.

Elmer Verner McCollum, For.Mem.R.S.

Prof. McCollum, also elected a foreign member of the Royal Society, is best known for his pioneer work on vitamins, which ranks in importance with that of Gowland Hopkins. Like Hopkins, he found that rats would not grow and thrive on 'purified' diets containing proteins, fats and carbohydrates in correct proportions. Unsuccessful attempts to make such diets life-sustaining by improving their palatability led him to the classical experiment (with M. Davis), published in 1913, showing that butter and the ether-soluble material in egg-yolk contained a growth-promoting substance lacking in olive oil and lard, which was designated "fat-soluble *A*". In 1915, McCollum discovered another growth factor, present in water-extracts of wheat germ and egg yolk, which was called "water-soluble *B*", and provisionally identified with Funk's "anti-beriberi vitamine". McCollum initiated the practice of assigning letters to the vitamins, which later proved somewhat unsatisfactory, but the combination of letters with Funk's new word gave the world a term with great popular appeal. Born in Kansas in 1879, McCollum has had a most productive scientific career. Originally trained in chemistry, he turned to biochemistry during an appointment in agricultural chemistry in Wisconsin. During 1917–46 he was professor of biochemistry in Johns Hopkins University in Baltimore, and afterwards professor emeritus. In addition to his investigations on vitamins, he has made remarkable observations on the effects of dietary deficiency of zinc and manganese. He was among the first to grasp the bearing of modern nutritional science on human welfare, and the earlier editions of his book, *The Newer Knowledge of Nutrition* (with Nina Simmonds), became the 'Bible' of a generation of nutrition workers. During recent years he has made scholarly studies of the history of the science of nutrition.

Academician A. N. Nesmeyanov, For.Mem.R.S.

Academician A. N. Nesmeyanov, another of the new foreign members of the Royal Society, has just retired from the presidency (see following paragraph) of the Academy of Sciences of the U.S.S.R. He has thus taken a leading part in the organization of science in his country. He is the director of the Organo-Element Research Institute of the Academy. He is eminent as an organic chemist, particularly for his development of the chemistry of organic molecules which contain a metal or some element outside the usual few which compose most organic chemical compounds. It is a striking fact that, in the first century of its rapid development, organic chemistry has used very few elements. With the whole Periodic Table to choose from, Academician Nesmeyanov has set its head towards a much more expansive programme in its second century. Outside his main field he has developed several fields of great importance, notably the telemerization reaction, with applications including the synthesis of ω-amino-acids, substitutions in the ferrocene nucleus, and organo-silicon chemistry, including telemerizations involving silicon.

New President of the U.S.S.R. Academy of Sciences: Academician M. Keldysh

Academician Mstislav Keldysh, a prominent mathematician, mechanical engineer and computer expert, has been elected as president of the U.S.S.R. Academy of Sciences. He succeeds Alexander Nesmeyanov, who has resigned at his own request, pointing out that he had held this administrative office for more than ten years. Nesmeyanov himself nominated Keldysh as his successor. Academician Keldysh graduated from the physics and mathematics faculty of the University of Moscow in 1931 at the age of twenty and won his doctorate in 1938. He worked for several years in the Central Institute of Aerodynamics. Theories he elaborated have led to effective methods of eliminating 'flutter' in wings and tail units of aircraft. His theories also resulted in new designs for hydro-foil ships. From 1932 he was first a reader, and later a professor, in the Moscow State University. In 1943 he became a corresponding member of the Academy of Sciences and in 1946 was elected a full member. In 1960 he became a vice-president of the Academy. In mathematics, Academician Keldysh has made major contributions to the development of the calculus, to computing techniques and to various aspects of automatic remote control.

Physics at Sheffield : Dr. R. A. Smith, C.B.E.

DR. R. A. SMITH, who has been appointed to the chair of physics at Sheffield in succession to Prof. W. Sucksmith, is at present head of the Physics Department, Royal Radar Establishment, Malvern. After graduating with first-class honours in mathematics and natural philosophy at Edinburgh in 1930 and with first-class honours in mathematics at Cambridge in 1932, he did research work in the Cavendish Laboratory for which he received the degree of doctor of philosophy in 1936. From then until he became lecturer in physics at the University of Reading in 1939 he was Carnegie Research Fellow in the University of St. Andrews. In 1939 he was invited to join the Telecommunications Research Establishment, becoming head of the Physics Department in 1945. The research programme of the Physics Department at Malvern covers a wide field including semi-conductor physics, low-temperature physics, infra-red spectroscopy, microwave physics, electronics and plasma physics. It includes a theoretical physics group and a mathematical group, the latter being specially interested in electronic digital computation. Dr. Smith has written a number of papers and books including *Radio Aids to Navigation* and *The Wave-mechanics of Crystalline Solids*. He was made C.B.E. in 1960. Dr. Smith's appointment as professor of physics will date from October 1, 1961, and he will succeed Prof. Sucksmith as head of the Physics Department when the latter retires in September 1962.

Director of the British Industrial Biological Research Association : Dr. Leon Golberg

DR. LEON GOLBERG has been appointed director of the recently formed British Industrial Biological Research Association (see *Nature*, 188, 1072; 1960). Dr. Golberg is at present medical research director of Benger Laboratories, Ltd., and it is expected that he will take up his appointment with the Association towards the end of the year. Born in Cyprus, Dr. Golberg was educated in South Africa, where he graduated in 1935 with honours in organic chemistry at the University of Witwatersrand. The following year he gained an M.Sc. in physical chemistry. He then came to the United Kingdom and for two years was a member of Sir Robert Robinson's research team at Oxford, carrying out investigations in organic chemistry. In May 1939 he returned to the University of Witwatersrand, and he remained in South Africa throughout the Second World War, working on a variety of nutritional problems at the biochemical laboratory (which he himself established) of the Union Defence Force at the South African Institute for Medical Research. After the War he returned to the United Kingdom and spent six years studying medicine at Emmanuel College, Cambridge, University College Hospital Medical School, London, and Addenbrooke's Hospital, Cambridge. After qualifying in 1951, he became senior lecturer in chemical pathology at the University of Manchester, and in 1955 medical research director of Benger Laboratories, Ltd.

Research Reactors for Universities and Technical Colleges

IN reply to a question in the House of Commons on May 9, Mr. D. Freeth, the Parliamentary Secretary for Science, said that the Government had approved in principle the provision of three nuclear reactors which would be available to universities and colleges of technology for teaching and research. One would be sited in Scotland and one in Lancashire, and it was proposed to site the third in the London area, where it would be available to the Imperial College of Science and Technology, and other institutions in London. Mr. Freeth was advised that the Atomic Energy Authority was not at present developing small and medium reactors, but was undertaking research in many fields which would be applicable both to small and large reactors. In a written answer on May 9, Mr. Freeth said that the Atomic Energy Authority planned to concentrate at Culham all its work on plasma physics and controlled thermonuclear reactions. The site was being developed in three stages, of which the first, including a large experimental hall, should be completed early in 1962, while the second stage, to be developed by mid-1963, included further provision of laboratories and a lecture theatre.

U.K. and U.S.S.R. Collaboration on Peaceful Uses of Atomic Energy

A FORMAL agreement providing collaboration on the peaceful uses of atomic energy between the U.S.S.R. State Committee of the Council of Ministers for the Utilization of Atomic Energy and the United Kingdom Atomic Energy Authority was drawn up, following a meeting of representatives of the two bodies, held at the headquarters of the Authority in London during May 15–16. Among the representatives, and signing the agreement on behalf of the two bodies, were Prof. V. S. Emelyanov, chairman of the State Committee, and Sir Roger Makins, chairman of the Authority. Under this agreement, the bodies concerned will organize conferences and visits to facilities in their respective countries by comparable groups of specialists from the other country; normally, these will last for periods of 1–2 weeks, and provide for visiting groups of 4–8 specialists. The Authority and State Committee will undertake reciprocal exchanges of unclassified reports concerned with the peaceful uses of atomic energy. Information of commercial value will be exchanged only at such times and on such commercial terms as may be agreed in each case. It is hoped that this agreement will enable the interchange of new scientific instruments and equipment, including radioisotopes and apparatus designed for their application in medicine, biological research and industry. The agreement will remain in force for a period of five years. Among the fields of collaboration envisaged in the agreement are : nuclear physics ; solid-state physics; basic radiation chemistry; inorganic chemistry of elements of importance in nuclear science and technology; research on isotopes and research on the application of isotopes; plasma physics; high-energy physics; reactor physics; experimental fast reactors.

Conservation of Wild Life

A RECENT issue of *The Bulletin of the International Union for Conservation of Nature and Natural Resources* (9, No. 7, 3; 1960) outlines the efforts being made in various countries, especially Thailand and the

Netherlands, to promote the objectives of nature conservation. In Thailand the game law is being revised according to the experience of game laws in other countries, and the forest law, too, is also being examined since it is ineffective in preventing destruction; setting aside of the primitive regions as natural reserves and national parks is also under consideration. In the national budget of the Netherlands for 1961 a sum of about 2·2 million dollars has been earmarked for nature protection (as compared with the sum of 1·2 million dollars for 1959). 1·3 million dollars is intended for the purchase of reserves and 300,000 dollars for their management, figures which compare with 630,000 dollars and 210,000 dollars respectively for 1959. In addition, the personnel of the Institute of Ecological Research for Nature Protection has been increased from 16, in 1959, to 21.

The City Museum, Sheffield

The combined annual reports of the City Museum, Sheffield, for the two years 1958–60 form an inspiring record of progress and initiative by a relatively small staff (Pp. 20+4 plates. Sheffield: City Museum, 1961). The theme of service to the community underlies the work of this Museum. Prominent among its activities is that of evening opening in the summer until 8.30 p.m. and the organization of more than a hundred demonstrators at the Unesco exhibition, "The Earth as a Planet". New displays include Saxon jewellery and metal-work, medieval pottery and sculpture, British bats, and one illustrating the variety and forms in extinct animals.

South African Prehistory

The January and February issues of the *South African Journal of Science* contain articles of considerable interest to archæologists. R. J. Mason discusses the problem of the earliest tool-makers in South Africa, P. V. Tobias brings forward new evidence and new views on the evolution of man, and Gordon Cramb continues his report on the excavations undertaken at the Holley shelter near Wartburg, Natal—the first report appeared in the same journal as long ago as 1952. Mason's conclusions are certainly very interesting in view of the human finds of very early date in the region. He says that up to now in South Africa there is no evidence for stone tool-making earlier than the complex earlier Acheulean stage, which is possibly equivalent to Olduvai Gorge Bed 2. There seems to be evidence at the limeworks site for the use of bone for tool-making purposes at an earlier date, but at present no stone implements have been found with them. Tobias does not agree with Dr. Wells, who has suggested that the basic human type in South Africa was possibly proto-sapiens. He claims that an early proto-sapiens such as that found at Kanam in Kenya is not early Pleistocene but Middle Pleistocene in date. He argues that the 'Rhodesioids' are derived from the African Middle Pleistocene hominids, and, in turn, these later gave rise to the Boskopoid and Bush types. Tobias also discusses the roles of cultural and natural selection in South African human evolution. A very extensive bibliography is appended. The Holley rock-shelter site has yielded artefacts belonging to the later Stone Ages from the upper layers. Below them a series of Middle Stone Age tools has been unearthed. From both these levels carbon samples were collected and these were analysed at the British Museum. The results would seem to be: 18-in.–24-in. layer 4,490 years ± 150 years, and 24-in.–30-in. layer 18,200 years ± 500 years.

Instrumentation in Industry

As a means of increasing the application of scientific method to industry, the Department of Scientific and Industrial Research has produced another of its popular booklets. This one, *Instruments in the Factory*, has been written by Dr. J. Thomson, director of the British Scientific Instrument Research Association, and shows that, despite the increasing use of instruments in modern manufacturing processes, there is still scope for improving instrumentation in most industries (Pp. 12. London: Department of Scientific and Industrial Research. 1961). Thermostatic control of water temperature is an example of how instrumentation can be extended. The smoke detector is another; its usefulness is easy to recognize, and the absence of smoke is a good indication of the efficient use of fuel. Another example occurs in flow measurement: often, particularly in smaller firms, accurate measurement of the flow of liquids in manufacturing processes can save a large amount of money. Simple robust methods are available. In the same way the 'thickness' of a liquid can also be measured with advantage. Manufacturers who would like to pass from 'instrumentation' to 'automation' will find from a study of this booklet that automatic control can often take very simple forms; instrumentation and automation can be used to improve products.

Hyperon Stars

The extension of V. A. Ambartzumian's hypothesis of stellar evolution led G. S. Saakyan (*Priroda*, 11, 14; 1960) to develop a new hypothesis of stellar evolution based on the findings of certain recent discoveries of new elementary particles. According to this hypothesis dense stars of the type of 'white dwarfs' on further contraction become neutron stars. During this process their density changes from approximately 10^4 gm./cm.^{3} to about 10^8 gm./cm.^{3}. With a further increase of density to 10^{15} gm./cm.^{3} these stars become hyperon stars representing a more stable state under such conditions. The mass of such hyperon stars in equilibrium is approximately the same as that of the Sun, while the size of their radius is of the order of a few kilometres. Only the central part of such stars contains hyperons. The outer zone is made of neutrons, while the outermost part is made of bare nuclei and electrons. The enormous pressure inside such stars is balanced by the force of gravity, but when such an equilibrium is disturbed hyperon stars are liable to explode with a terrific violence, not unlike the explosions leading to the formation of the 'nova' stars.

Scientific Information Notes

Scientific Information Notes for February–March 1961, issued by the National Science Foundation, notes that the Foundation is supporting a two-year investigation of the line-formula notation for representing chemical structural formulæ as linear arrays of symbols. This is part of an extensive study of chemical notation systems. The Foundation is continuing to support the Harvard University project for research on automatic translations and mathematical linguistics. It is also giving partial support to the abstracting office of the International Federation for Documentation, which is developing a world inventory of scientific abstracting services, and establishing an international clearing house for information on abstracting services and techniques. The Federation has also recommended the formation of a Group on Mechanical Storage and Retrieval; the Ford Foundation has announced a grant of 8 million dollars to the Council on Library Resources, Inc., for continued research to improve library methods, with emphasis on ways of storing and finding information in the library of the future.

Peasant Agriculture in the Tropics

A VALUABLE review of different systems of peasant agriculture in various parts of the tropics is made by E. W. Momber, School of Agriculture, University of Cambridge, in a recent issue of *Rural Life* (6, No. 1; 1961). Momber analyses existing practices in Northern Rhodesia, Tanganyika and Nigeria and shows that nearly all peasant systems were evolved to carry a subsistence economy where there was plenty of land and few people, and that the traditional systems of peasant agriculture are not basically unsound for the purpose for which they were designed. To-day they are being asked to perform tasks which they were not designed to carry out.

Sheep Husbandry in Northern Ireland

A FEATURE of farming in Northern Ireland during recent years has been, says the Ministry of Agriculture of Northern Ireland (Government of Northern Ireland: Ministry of Agriculture. Leaflet No. 47 : Sheep Husbandry. Pp. 26. Belfast: Ministry of Agriculture, 1961), an increase of the number of sheep reared from 654,000 in 1945 to 1,097,000 in 1960. Important factors in this development have been the improvement in pasture manuring and management and the relatively high cost of store cattle. The leaflet discusses breeds of sheep, the types and sizes of sheep flocks, the mating, management and diseases of sheep and the handling and care of wool. It is written in clear, non-technical language and is certainly a very good exchange for a postcard sent to Belfast.

Damage to Maize in Nigeria

EXAMINATION of samples of maize obtained from market traders at Ibadan, Nigeria, over a period of fourteen months by G. H. Caswell of the Department of Agriculture, University College, Ibadan, Nigeria, showed that damage to maize by *Calandra oryzae*, L., the only important pest of stored maize in this region, is slight compared with damage by the same insect in other countries (*J. West Africa Sci. Assoc.*, 6, No. 1, February 1961). This is probably due to the fact that farmers use a system of shifting agriculture, and store maize on their farms where *Calandra* is not endemic. Should the practice of central storage become more common, damage is likely to increase.

The Institution of Metallurgists

AT the seventeenth annual general meeting of the Institution, held in London on May 17, Dr. N. P. Allen, superintendent of the Metallurgy Division, National Physical Laboratory, was elected president for the year 1961–62, in succession to Mr. W. E. Bardgett. The following elections were also made: *Senior Vice-President*, Dr. E. G. West, technical director, Aluminium Development Association; *Vice-Presidents*, F. Dickinson, director and general manager of the Development and Research Department, International Nickel Co. (Mond), Ltd., and Dr. L. Northcott, principal superintendent, Materials Division, Armament Research and Development Establishment, Fort Halstead (War Office); *Honorary Treasurer*, L. W. Derry, head of the Metallurgy Department, Battersea College of Technology; *Members of Council*, H. Morrogh, director, British Cast Iron Research Association, Alvechurch, Birmingham, S. S. Smith, research manager, Imperial Chemical Industries, Ltd., Metals Division, Kynoch Works, Witton, Birmingham, and Dr. J. C. Wright, reader in Industrial Metallurgy, Birmingham College of Advanced Technology.

The Linnean Society of London

AT the anniversary meeting of the Linnean Society of London, held on May 24, the following were elected officers for the session 1961–62: *President*, Prof. Thomas Maxwell Harris; *Treasurer*, the Earl of Cranbrook; *Secretaries*, Dr. C. R. Metcalfe (Botany), Dr. H. G. Vevers (Zoology), Dr. John Smart (Editorial); *Vice-Presidents* appointed were: Prof. A. R. Clapham, Prof. C. F. A. Pantin, the Earl of Cranbrook and Dr. W. T. Stearn. *New Members of Council* elected : Mr. P. R. Bell, Mr. J. B. Gillett, Prof. Tom Harris, Dr. D. M. Kermack and Dr. Sydney Smith. *Linnean Gold Medals* were presented to Mr. Edmund William Mason and Dr. Frederick Stratten Russell. Dr. Mary Agnes Chase, of the United States, and Dr. Franz Petrak, of Austria, were elected foreign members.

The H. G. Wells Society

THE H. G. Wells Society has recently been founded to promote and encourage an active interest in, and an appreciation of, the life and work of one who made such great contributions in many directions during the first half of this century. Educated as a scientist, he inspired persons of all persuasions to take nothing for granted and to examine fundamental principles in all activities, particularly Government, history, planning, possibilities of science and its potential assistance to mankind. The new Society is non-political and non-sectarian, and seeks only to find that which is good in the thought, word and deed of a great man and which can be used as a memorial to one who filled a great gap in human thought. Further information can be obtained from the hon. secretary, Mr. J. R. Hammond, 39 Rugby Road, West Bridgford, Nottingham.

The Royal College of Surgeons of England

A GRANT of £250,000 has been made to the Royal College of Surgeons of England by the Wolfson Foundation. The gift will be applied primarily to the provision, furnishing and equipment of the Hunterian Museum. The Museum—now being rebuilt following its destruction by bombing—is expected to be finished by the spring of 1962, and is to house the collection of anatomical and pathological specimens collected by John Hunter and purchased by the Government of the day, after his death in 1793.

College of Advanced Technology, Birmingham

IN support of the College policy to promote and develop research activities, Messrs. Joseph Lucas, Ltd., Birmingham, have established a fellowship, to be known as the Joseph Lucas research fellowship, in production engineering which will be tenable normally for a period of two years with provision for extension to three years, and valued at £1,300–£1,500 per annum.

University News : Cambridge

The following appointments of overseas fellowships at Churchill College have been made: Prof. A. Schlüter of the Max Planck Institute, Munich, during March–September, 1961; Prof. G. Fodor of the Hungarian Academy of Sciences during April–July, 1961.

Leeds

The following appointments have been announced: Dr. A. E. Guile as senior lecturer, and J. M. Stephenson as lecturer, in the Department of Electrical Engineering; Dr. D. H. Niblett as lecturer in the Department of Physics; Dr. T. A. Scott as lecturer in the Department of Biochemistry; D. J. Harberd as lecturer in the Agricultural Section of the Department of Agriculture.

Liverpool

The following appointments have been announced. *Readerships:* Dr. R. S. Benson (mechanical engineering); J. O. L. King (animal husbandry); Dr. J. H. Leck (electronic engineering); Dr. R. B. Whittington (civil engineering); Dr. A. Young (numerical analysis). *Senior Lecturers:* J. W. Dransfield (veterinary anatomy); Dr. W. H. Evans (physics); Dr. D. Flinn (geology); J. Halling (mechanical engineering); Dr. D. Hull (metallurgy); Dr. J. W. Lynn (electric power engineering); Dr. W. R. H. F. Muirhead (physics); Dr. N. Rast (geology); Dr. J. P. Riley (oceanography); Dr. C. F. H. Tipper (inorganic and physical chemistry); Dr. H. Wilson (pharmacology).

London

Dr. M. G. Fleming, reader in mineral technology in the Imperial College of Science and Technology, has been appointed to the University chair of mineral technology tenable at that College. Dr. O. J. Lewis, senior lecturer at St. Bartholomew's Hospital Medical College, has been appointed to the University readership in anatomy tenable at that College Dr. R. F. Strickland-Constable, senior lecturer at the Imperial College of Science and Technology, has been appointed to the University readership in chemical engineering tenable at that College.

Titles have been conferred on the following: Dr. Alexander Lawson (professor of organic chemistry), in respect of his post at the Royal Free Hospital School of Medicine; Mr. Ralph Shackman (professor of urology), in respect of his post at the Postgraduate Medical School of London; Dr. E. G. C. Clarke (reader in chemistry), in respect of his post at the Royal Veterinary College.

Announcements

Mr. L. A. Thomas has been appointed chief physicist at the Hirst Research Centre of The General Electric Co., Ltd., Wembley, Middlesex. He will be a member of the staff of the Central Research Laboratories with special interest in the programmes of long-term and fundamental research. He was appointed head of the Materials and Components Division in 1960 and retains his responsibilities in this field of the work of the Centre.

The annual general meeting of the Royal Society of Tropical Medicine and Hygiene will be held in Manson House, 26 Portland Place, London, W.1, on June 15 at 7.30 p.m. The new president, Sir George McRobert, will be inducted in succession to Sir William MacArthur. The Chalmers Medal will be presented to Dr. C. E. Gordon Smith.

The third International Congress on Catalysis is to be held in Amsterdam during July 20–25, 1964. The theme of the Congress will be "The Mechanism of Heterogeneous Catalysis". Further information can be obtained from Dr. D. M. Brouwer, c/o Badhuisweg 3, P.O. Box 3003, Amsterdam-N, Netherlands.

The sixth International Hæmatology Symposium will be held at the State Agricultural College, University of Ghent, during July 24–28. Further details can be obtained from Prof. J. Van den Brande, Rijkslandbouwhogeschool, Coupure Links, 235, Ghent (Belgium).

The annual general meeting of the Freshwater Biological Association will be held in the meeting room of the Zoological Society of London, Regent's Park, London, N.W.1, on June 20. Further information can be obtained from the Director, Freshwater Biological Association, Windermere Laboratory, The Ferry House, Far Sawrey, Ambleside, Westmorland.

The British National Committee for Physics is organizing a conference on "Optical Instruments and Techniques", under the auspices of the International Commission for Optics, in London during July 10–14. Further information can be obtained from Mr. K. J. Habell, National Physical Laboratory, Teddington, Middlesex.

The Building Research Station of the Department of Scientific and Industrial Research is holding open days for the new Materials Laboratory during July 10–13. Further information can be obtained from the Director, Building Research Station, Bucknalls Lane, Garston, Watford, Herts.

The Institute of Physics and the Physical Society is organizing a conference on "Thermoelectricity" at Durham Colleges, University of Durham, during July 10–12. Among the topics to be considered are: basic properties of thermoelectric materials, solid and liquid; methods of determining electrical conductivity, thermal conductivity, and thermoelectric power; properties of materials, problems and techniques associated with device developments; thermoelectric devices and their applications. Further information can be obtained from Prof. D. A. Wright, Department of Applied Physics, Durham Colleges, Durham.

The B.B.C. and the Council for Nature announce that they are organizing a competition for amateur cine-photographers for natural history films suitable for showing on television (35 mm. and 16 mm. at 24 frames per sec.). The closing date is February 28, 1963. Further information can be obtained from the Council for Nature, 41 Queen's Gate, London, S.W.7.

The Trustees of the Plastics Industry Education Fund invite, from young people working in the plastics industry, applications for a limited number of training grants towards the cost of full-time study on an approved course leading to a degree or diploma in science, technology or industrial design. Applications must be submitted to the Secretary, Plastics Industry Education Fund, 6 Mandeville Place, London, W.1, by July 15.

The article entitled "Measuring Indigestion", which appeared in the May 13 issue of *Nature* (p. 596), refers to an original paper appearing in *Research in Industry*, published by Stanford University.

UNIVERSITY COLLEGE OF SWANSEA

NEW CHEMISTRY LABORATORIES

NEW chemistry laboratories were opened at University College, Swansea, on May 1 by Sir Alexander Todd. When, in 1920, a department of chemistry was established by J. E. Coates in Swansea, accommodation was provided in temporary buildings the useful life of which was expected to be ten years. In fact, the Chemistry Department has occupied this accommodation until this year, when the new laboratories became available.

The building consists of three major units: a north wing with teaching laboratories; a south wing with research laboratories; and a central spine which contains the lecture theatres, main stores and central services. Accommodation is on three floors, with a total area of 66,000 sq. ft.

The three floors of the teaching wing are essentially the same. Each consists of one general and one honours laboratory accommodating 60 and 48 students respectively, and built on either side of common preparation and balance rooms. The ground-floor honours laboratory has special facilities for organic chemistry; the first and second floor honours laboratories are specially designed for physical and inorganic chemistry respectively. In the general laboratories, each working space is provided with two sets of lockers so that a total of 360 elementary students can be accommodated during one session.

The research wing contains principally staff rooms and research laboratories. The ground-floor is devoted to organic chemistry and has six staff rooms facing south and two six-man research laboratories with an interconnecting service laboratory facing north. The arrangements on the first floor (physical chemistry) and the second floor (inorganic chemistry) are similar. This wing also contains professors' suites, a departmental library with book-stack, microfilm room and reading room, and a seminar room.

There are a number of general facilities for both teaching and research in the central spine. These include two lecture theatres, both stepped, windowless and mechanically ventilated, with seating for 320 students in the larger theatre and 105 students in the smaller one; at second-floor level above the large lecture theatre is a combined lecture theatre and examination room seating 120 students; there are three main stores directly above each other in the central spine and connected by a goods lift. In addition, in the central spine, there is an engineering workshop, an instrument room and separate workshops for glass-blowing and for electronics. A semi-technical area is situated under the small lecture theatre and is equipped for operations such as fractionation and solvent extraction on a pilot plant scale. A number of rooms with special facilities open off the semi-technical area: a cold room; a walk-in fume cupboard; a fire and flood laboratory; a centrifuge room and a constant-temperature room. The first floor of the central spine included a microchemistry laboratory, dark rooms and special laboratories for infra-red and Raman spectroscopy. On the second floor are a radio chemistry laboratory, special instrumentation rooms and a liquid-air plant.

Benches in the laboratories have been designed to give flexibility and ease of access to services for

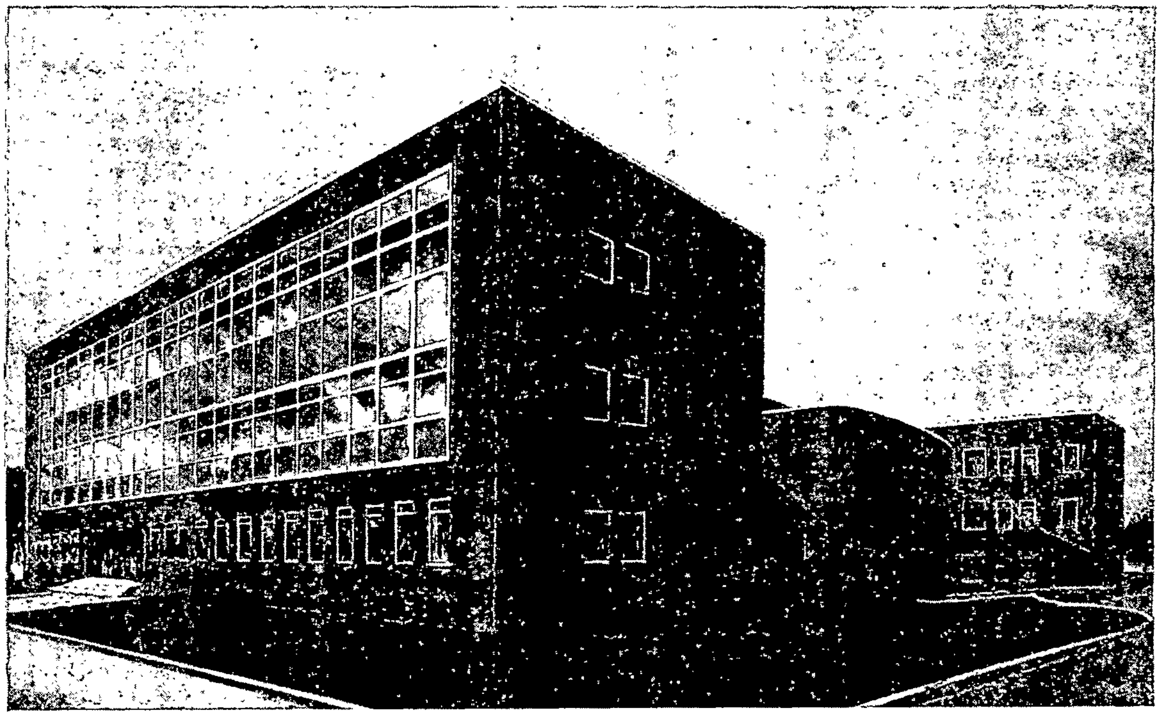

Fig. 1. New Chemistry Laboratories, University College of Swansea

maintenance. Most of the benches, both of the island and wall type, have tops supported by cantilever brackets which fit into specially designed service stands fixed to the walls and floor. Underbench cupboard and drawer units then slide into a position below the bench tops and conceal the service racks. In the research laboratories the tops can be fixed at either standing or sitting height, or can be removed entirely leaving only the stands and associated services. The service racks are formed by a number of metal supports spaced at approximately 3-ft. centres and connected at bench-level by a 9-in. wide horizontal teak strip and a 6-in. deep teak facia. Curved brackets are fixed to the metal strands which support the service pipes, from which outlets are taken at suitable positions. Where a concentration of service is required, plumbing has been simplified by the use of service towers, which results in a clear bench top and a generally neater appearance. In the physical chemistry research laboratories the bench tops and cupboards form movable integral units. All services are available along the walls, with electrical services also available from ceiling outlets. This gives great flexibility in the arrangement of the laboratories.

Bench tops are of Burma teak (*Tectona grandis*); all other exposed timber and veneers are of West African mahogany. Teak has also been used throughout as flooring in laboratories. Reagent shelves have been covered with white 'Vitrolite' and the working tops of fume cupboards formed from a sheet of armour-plated glass.

The number of students taking courses in chemistry now exceeds 250, including 37 honours students and 26 research students and fellows. These numbers are expected to increase considerably in the next five years, during which period the College is planning to increase the number of students from 1,500 to 3,000.

The new facilities make possible very substantial expansion of the research programme in Swansea. As it is, the work of the Department covers a wide range of interest. There is a group working with D. A. Long in the field of molecular spectroscopy with special emphasis on Raman studies. Other groups are concerned with the infra-red spectroscopy of amides (H. E. Hallam *et al.*), the kinetics of nitrosation reactions (G. Stedman *et al.*) and solid-state chemistry (K. J. Gallagher *et al.*). The organic chemists are largely concerned with natural products. This work, which is under the general direction of Prof. C. H. Hassall and Dr. R. F. Curtis, involves work on peptides, cardenolides and alkaloids. A major investigation, dealing with the pathways of biosynthesis of complex phenolic compounds, combines techniques of organic chemistry with others drawn from the relatively young field of chemical genetics. There are also investigations in the field of steroid chemistry (G. H. R. Summers *et al.*) with particular emphasis on reaction mechanisms.

SCIENCE AND INDUSTRY—THE PROBLEM OF COMMUNICATION

A CONFERENCE, organized by the Department of Scientific and Industrial Research and held in Swansea during April 18–19, had as its primary object the critical examination of present-day methods of disseminating scientific and technical knowledge. Both the papers and the lively discussions which followed indicated the growing concern in scientific and industrial circles with the many-sided nature of this problem.

Opening the conference, Lord Brecon, Minister of State for Welsh Affairs, emphasized the relation between the growth of scientific knowledge, the resultant industrial innovation and the growth of industry. His reference to the time-lag between technical advance and industrial use of new techniques and new materials was echoed by several speakers.

Nine papers were briefly presented to enable delegates themselves to participate in the frank and critical appraisal of the problems and solutions as presented. The first paper, by W. S. Robertson, chief executive of the Scottish Council for Development and Industry, reminded delegates that as the volume of available information multiplied there was a proportionate increase in the difficulty of condensing and making that information effectively available to those who could use it. The answer to the increasing volume of literature, it was suggested, might lie in the development of mechanized recording and retrieval systems, but Mr. Robertson maintained that there was still nothing quite so effective as personal contact for passing on new ideas and know-how. He thought that scientific and technical, as well as commercial, people should be encouraged to travel more widely and more frequently, and he condemned the inhibiting parochial attitude of many firms which restricted the development of this most useful means of exchanging ideas.

Dr. D. J. Urquhart, director of the National Lending Library for Science and Technology, also emphasized personal contact, and likened the seeker after scientific information to the stranger in a vast, growing, changing city, the maps of which became out of date almost as soon as they were published. The best and almost only way of reaching an objective quickly was to ask other people working in the specified field. Dr. Urquhart stressed the assistance that libraries and information scientists could provide in making these contacts and warned the conference that existing facilities were inadequate. Quoting Wales as an example, he pointed out that there were only two public libraries with a reasonable holding of scientific periodical literature. The educational aspects of the problem were discussed in the paper by Dr. M. R. Hopkins, senior lecturer in physics at Swansea. He criticized the attitude of narrow utilitarianism which leads to a programme of teaching preoccupied with its immediate purpose. He suggested that the training of every educated man and woman should include some teaching of the fundamental principles of scientific thought, and that both scientists and non-scientists should be educated in the basic skills of communication. Speakers from both platform and floor supported this view; it was pointed out that not one university department specializing in documentation studies existed in Britain. A large increase in the British research effort in this field and the allied one of information retrieval was called for. Following Dr. Hopkins several speakers demanded better facilities for documentation research and indicated how poorly this field was supported in Britain. Dr. R. M. Lodge, research manager of British Nylon Spinners, Ltd., spoke on the communication network in an industrial organization and indicated the difficulties of presenting technical information at many different levels within the firm.

The mass media of communication—press, radio, television, films, exhibitions and conferences—were each dealt with in turn by acknowledged experts. It was generally accepted that the primary value of radio, television and films was in creating a healthy climate of opinion to encourage scientific and technical development. Dr. T. Margerison, science editor of the *Sunday Times*, felt that more use could be made of television by the inclusion of news reports of scientific and industrial developments in magazine-type programmes, and the possibility of implanting the germ of an idea in this way should not be overlooked. Mr. P. Cudlipp, editor of the *New Scientist*, reviewing the function of the general science journal, stressed the value of scientists and technologists keeping themselves broadly informed on a wide range of scientific disciplines. He referred also to the need for scientists themselves to take a hand in the preparation of material that the layman could understand, and noted the growing number of science correspondents in the popular press—which was a recognition of the public interest in science. A better balance and more careful reporting of science news had been achieved, but there was still room for improvement. Exhibitions and conferences were dealt with by Mr. E. H. Underwood, the director of public relations for the U.K. Atomic Energy Authority, who stressed the importance of defining objectives and the audience aimed at, but once again, however, personal contact was cited as being very often the most valuable result of attending such functions. Mr. E. Anstey, of the British Transport Commission, and president of the Scientific Film Association, spoke on "Films to Illuminate and Persuade", directing attention to the use of film as a tool not only for spreading scientific knowledge but also for the popular understanding of science.

In a paper by Mr. L. W. Stevens-Wilson, head of the Steel Users Section, British Iron and Steel Research Association, attention was directed to the need for closer collaboration between specialist or vertically oriented technical information services and horizontal or regionally based services. The Department of Scientific and Industrial Research was strongly recommended to set up more branch offices, similar to those existing in Cardiff and Edinburgh.

The widely differing views of delegates and the relative value of the different methods of communicating information made it clear that there is no one ideal solution to the problem. It would appear that there is still need to strengthen all existing techniques. There was general agreement that in many sectors of industry the prevailing level of interest in research and development was not very high, and that the outstanding difficulty was not simply to improve the means of transmitting scientific and technical information but to stimulate interest at the receiving end in industry. How this was to be achieved remained largely an open question, but it must involve a strong element of personal contact to make an effective change in the habits of thought and climate of opinion in both industry and science.

E. E. WILLIAMS

AN INTERNATIONAL ANDEAN YEAR

ON the initiative of Unesco and by invitation of Dr. Angel Establier, head of the Scientific Office in Montevideo of that Organization in Latin America, who has been interested in such a project from its beginning, a meeting was held in Buenos Aires, during April 3–4, to discuss the planning of an International Andean Year. During such a programme, an intensive study would be carried out on the range of mountains known as the Cordillera de los Andes, from Panama to the southern part of the continent. A small number of scientists from different countries interested were present: Dr. H. O'Reilly Sternberg (Brazil); Dr. Guillermo Mann (Chile); Dr. Tobías Lasser (Venezuela); Dr. Ovidio Suarez (Bolivia); Eng. Eduardo Baglietto, General M. Olascoaga and Drs. F. Bonorino Udaondo, J. Roederer, Angel Cabrera, M. Sadosky, B. A. Houssay and V. Deulofeu, all from Argentina. Dr. A. Hurtado, from Peru, unfortunately could not attend. Dr. A. Establier represented Unesco and his office will be the centre for the various groups in preparing the project.

After an introductory welcome by the vice-dean of the Faculty of Exact and Natural Sciences at Buenos Aires, Dr. M. Sadosky, Dr. Venancio Deulofeu was elected chairman and Dr. Establier acted as advisory secretary. Four sessions were held.

All present agreed in considering that the project to institute an International Andean Year will be of great importance not only because of its width of interest and of the scientific results which are likely to accrue, but also because of the number of scientists involved and the expected international participation from countries outside South America. It was also considered that a project of this magnitude will have a favourable impact on the progress of science and the future scientific development of most of the South American countries.

Discussions dealt with the fields which it would be desirable to cover during the International Andean Year. As a preliminary list it was considered possible and convenient to work on the following subjects: 1, geology; 2, botany; 3, geophysics; 4, human biology; 5, zoology; 6, human ecology; 7, geomorphology including glaciology; 8, physics of high altitudes; 9, soil sciences; 10, geography; 11, agronomic sciences (in collaboration with the Food and Agriculture Organization); 12, sociology; 13, ethnography (both 12 and 13 in collaboration with institutes of social sciences); 14, archæology; 15, anthropology; 16, economics (in collaboration with the Comisión Económica para América Latina).

In each of these fields some subdivisions have already been made and, as an example of the type of work which would be involved, some specific projects were mentioned. For example, it was suggested that in studying the geology of the Andes, it would be desirable to concentrate the efforts in examining the evolution of the Andean range, especially the tectonic and magmatic cycles of the Andean syncline, tertiary and quaternary vulcanism and the magmatic provinces in the Andes.

A further meeting is being planned for December 1961, and will be held in Santiago de Chile, to consider reports to be presented by the scientists participating in the meeting in Buenos Aires and to elaborate further and develop the specific projects in each scientific field.

In the meantime, the Unesco Scientific Office in Montevideo will start compiling a bibliography of research done on the Andes, and collecting the names of scientists who have been active in that field, or who, by their training, are likely to be interested in participating in any of the activities planned for the International Andean Year.

Further information on this project can be obtained from Dr. A. Establier, Centro de Cooperaciôn Científica de la Unesco para América Latina, Boulevard Artigas 1320, Montevideo, Uruguay.

V. DEULOFEU

SOLAR VARIATIONS, CLIMATIC CHANGE AND RELATED GEOPHYSICAL PROBLEMS

UNDER the above title, a symposium was arranged by the New York Academy of Sciences, through the Academy's Section of Geological Sciences and its Division of Oceanography and Meteorology, in co-operation with the American Meteorological Society. The meetings were held in New York during January 24–28. The papers given at the symposium are to be published by the Academy in a forthcoming volume of its *Annals*.

Understandably, the United States provided about four-fifths of the sixty or so participants who offered papers or contributed to the discussions, but a number of workers active in the fields covered by the symposium were present from Canada, the United Kingdom, Holland, Germany and Hungary. Swedish, Russian and Australian contributions had been invited, but their authors were unable to be present. Abstracts of the papers were provided and the meeting as a whole was admirably organized. The generous hospitality of the New York Academy of Sciences was indeed a feature.

The organization of the conference and the arrangements for overseas visitors were largely in the hands of Dr. Rhodes W. Fairbridge, professor of geology at Columbia University, to whom indeed a great part of the success of the meeting was due. Dr. Fairbridge's arguments for the relationship of changes of sea-level, great and small, to the fluctuations of climate which have affected and continue to affect the volume of the Earth's ice-sheets and glaciers, have become widely known (cf. his recent article in *Scientific American*, 202, No. 5, 70; 1960). A fuller statement has now been published in *Physics and Chemistry of the Earth*, 4 (Pergamon Press, 1961). Developing as they do from his earlier work on the eustatic changes shown on the coast of West Australia, they integrate a vast amount of carefully assembled field evidence on a world-wide scale and, cautiously yet persuasively presented, they will be found acceptable by many workers. Nevertheless, it can be agreed that we do not yet know enough about the other agencies that may have affected the volume of the hollows in which the oceans lie.

Climatic change is demonstrably a subject with exceptional ramifications, and the contributions of a great many scientists from differing disciplines are repeatedly called for. Accordingly, the scope of the symposium was enormously wide, beginning with six papers on solar physics under the chairmanship of Dr. Donald H. Menzel (Harvard University). Climatic effects potentially attributable to solar variation were discussed under the chairmanship of Dr. Sigmund Fritz, replacing Dr. H. Wexler, who could not be present. It is evident that the only effects of solar variation that are so far generally accepted are those observable in the extreme ultra-violet end of the solar spectrum, affecting the high atmosphere and the Earth's magnetic field, although some of the apparent relationships with atmospheric circulation patterns are sufficiently suggestive to justify further attention. Among a variety of papers on various aspects of the radiation balance and the general circulation, H. H. Lamb (Meteorological Office, Harrow) presented some of his recent work on displacements of the circulation pattern (cf. *Geografiska Annaler*, 1960). A further session was devoted to meteorological satellites. Dr. Helmut E. Landsberg (United States Weather Bureau) took the chair at a session entitled "Glaciology, Oceanography and Climatology" ; here Dr. William L. Donn presented a summary of the Ewing - Donn theory of the ocean control of Quaternary climate (*Science*, 1958), unfortunately with insufficient time for discussion of a controversial topic in which many would gladly have joined. A preceding paper by Dr. T. N. V. Karlstrom (Coast and Geodetic Survey, Washington) on the glacial history of Alaska provided evidence manifestly difficult to reconcile.

With Dr. R. F. Flint (Yale University) in the chair, followed by Dr. E. S. Deevey (Yale University), palæoclimatology came under review, including several papers around the theme of palynology. Dr. E. H. Willis (University of Cambridge) commented on some of the Fenland evidence. Among the most interesting contributions was that of Dr. Calvin Heusser (American Geographical Society), who gave evidence for the approximate contemporaneity of Late- and Post-Glacial events in the Rockies and the Southern Andes. With Prof. F. E. Zeuner (University of London) in the chair, a final session was devoted to papers around the theme of "Climatic Change and Man". Archæological studies in the United States and in the Near East were noteworthy; Dr. Ralph Solecki's discussion of some of the preliminary findings at the Shanidar cave in Northern Iraq was of great interest, and attracted attention.

It will be evident from this brief summary that a remarkable diversity of papers came up for discussion. Throughout the symposium the impression prevailed that there are many who are still hopeful that some kind of periodicity will appear, based on such solar manifestations as we can observe. From others, dispiriting criticisms equally abound. Dr. Reid Bryson (University of Wisconsin), for example, has applied modern statistical methods to the analysis of tree-ring spectra and found that the usual sunspot cycles fail to appear. On the other hand, several contributors provided support for relationships between solar variations and the pattern taken by the general circulation.

It became abundantly clear how large a number of investigators are patiently accumulating evidence of the amplitude, character, effects and especially the dating of climatic fluctuations all over the world. Speculations regarding the causes abound; supporters of each of the popular theories—solar variation, atmospheric turbidity, carbon dioxide, ozone, variations in the Earth's orbital elements—find their several gods alternately set up and cast down. Workers in one field find themselves unable to judge the validity of the evidence from other disciplines; in this regard, the sessions and the informal discussion resulting from personal encounters between different kinds of specialists are for many a real help. A great deal of enjoyment is had by all, and those who are tempted to advocate simple explanations are repeatedly reminded of the complexity of the problems they so hopefully seek to solve. It now seems almost certain that no one simple panacea is in any way adequate to explain the intriguing patterns of climatic fluctuation to which the evidence points. Almost all the many processes involved seem likely to play some essential part, small or large. The forthcoming volume of papers will provide welcome reading.

GORDON MANLEY

EXPERIMENTAL TAXONOMY OF FLOWERING PLANTS

A SYMPOSIUM on the experimental taxonomy of flowering plants was held at the Linnean Society on March 3. The chair at the morning session was taken by the president, Prof. C. F. A. Pantin, and at the afternoon session by Dr. W. G. Templeman.

In a brief introduction, Prof. D. H. Valentine said that the symposium should provide a good illustration of both the coherence and the wide range of experimental taxonomy. In the papers to be heard, groups at all levels, from the local population to the genus, would be treated, and the problems would be approached from a variety of points of view—genetical, ecological and taxonomic.

Dr. A. D. Bradshaw, of the University College of North Wales, Bangor, then gave his paper on "Evolution within Plant Species in Relation to Soil Mineral Factors". He pointed out that while a considerable amount is known about evolution in relation to climatic and biotic factors, soil factors have, comparatively, been neglected. This is surprising, as an examination of the differences between closely related species shows that they often possess markedly different soil preferences, which indicates that soil factors must play an important part in evolution. Experiments have been done in sand cultures on a number of common species, especially *Festuca ovina* and *Trifolium repens*. The fescues used were all of the 28-chromosome type, and selected tillers were grown in a range of solutions with varying concentrations of calcium. Populations from chalk and peat soils showed a markedly different response to growth; and an experiment on samples from base-rich and base-poor soils from the Breckland showed a similar difference, although the populations were morphologically identical. *Trifolium repens* gave the same kind of response in relation to variation in both calcium and phosphate concentrations, but the phosphate and calcium responses were not parallel. It would appear that populations of both species are physiologically differentiated in relation to their mineral nutrition; and such differentiation cannot be neglected in considering the evolutionary processes in these and other common species.

In the discussion on this paper, it was pointed out that much information of a similar kind was available for cultivated plants, notably rice, but that a great deal of it was inaccessible or not widely known.

The second paper, on "Interspecific Hybridization as an Evolutionary Stimulus in *Œnothera*", was given by Dr. P. H. Raven, of the Rancho Santa Ana Botanic Garden, California. Dr. Raven first described *Œ. brevipes* and *Œ. clavaeformis*, a pair of annual species which occur in arid areas in western North America. The species differ in a number of morphological characters (habit, flower colour, etc.), in habitat, and also in their floral biology. In one, the flowers open at about sunrise, in the other, in the late afternoon, and they are pollinated by different but closely related species of bees, which are highly specific to these flowers. Geographically, the species have a rather broad area of overlap, and natural hybrids are sometimes formed (the species are occasionally visited by insects other than the bees mentioned above). Both species have 14 chromosomes; 7 bivalents are formed in most cells, though occasionally rings of 4 or 6 chromosomes are observed; fertility is high. In the hybrids the multivalents are more frequent, larger rings or chains of up to 12 chromosomes being recorded; fertility is low, and only 5–15 per cent of good pollen is formed. Although most of the hybrids between the particular pair of populations studied appeared to be F_1's, other populations can be found (taxonomically of subspecific status) which are probably of hybrid origin. It would appear that occasional hybridization of the kind described may well play an important part in increasing the number of evolutionary pathways available, especially in areas such as this, in which considerable climatic changes have been occurring. In general, it may be said that the retention of the ability to hybridize and to form stable recombinant phenotypes may be regarded as a significant part of the adaptive system in higher plants. There was a short but active discussion of this paper, in which the evolution of pollinating mechanisms and the part played by chromosome interchanges in the genus were discussed.

The final paper in the morning session was given by Dr. N. W. Simmonds, of the John Innes Institute, on "Classification and Nomenclature in Bananas and Potatoes". Dr. Simmonds dealt with bananas first. He pointed out that we now had a good knowledge of the probable course of evolution in the group. The cultivated bananas had arisen from the diploid species *Musa acuminata* and *M. balbisiana* as a result of polyploidy and hybridization, and consisted of a group of sterile, parthenocarpic clones, mainly triploid in constitution. In the potatoes, the cultivated plants probably originated from wild diploid species, as yet not certainly identified, which had developed into the cultivated tetraploid species *Solanum andigenum;* and this in turn, introduced into Europe as a small sample some four hundred years ago, had given rise to *S. tuberosum*. This resembled the banana in being clonally propagated, but was unlike it in being sexually fertile. In both groups, it is practically impossible to apply the normal nomenclatural rules in any useful way. The banana now comprises six groups of sterile clonal cultivars which are not species in any reasonable meaning of the word; and to attempt to apply the Linnean names *M. paradisiaca* and *M. sapientum*, which represent two of these cultivars, would merely lead to confusion. In potatoes, many of the described species with Latin names refer to single clones, others to an arbitrary selection of plants from continuously varying populations; further difficulties arise in the identification of the Linnean type. In both groups, the best procedure is to discard the Latin nomenclature below the generic level, and apply the *Code for Cultivated Plants*. Rates of evolution in crop plants are high, and crops change; and this must be recognized by an appropriate flexibility of nomenclature. In the discussion, sympathy was expressed with Dr. Simmonds's view of the problem; nomenclatural divisions should resemble a neat fence rather than a barbed-wire entanglement.

In the first paper of the afternoon session, Dr. J. R. Ellis, of the Galton Laboratory, University College, London, spoke on "*Fragaria–Potentilla* Intergeneric Hybridization and Evolution in *Fragaria*". He first reviewed briefly the cytology and distribution of the genus *Fragaria*, and the preliminary experiments on hybridization in this group by Mangelsdorf and by J. K. Jones. Dr. Ellis then described in detail his own experiments, in which he used as seed parent both the garden strawberry, *Fragaria grandiflora* ($2n = 56$), and the artificial allopolyploid *F. vesca-grandiflora* ($2n = 70$). When *Potentilla erecta* ($2n = 28$) was used as pollen parent, hybrid seedlings were produced, but none survived to maturity; but with *P. fruticosa* ($2n = 14$) and *P. palustris* ($2n = 42$) as pollen parents not only did many hybrid seeds germinate but also a number of seedlings grew to maturity. There was great variation in the vigour of the hybrids, which were sterile, and all resembled their *Fragaria* more than their *Potentilla* parent; fertile amphiploids, which may be of value in strawberry breeding, have not yet been obtained. Studies of meiosis in the hybrids have been useful, as they have thrown light on the homologies of the genomes comprising the garden strawberry. Dr. Ellis also suggested that the wild species *Duchesnea indica* might be a *Fragaria–Potentilla* amphiploid. In the discussion on this paper, the bearing of Dr. Ellis's results on the taxonomy of *Potentilla* and its allied genera was referred to, as well as the cytological phenomenon of double non-reduction, observed in both *Fragaria* and *Solanum*.

The final paper, on "The Experimental Taxonomy of *Anthoxanthum* L.", was given in two parts. Dr. M. Borrill, of the Welsh Plant Breeding Station, Aberystwyth, spoke first, on the genetic aspects. In Europe and the Mediterranean, three main groups can be recognized: the arctic-alpine perennial diploid *A. alpinum*, the Mediterranean annual diploids *A. puelii* and *A. aristatum*, and the widely distributed tetraploid *A. odoratum*. Although the latter resembles *A. alpinum* very closely, it also possesses certain features, such as leaf pubescence, which occur in the Mediterranean diploids. *A. odoratum* hybridizes readily with the Mediterranean diploids, *A. alpinum* only with difficulty. However, a sterile diploid hybrid between *A. puelii* and *A. alpinum* was obtained, and from this a tetraploid plant was made by colchicine treatment. This plant is a vigorous perennial, is reasonably like *A. odoratum*, and is fairly fertile. It is also moderately self-fertile and can be inbred, unlike the very self-incompatible natural tetraploid. It seems reasonable to suppose that *A. odoratum* arose from a cross similar to that made artificially, though not necessarily from exactly the same parents.

Dr. K. Jones, of the Royal Botanic Gardens, Kew, then spoke about the cytological aspects of the problem. Natural populations of *A. odoratum* have invariably been found to be composed entirely of interchange heterozygotes. Some bivalents are always formed, but quadrivalents are common, and up to 10 chromosomes may be associated in a ring. These facts can be related to the probable mode of origin of the species. The artificial F_1 hybrid *A. alpinum* × *A. puelii* (described by Dr. Borrill) is a complex interchange heterozygote in which pairing varies from 5 bivalents to 1 bivalent and a ring of eight. The artificial amphidiploids derived from this hybrid are thus polyploid interchange heterozygotes, and, in the plants which have been studied, disjunction is not always regular. As a result of selection, the fully fertile natural tetraploid has developed in which there is regular disjunction and self-incompatibility. *A. odoratum* has thus become a stable and permanent interchange heterozygote.

A general discussion on all the papers was opened by Prof. Irene Manton, of the University of Leeds. After referring to a number of specific points, she raised the general question of the time scale of evolution, pointing out that in many of the groups discussed some fairly precise statements had been made which, if followed up, could give more exact information about the speed at which evolutionary adjustments happened than had hitherto been available. Thus it seemed certain that the physiological adjustments to soil described by Dr. Bradshaw must in some cases have occurred rapidly, since one example involved a disused quarry the age of which could be precisely determined. Evolution in *Œnothera*, described by Dr. Raven, seemed to be related to recent changes in the climate of western North America. In bananas, where parthenocarpy was a significant character, artificial selection by man must have been involved in the original Malayan habitat which could perhaps be roughly assessed in years; a significant part of the evolution of the cultivated potato as we know it to-day must have taken place in historical time. Recent advances in the experimental approach to evolution would now justify closer attention to the question of timing than would have been possible a few years ago, and it was strongly recommended that this attention should be given. In the discussion several speakers endorsed the view that certain sorts of evolutionary adjustment can occur surprisingly rapidly. Prof. G. L. Stebbins pointed out that the first stages in the evolution of the potato had not been quite so rapid as Prof. Manton had suggested, as the crop had a very long history in South America. He agreed with Prof. Manton as to the difficulty and complexity of the problem. The rate at which chromosome changes occurred often seemed to show little correlation with rate of change in the gene complexes which controlled morphological and physiological characters, and the causes of both kinds of change were still obscure. More accurate and detailed knowledge of the history of Tertiary floras might eventually provide a basis for firm conclusions.

D. H. VALENTINE

THE INDIAN INSTITUTE OF SCIENCE

THE Indian Institute of Science owes its existence to the vision of the late Mr. Jamsetti Nusserwanji Tata. In 1889, Mr. Tata, realizing the vital part that science could play in the advancement of human welfare, conceived the idea of founding a research institute which would have as its object the industrial welfare of India. Unfortunately, the founder did not live to see the fruition of his idea and it was left to his two sons, the late Sir Dorab Tata and the late Sir Ratan Tata, to fulfil their father's wishes, with the active support of the late Lord Curzon, then Governor General of India, and Sir K. Seshadri Iyer, who was at that time the Dewan of Mysore. The history of the Institute is presented in the February issue of *Science and Culture**; a short account of the Institute on the occasion of the jubilee also appeared in *Nature*, 183, 644 (1959).

Mr. Tata offered property then worth two hundred thousand pounds (twenty-seven lacs of rupees) as an endowment for launching the Institute. In addition, the Government of Mysore offered 372 acres of land at the north end of Bangalore as a gift so that the Institute would be situated in one of the most favourable locations in India.

The Indian Institute of Science came into formal existence on May 27, 1909, as a postgraduate institution for the promotion of advanced studies and original research. The first batch of students was admitted in July 1911 to the Departments of General and Applied Chemistry and Electrical Technology. The Department of Organic Chemistry was added soon after. The Department of Biochemistry was opened in 1921, and the Department of Physics in 1933, when Sir C. V. Raman took charge as the first Indian director of the Institute.

From such modest beginnings it has progressed in a number of directions, and is to-day considered to be the leading centre of research and training in engineering and science in India.

The Institute functions as an autonomous body in accordance with a scheme formulated by the Government of India, under the Charitable Endowments Act. The Quinquennial Reviewing Committee (1955) recommended that, in place of the diplomas which it had so far been conferring, the Institute should confer degrees. The Institute is now deemed a university under the University Grants Commission Act of 1956.

During the Second World War the Institute took up for investigation a large number of schemes of research sponsored by the Council of Scientific and Industrial Research, the Council of Agricultural Research, the Indian Medical Research Council, and the Governments of Madras and Mysore. During that period, the Institute planned and established the Department of Aeronautical Engineering. At the close of the Second World War, a further four-year expansion programme was launched with grants from the central Government. Under the programme, the Departments of Metallurgy (1945) and Chemical Technology and Chemical Engineering (1951) were established and laboratories to carry out work on fermentation technology and pharmacology were set up.

For the training of power engineers, a Power Engineering Department was established in 1947, with separate laboratories for electrical, mechanical, civil and hydraulic engineering. A section on Economics and Industrial Psychology, including industrial relations, and affording facilities for research in these subjects, was also started in the same year.

In 1955, under a scheme for the development of facilities for technical education, additional postgraduate courses in automobile engineering (1956), foundry engineering (1956), soil mechanics and foundation engineering (1957), electronic engineering (1956), ultra-short and microwave engineering (1956), line communication engineering, and acoustical engineering were provided. Further facilities for research in technical gas reactions, physical metallurgy, hydraulic machines, internal combustion engineering, electrical measurements and measuring instruments, transmission, distribution and net-work practices have been added.

Recently a Department of Applied Mathematics and a section of Industrial Engineering Administration have been established.

The Library of the Institute, with about 63,000 volumes of current scientific and technical journals and books, occupies a high place among scientific libraries in India. The Institute celebrated its golden jubilee, commencing February 2, 1959, to mark the completion of fifty years of notable service to the cause of science and engineering in India.

THE INSTITUTE OF SEAWEED RESEARCH

THE annual report of the Institute of Seaweed Research, Inveresk, Midlothian, Scotland, outlines the expansion in the seaweed industry both in Britain and overseas*. This is due partly to an increase in the use of the seaweeds themselves and partly to the greatly increased use of seaweed extracts.

Seaweed meal factories at Gairloch, Lochmaddy, Kirkwall and Sanday all increased their production during 1960, and the products have found a ready market especially to compounders of animal feeding stuffs.

A retail market for seaweed manure has been developed by eight firms, and a new company has produced a soil conditioner made from seaweed, a liquid seaweed extract and a compost accelerator with a seaweed base. Liquid extracts are being used increasingly in agricultural practice.

Alginates continue to be of primary importance, and the Scottish market is holding its own against overseas competition, particularly from France and

---

* Institute of Seaweed Research, Inveresk. Annual Report for 1960. Pp. 23. (Inveresk, Midlothian: Institute of Seaweed Research, 1961.)

Nova Scotia. America, Iceland and Norway are all producing alginates commercially and there are new ventures in Holland, Australia and South Africa. Increased attention is being paid to the technology of seaweed products, and their use increases, especially in the food, textile-printing and paper-making trades.

The commercial use of mannitol is extending and it may be that its extraction from brown algae will become necessary, since its availability as a by-product in the manufacture of sorbitol does not meet the demand.

The Institute has continued to support fundamental research in a number of universities, and a summary is given of work on algal chemistry carried out in the University of Edinburgh under Dr. E. Percival and Dr. D. J. Manners, and on microbiology under the direction of Prof. G. E. Fogg at University College, London.

The report concludes with lists of publications during 1960, some of which are linked with the Institute while others concern relevant work of scientific importance or commercial development elsewhere.

PUBLIC HEALTH ENGINEERING

POSTGRADUATE courses in public health engineering were first given as a joint venture between the Imperial College of Science and Technology and the London School of Hygiene and Tropical Medicine during 1950. They were inspired by the International Health Division of the Rockefeller Foundation, which, besides giving generous financial aid during the first three years, also awarded many bursaries to enable students to attend the courses.

The courses have now become well established and, during the past eleven years, have been followed by 130 full-time and numerous part-time students from many parts of the world. From the start the aim of the courses has been to give a broad education in public health engineering, and emphasis has been placed on the importance of the public health aspects of the engineer's work.

The engineering studies have been supported by specially arranged courses in basic sciences, especially biology and chemistry, which are essential to the public health engineer but not normally taken by engineers, if at all, beyond the level achieved at school or first year at university. This broad treatment has made it possible to satisfy to a considerable degree the requirements of students from many different countries and of varying interests and experience.

It is now felt that some provision for alternative courses would be a great advantage, and it is proposed to provide two types of course from October 1961*. The first is similar to the course which has been given since 1950. It is intended for engineers who will be employed mainly on the design or control of public health engineering works in Government or local authority departments, public works departments, water or sewerage undertakings or consulting engineers' offices. The second will be a new, broader type of course intended for persons with education and experience in engineering who are concerned with the general application of public health engineering measures rather than with detailed design. Such students will usually find employment in newly developing countries where many of the works with which they deal may be comparatively simple from the engineering point of view. These students require a complete knowledge of public health principles and practice, since their work is closely integrated with the public health services and they may have to initiate new methods of environmental control to meet a variety of health problems.

CHEMOTHERAPY OF MALARIA

IN a recent issue of the *W.H.O. Chronicle**, Dr. L. J. Bruce-Chwatt, head of the Research and Intelligence Section of the World Health Organization's Division of Malaria Eradication, has outlined changes being made in the drugs used in the campaign to eradicate malaria. Dr. Bruce-Chwatt suggests that research on the biochemistry of anti-malarial drugs is badly needed and directs attention to the renewed interest in drug combinations and associations.

The rationale of the present use of drugs in malaria eradication programmes carried out by the World Health Organization is as follows:

(1) Schizontocidal drugs (chloroquine or amodiaquine) are used occasionally in the early stage of the attack phase, more generally in the late stage of the attack phase, and always in the consolidation phase for the 'presumptive treatment' given to all suspected cases of malaria for relief of clinical symptoms. The administration of a single dose of the drug to all detected fever cases is one of the characteristics of the surveillance activity that starts towards the latter part of an attack phase of malaria eradication, covers the whole of the consolidation phase, and extends over at least part of the maintenance phase.

(2) A sporontocidal drug (generally pyrimethamine) is often associated with the schizontocidal drug in the 'presumptive treatment' of the attack and consolidation phases with the purpose of making the suspected case of malaria non-infective to *Anopheles* vectors.

(3) Mass administration of schizontocidal drugs, alone or in association with such sporontocidal drugs as pyrimethamine or primaquine, has also been adopted during the attack phase together with residual spraying when the conditions are such that anti-anopheline measures are unlikely to have a rapid or complete effect. This use of drugs is still tentative; they have been given either as a single dose at long intervals at the time of residual spraying or as a repeated (weekly or monthly) dose for some definite period.

---

* *W.H.O. Chronicle*, 15, No. 4 (April 1961).

The distribution of medicated salt is actually a variant of mass drug administration, applicable in conditions when residual spraying is not, for various reasons, feasible. Chloroquine or pyrimethamine has been used for admixture with salt, but the latter drug is no longer advocated for this purpose.

(4) Radical treatment of relapsing malaria means generally the use of 8-aminoquinolines for infections due to *Plasmodium vivax* and *P. malariae*, since that due to *P. falciparum* is cured easily by a standard three-day treatment with chloroquine or amodiaquine. The proper administration of daily primaquine or quinocide over a fourteen-day period is often difficult without a wide network of medical services, and in such cases large single doses or smaller repeated doses of a sporontocidal drug (pyrimethamine) have been tentatively given.

The following aspects of chemotherapy are among those of immediate interest for malaria eradication. There is a great difference between the approach of the clinician interested in treatment of a case of malaria and that of the malariologist whose aim is the eradication of this infection from a large community. From the point of view of the clinician no new anti-malarials are really necessary; he has quinine or, preferably, one or other of the 4-aminoquinolines for treatment of severe infections; if he wants to prevent relapses one of the modern 8-aminoquinolines—safe when given with some elementary precautions and almost 100 per cent reliable—is available; for protection from infection the clinician has the choice of proguanil, pyrimethamine, and (in the second place) chloroquine or amodiaquine; any of these drugs will serve his purpose when given at proper and regular intervals.

For the malariologist, each of these drugs has one flaw: it must be given in regular, repeated doses to achieve its effect on the transmission of malaria. In this respect they are often a failure when used on a large scale in countries without extensive and well-organized medical and public health systems. In reassessing the problems of chemotherapy in malaria eradication two questions may be asked: How can the best use be made of the anti-malarials now available?, and, What new drugs are needed, if any ?.

Improvements in operational conditions, better co-operation from an enlightened community, or the introduction of some relatively simple technical innovations may remove a number of obstacles to a wider use of drugs in malaria eradication, but are not always feasible in under-developed areas with inadequately organized public health services.

What new drugs are needed ? The answer is that at least two types of anti-malarials must be developed : (1) A potent and safe schizontocidal drug which will maintain its effect for 3–6 months after a single dose. It would be advantageous if this drug had a rapid and prolonged sporontocidal action. (2) A good and safe anti-relapse drug capable of effecting a radical cure of *vivax* and *malariae* infections when given in a single dose or, at the most, in a three-day course of treatment. Over the past five years the development of new anti-malarial drugs has not been so fast or so successful as expected.

There are two reasons for the apparent lack of drive in research on new anti-malarials: one is the empirical approach to the investigation of new compounds and the other is the growing difficulty of gauging their value in human malaria; little is known about the metabolism of the infected cell.

PHYSICAL ANTHROPOLOGY OF AUSTRALIAN ABORIGINES

SINCE 1951 the Department of Anatomy of the University of Adelaide has sent out seven field expeditions to study the physical anthropology of the aborigines in different parts of Australia, and the first complete trans-continental survey—from Fowler's Bay (Yalata) on the south coast to the Liverpool River in northern Arnhem Land has now been compiled.

The survey covered most metrical and non-metrical characters. Much of the information collected has yet to be analysed statistically, but some features are emerging to warrant preliminary consideration. These have been reviewed by Prof. A. A. Abbie of the Department of Anatomy, University of Adelaide, South Australia*.

Divergent opinions on whether the aborigines are homogeneous or heterogeneous lend interest to a comparison of some physical measurements of three aboriginal groups, separated from each other by some 800 miles of territory and all living in different environments.

The groups are, respectively, (*a*) a composite southern group assembled near Yalata on the south coast ; (*b*) two neighbouring tribes of central Australia —the Pintubi and the Wailbrai : and (*c*) a tribe near the mouth of the Liverpool River in northern Arnhem Land, the Burera. In the present paper only adult males are considered as being most representative of their groups. The numbers examined—Yalata, 33 ; Pintubi, 38 ; Wailbrai, 30 ; Burera, 26—are about the maximum obtainable in any tribe in a reasonable time. All except the Yalata group had come under European influence only shortly before the time of examination.

The figures indicate that, right across the continent, through a wide diversity of environments, the aborigines exhibit an extraordinary degree of physical homogeneity.

Up to the age of about 5 years, the physical proportions of aboriginal children are about the same as those of comparable Europeans. Between 5 and 6 years, however, aboriginal children suddenly show a marked extension of the inferior extremities that reduces the relative sitting height to about 50 per cent —close to the proportions of European children of around 12 years. Thereafter, until the cessation of growth, the aborigines preserve their six years' advantage and finish with a relative sitting height close to 46 per cent.

So far this has been worked out fully only for the central Australian males, but a preliminary survey of the data indicates that it holds for both sexes and for most northern and most southern groups as well.

New-born aborigines are pinkish-yellow with some darker colouring around the nipples, navel, genitalia and buttocks. The rate of darkening of the skin seems to depend on the degree of exposure to the

---

* *Australian Journal of Science*, 23, No. 7 (January 1961).

Sun and full pigmentation may be acquired in one week or not for two or three weeks. The oral mucosa may be patchily pigmented in infancy, but usually not until eruption of the first permanent molars. The darker colouring starts around the anterior gum margins and spreads to the general mucosa and the palate with advancing maturity. There is a tendency towards fading in old age. In tribes that practise circumcision, at the time of operation (about puberty) the glans penis is pink or only slightly pigmented; in adult circumcized males the glans is as dark as the surrounding skin.

In most aborigines the skin is reddish-brown or chocolate, but more intense exposure—as in the desert or far north—produces a much darker colour. Those who wear clothes regularly tend to lose some of their melanin and fade, sometimes to near the original pinkish-yellow in parts. Such people are liable to sunburn on unaccustomed exposure.

Head hair is usually dark brown to black, but blondness—ranging from quite flaxen to reddish-brown—is common in the children of central and south Australia. The fine hair of the body is also fair, but all other aspects of pigmentation—skin, eyes, eyebrows and lashes—are as in all other aborigines. In boys the scalp hair begins to darken at 8–10 years and becomes black or dark brown, like the hair of axillæ, pubes and beard, before the age of twenty. Girls start to darken later—in adolescence—and even when adult may still only be mid-brown on the scalp although axillary hair and pubic hair is dark brown or black. In the far north light scalp hair is less common, but it occurs, and usually with a redder tinge. Light body hair is quite common there in women and children, however. This blondness probably has a genetic basis; it is certainly not due to kwashiorkor, or other nutritional disturbance.

Aborigines living under native conditions have relatively low blood pressures. In the western desert men at 40 years averaged 75–109 mm. mercury and women slightly less. At Government settlements, where living is easier and some European food is available, male pressures were 79–119, female 76–110. In a more or less urban environment male pressures averaged 89–131 (very similar to European males under similar conditions), female 75–115. In northern Arnhem Land pressures expressed on the same basis were: males 84–116, female 82–113.

All aborigines so far examined have high serum protein-levels, especially in the γ-globulin range. Serum cholesterol-levels are comparatively low in desert-living aborigines and there does not appear to be any rise with age as occurs in Europeans. Aboriginal cholesterol-levels rise with increasing Europeanization (roughly paralleling the rise in blood pressures), but not, so far, to European-levels. Serum phospholipid and mucoprotein-levels also rise under the same conditions.

WEATHER FORECASTING BY NUMERICAL METHODS

THE advent of the electronic computer has made it possible to attempt weather prediction by numerical processes. The idea is to observe an initial state of the atmosphere, apply Newton's laws and the laws of conservation of energy and mass, together with the appropriate gas laws, and hence predict the condition of the atmosphere at some time in the future, rather as the motions of heavenly bodies are predicted in astronomy. The earliest attempt was made by L. F. Richardson between the World Wars and is described in his classic book. Richardson visualized an army of computers, just able to keep up with the weather. He did not visualize computing machines, and their widespread use has changed the position, for an electronic computer can get ahead of the weather quite easily.

Active work on this subject is now proceeding in the United Kindom, Belgium, Holland, Norway, Sweden, Japan, and several centres in the United States. A recent publication from the Meteorological Office* describes some of the work being done in the forecasting research division. This paper, considered together with recent work in the United States deserves special attention because, for upper-wind forecasting, numerical methods now surpass conventional methods of forecasting. This does not mean that the conventional forecaster with his weather-maps will disappear, because, as yet, it is only the winds which are forecast numerically, not the equally important weather. A housewife may like to know that Monday will be windy because this will facilitate drying clothes, but she is more interested in whether or not it will rain. Numerical methods at present either do not attempt to predict this or they do so very badly.

It is obvious that the atmosphere is a very complicated affair, yet the primitive (partial differential) equations expressing the laws mentioned above look beguilingly simple. They do, however, include all the motions of the atmosphere, the steady trade winds on the surface, the great jet-streams in the upper air, depressions and anticyclones, tornadoes and showers, to mention only a few of the varied phenomena. Almost always the first thing, therefore, is to simplify the equations so that only events significant to the scale of weather concerned remain. The resulting simplified system of equations and the somewhat artificial atmosphere it describes then become a 'model'.

In the United States experience is that the simplest and earliest model—the barotropic model—remains the best for forecasting large-scale phenomena. After pioneer work by J. Charney, the great labour of extensive trials has been borne by a joint numerical weather prediction group at Suitland, Maryland. The model regards the atmosphere as describable in every way by events at one level only, and the resulting simplified atmosphere is called the equivalent barotropic atmosphere. By extending the calculation to include almost the whole northern hemisphere, and by correcting artificially for the unexplained incorrect backward motion predicted for the phenomena of the largest scale, a useful extra skill above the conventional forecaster is obtained and, for long-range air navigation, winds forecast in this way are now used in the United States.

* Air Ministry: Meteorological Office. Scientific Paper No. 5: *An Experiment in Numerical Forecasting*. By E. Knighting, G. A. Corby, F. H. Bushby and C. E. Wallington. (M.O. 682.) Pp. iii+67. (London: H.M. Stationery Office, 1961.) 5s. net.

In a barotropic atmosphere, by its very nature, kinetic energy cannot be generated, and this is clearly unnatural since without the continuous generation of energy the atmosphere would slow down and soon be stopped by the drag of the air on the ground. This fundamental unreality would appear to be very unsatisfactory. However, it is now generally accepted that the large-scale motions of the general circulation, for which the barotropic model succeeds so well, do not have their own source of energy, but derive it from the more ordinary phenomena, such as the depressions of temperate latitudes. In most fluid-flow problems the small vortices obtain their energy from the general flow, and it is a remarkable property of the atmosphere that here the reverse occurs. It is therefore reasonable that phenomena which have no internal energy source can be described by a model which provides none, but this model would be expected to fail when kinetic energy was obviously being generated. This is found to be the case and most of the active groups working on the problem are experimenting with more complicated models which can provide the necessary source.

In the Meteorological Office the effort available is relatively small, and it has been mainly concentrated on the two-layer models which arose naturally out of Sutcliffe's early work. In the work of all groups, much of the success which has been claimed for the complicated models appeared to rest suspiciously on the isolated events which had been used to test them, the model being adapted until it succeeded, but presumably its success was isolated because these models have not appeared in service use. The Meteorological Office, in its Scientific Paper No. 5, has now published the results of a substantial test of a two-layer model, and some significant success is achieved. The forecasts appear to have a just significant superiority over conventional methods. The workers have been handicapped by the need to work over a limited area so that the influence of events outside the region of computation is not negligible, and it is to be hoped that they will be able to increase their scale of operations in the future.

It seems that the slow improvement in the accuracy of weather forecasting must be accepted. Conventional methods using weather charts, the dynamic methods discussed above and elaborate statistical methods all seem to achieve a success only a little better than persistence. They then progress either no more, or very slowly. It may be that the block is because the weather is in fact indeterminate and it will never be possible to do much better, but surely that is a gospel of despair.

A. W. BREWER

PRECIPITATION OF SUB-MICRON DUST IN STILL AIR BY CLOUD-SIZE WATER DROPLETS

By DR. M. M. BHADANI and N. G. T. LUDLOW

Department of Mining and Minerals Engineering, The University, Edgbaston, Birmingham, 15

A SEARCH of available literature indicates doubt as to the possibility of precipitating sub-micron dust dispersions in air by means of water droplets falling under gravity. The results of a preliminary investigation of this problem by Bhadani[1] indicate that such precipitation occurs readily under conditions described in this article.

Some fields, in which further extensions of research into the behaviour of fine aerosols in general may have special significance, are discussed briefly.

That such fine dust is produced in certain industrial processes is discussed by Sichel[2], who records large percentages of dust of less than $0{\cdot}1\mu$ from mine-drilling operations. In certain foundry operations, too, high percentages of $0{\cdot}05$–$0{\cdot}10\mu$ grains have been reported[3].

The potential significance of sub-micron particles in lung pathology has been established by Pollicard[4], Dautrebande *et al.*[5], and others, who have shown that such fine particles can penetrate into the lung alveoli.

A method of coagulation of fine dust and sodium chloride aerosols, both in Brownian motion, is described in refs. 6–8. When breathed into the lungs, the hygroscopic sodium chloride-dust agglomerations grow larger by absorption of moisture and are deposited in the larger air tracts before reaching the alveoli.

The finer particles present in atmospheric pollution comprise both man-made and naturally occurring substances. Cartwright and Skidmore[9], in surveys of airborne dusts in South Wales coal mines, concluded that atmospheric pollution entering the mines with the ventilating air current made it difficult to assess the sub-micron dust actually produced in the mining operations.

In meteorology great importance is attached to the function of fine particles present in the atmosphere in acting as condensation or freezing nuclei in the process of cloud and rain formation. Simpson[10] notes the presence in air of naturally occurring hygroscopic nuclei such as salt from sea spray and nitrous acid from atmospheric nitrogen, in addition to non-hygroscopic materials. Nolan and Doherty[11] have recorded the presence in Dublin air of condensation nuclei of $0{\cdot}01$–$0{\cdot}10\mu$ size and with varying concentrations up to about 9×10^4 particles/c.c. of air and more. Bowen[12] has produced evidence showing a possible relationship between regularly occurring meteoric dust streams and peak rainfall periods in various parts of the world. Cwilong[13] has found nuclei concentrations of about 10^5 particles/c.c. of air coinciding with abnormal rainfall and meteoric dust showers. Ludlam[14] has estimated that cosmic dust may settle into the atmosphere at a sufficient rate to provide concentrations of Aitken nuclei near ground-level of 100 particles/c.c.

When bulk coal from the top seam of the Khost-Sharig colliery, Baluchistan, Pakistan, or silica dust (that is, dust produced by grinding) is dispersed in air in a confined space, the larger particles soon settle out by gravitational effect, leaving behind a fine residual dust suspended in the air medium. Residual dust, prepared in this way in a metal chamber (17 in. × 17 in. × 30 in.), has been found to consist of particles largely in Brownian motion.

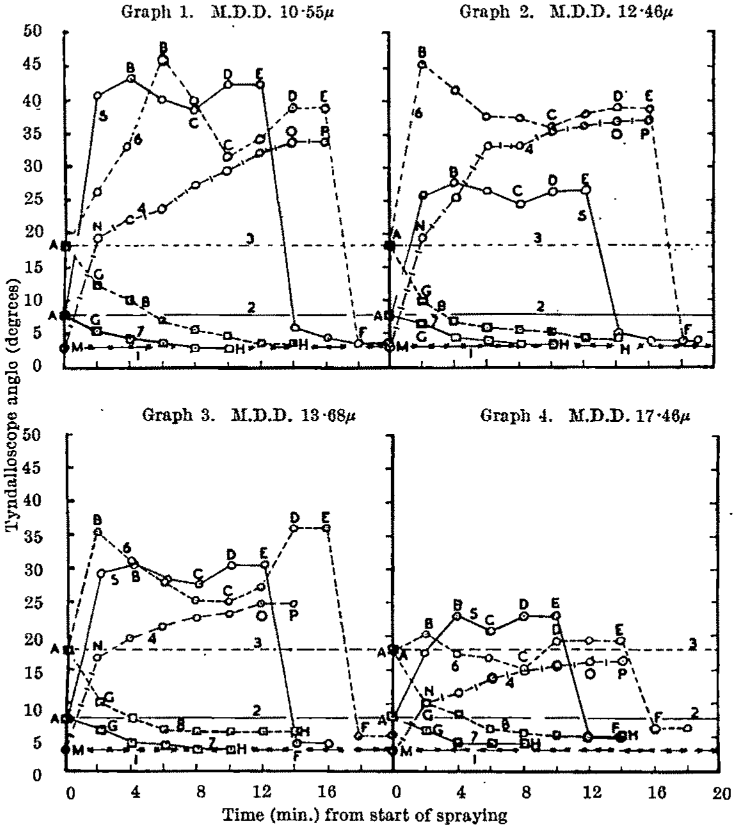

Fig. 1. Water spray precipitation for residual coal and silica dusts, with related curves. Average mean diameter of dusts used, 0·14μ. (1) Instrumental zero reading of +3°. (2) Constant scatter angle for residual Pakistani coal dust dispersion in the absence of spray. (3) Constant scatter angle for residual silica dust dispersion in the absence of spray. (4) Curve for spray in the absence of dust. (5) Precipitation cycle for residual Pakistani coal dust with continuous water spray. (6) Precipitation cycle for residual silica dust with continuous water spray. (7) (AGH). Precipitation curve for residual Pakistani coal dust with intermittent spray. (8) (AGH). Precipitation curve for residual silica dust with intermittent spray. M.D.D. = mean droplet diameter

The average mean diameter of the particles was 0·14μ and the concentration 9×10^4 particles/c.c. of air. The concentration in the chamber was measured by means of the light-scatter angle of a Tyndalloscope. The Tyndalloscope readings of the residual dust suspensions before commencement of spraying were found to remain constant for several hours, the values being 7·8° and 18° for the coal and silica dusts respectively. This indicates a steadily maintained dust dispersion in which coagulation, diffusion or settling were not important factors during the period of the experiments.

When the steady state of the residual dust suspension in the chamber was indicated by the constant Tyndalloscope reading, water droplets were introduced into the upper portion of the chamber by means of a May[15] type spinning top driven by compressed air. The Tyndalloscope angle was read at 2-min. intervals during the precipitation cycles.

Four sets of typical precipitation cycles and related curves for residual coal and silica dusts are shown in Fig. 1, graphs 1–4, using water spray with mean droplet diameters of 10·55, 12·46, 13·68 and 17·46μ in separate experiments. The same rate of water-flow (2·4 c.c./min.) was used in each case.

Particular consideration is given here to the continuous spray precipitation curves 5 and 6 for coal and silica dust, respectively.

Entering these curves at *A*, on the line of steady scatter angle of the coal or silica dispersed in the chamber, the sprayer is started. The Tyndalloscope scatter angle increases rapidly from *A* to *B* as the combined effect of mist in the presence of dust is registered. From *B* the angle decreases sharply to *C* and then soon again increases to *D*, after which it remains constant, indicating equilibrium conditions. At *E* the spray is stopped and the portion of the curve *E* to *F* is clearly related to the diminution of concentration, as the droplets plus remaining precipitable dust fall to the floor of the chamber.

An interesting feature of these continuous spray precipitation curves is the fall in scatter angle *B*–*C* followed by the rise *C*–*D*. It is thought that this may be in part due to a temporary shower of dust-laden droplets. Evidence of substantial dust precipitation by droplet assimilation is seen in Fig. 2. This shows an electron microscope photograph of a droplet which has fallen directly on to a 'Formvar'-covered specimen grid, placed in the floor of the chamber.

Comparing all the precipitation curves for the coal and silica dusts, it is noticeable that the smaller droplets are somewhat more effective in eliminating the dust from suspension than the larger droplets. Also the coal dust is more readily precipitated than the silica dust.

The reasons for the diverse precipitation characteristics of coal and silica are not fully understood. The contrasting physical properties of coal and silica in the presence of water vapour may be important in this connexion. It is well known that coal absorbs water vapour[16–19]. To illustrate this point in the present work, equal weights of the bulk silica and coal dusts were placed in separate vessels on the floor of the experimental chamber, sheltered from falling droplets, but with open

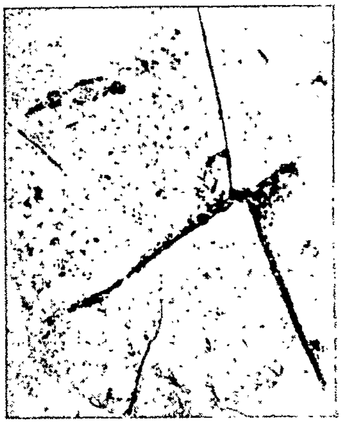

Fig. 2. Electron microscope photograph of dust-laden water droplet (× 1020)

access to the atmosphere of the chamber. It was found that the increase in weight of the coal dust attributable to water vapour adsorption was more than 100 per cent, whereas that of the silica dust was negligible.

Our thanks are due to Prof. Stacey G. Ward, head of the Department of Mining and Minerals Engineering, for help and advice in the research and in the preparation of this article.

VISCOSITY OF DUSTY GASES

By Dr. WAYNE T. SPROULL

Western Precipitation Division, Joy Manufacturing Co., Los Angeles

IF dust is added to gas flowing turbulently through a pipe or other system, the difference, H, in pressure required to maintain the flow at its original (clean) rate, V, decreases immediately. For air, a dust concentration of ¼ kgm./m.^{3} decreases H about 13 per cent. Or, if H is held constant, the addition of the dust increases the flow-rate about 6½ per cent, the flow being proportional to the square root of H. These quantitative results were determined by Dr. Leo W. Briggs in our laboratory in 1945, but never published. The qualitative observation that the gas-handling capacity of a cyclonic dust collector increases considerably with the dust concentration was familiar here about 1935 or earlier.

Curiosity about this effect led to the present investigation. Obviously, addition of 0·25 kgm. of dust to a cubic metre of clean air, which has a mass of about 1·2 kgm., will increase its density to about 1·45 kgm./m.^{3}. Such a 21 per cent increase in the density could be achieved by, for example, cooling the air sufficiently, and both theory and experiment agree that such an increase in density due to temperature reduction will *increase* the value of H required to keep V constant by 21 per cent. Yet Briggs found that H *decreases* about 13 per cent when this same 21 per cent density increase is achieved by suspending dust in the air (or other gas).

The probable explanation seemed to be that addition of the dust must decrease the viscosity of the gas in order to account for its decreased resistance to flow through pipes, etc. Moreover, the decrease in the viscosity must be quite a large one, because empirical equations such as the so-called 'Fanning equation' show that, for a constant flow-rate V, H varies as the 0·25 power of the viscosity. Thus, the observed 13 per cent reduction in H for a dust concentration of ¼ kgm./m.^{3} would imply a 43 per cent reduction in the viscosity. This seemed difficult to believe; yet no other explanation could be found.

In 1958, I conducted some preliminary tests with a viscosimeter and found a decrease of about 40 per cent in the viscosity of air, from about 180 to about 110 μpoise, when limestone dust was suspended in it at a concentration of about ¼ kgm./m.^{3}. These results were published only in abstract form[1]. The viscosimeter used in 1958 was constructed with a horizontal disk, suspended by a torsion wire, 5 mm. above a second horizontal disk driven by a motor at 78 rev. per min. Dust settled rapidly on the disks at the heavy concentration required, and this left some room for doubt about the reliability of the results.

Therefore the experiments were repeated in 1960, using a viscosimeter having a vertical sensing cylinder suspended coaxially within a rotating cylinder, as shown in Fig. 1. It was not possible to work under steady-state conditions in either the 1958 or 1960 experiments. If dust-laden air from the dust-dispersing device had been blown steadily through the viscosimeter cabinet with a dust concentration of ¼ kgm./m.^{3} over a period of, say, 20 min., the dust settling within the cabinet would have been so great as to fill it about half full and completely spoil the operation of the viscosimeter. Even in 1 min., the dust settling on the floor of the cabinet amounted to about 1 in. at these heavy concentrations. Thus each test had to be conducted rapidly and a result obtained within 1 min. The procedure was to blow clean air through the viscosimeter cabinet at the maximum rate attainable without undue disturbance of the inner sensing cylinder. After noting the 'zero' deflexion, the outer cylinder was started rotating; the change in the deflexion was taken as a measure of the viscosity of the clean air (about 180 μpoise). Next, dust was fed into the disperser at a rate sufficient to yield the desired concentration, for about 1 min. During this time, the deflexion of the inner cylinder decreases due to the reduced viscosity, and the reduced value must be determined.

The annulus between the two cylinders was 5 mm. wide in some tests and 7½ in others. More than one value was also used for the speed of rotation, 25 and 50 rev. per min.; for the dust concentration, 60 and 240 gm./m.^{3} approximately; and two types of dust were used. One was limestone dust consisting 40 per cent by weight of particles smaller than 10μ diameter; the other was talc dust 99 per cent by weight smaller than 10μ. Although the density of the individual particles was nearly the same for these two dusts (2·5 gm./c.c. for talc and 2·6 gm./c.c. for limestone), the talc dust had a bulk density of only about 0·3 gm./c.c., as contrasted with about 1·3 gm./c.c. for the limestone dust. The results follow:

Test series	Dust	Approximate concentration (gm./m.^{3})	Cylinder speed (r.p.m.)	Annulus width (mm.)	Observed viscosity reduction (per cent)
1	Limestone	240	50	7½	40
2	Talc	240	50	7½	38
3	Talc	60	50	7½	10
4	Talc	60	50	5	10
5	Talc	240	50	5	35
6	Limestone	240	50	5	24*
7	Limestone	240	25	5	24*

Each of the seven values in the last column of the above table is an average of several tests. The last two, marked with asterisks, are to be discounted on the grounds that with the narrow 5-mm. annulus, the comparatively coarse limestone dust could not be forced through the apparatus fast enough to prevent excessive settling, without disturbing the sensing cylinder unacceptably. Consequently, settling reduced the dust concentration in series 6 and 7 to a value considerably less than the ¼ kgm./m.^{3} at which it entered the viscosimeter cabinet. These two series did indicate, however, that the result is insensitive to cylinder speed.

The tests of two such different dusts as limestone and talc, with nearly identical results, indicate that the concentration of the dust (mass per unit volume of the gas) is the main factor in the effect, and that the particle size and bulk density of the dust are relatively unimportant. The present results confirm the 1958 results and indicate that dusty gas flows through pipes with a smaller resistance than clean gas, because the dust reduces its viscosity. This work has also been published in abstract form[2] only.

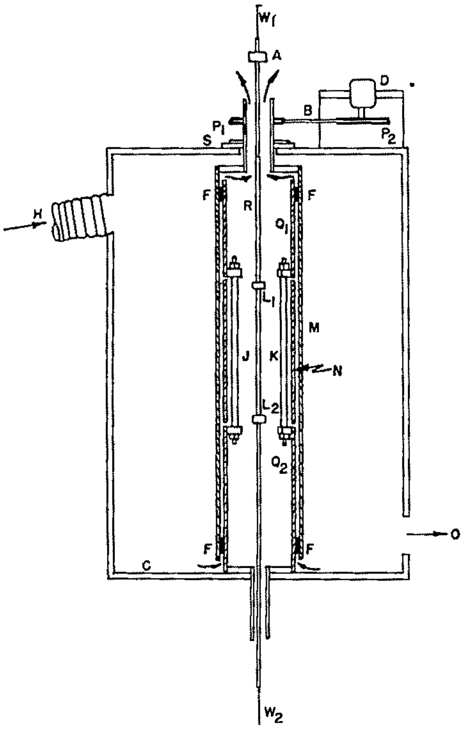

Fig. 1. Vertical section of the viscosimeter and enclosing cabinet. Dust-laden air is blown in at *H* and out at *O*. Some of it also escapes via the route shown by the arrows near *F* and *A*, which carries it through the annulus between the outer driven cylinder *M* and the inner sensing cylinder *N*. *N* is attached by lugs *L* to rod *R*, which is supported and aligned by taut wires W_1 and W_2. The torque transmitted to *N* by the viscous action of the gas in the annulus twists wires *W* through a few degrees, the angle being measured accurately by means of a light beam reflected from mirror *A*. The stationary cylinders Q_1 and Q_2 eliminate end-effects at the top and bottom of cylinder *N*

What is the physical explanation for such a large reduction in the viscosity of a gas when dust is suspended in it? Elementary kinetic gas theory states that the viscosity, η, is given by:

$$\eta = \tfrac{1}{3}\rho\bar{c}\lambda \tag{1}$$

where ρ is the gas density, $\bar{c}$ is the average molecular velocity, and λ is the mean free path. At constant temperature, as in the present experiments, $\bar{c}$ remains constant. The addition of dust can only increase the density, ρ; hence the observed decrease in viscosity is presumably due to a decrease in the mean free path, λ, which in simple kinetic theory is given by:

$$\lambda = \frac{1}{\sqrt{2}\pi N\sigma^2} \tag{2}$$

where N is the (Loschmidt) number of molecules per cubic centimetre and σ is the diameter of the molecules.

If the dust cloud is regarded as a second 'gas' mixed with the true gas in which it is suspended, the expression for λ_g, the mean free path of the gas molecules in the dust-laden gas, becomes[3]:

$$\lambda_g = \frac{1}{\sqrt{2}\pi(N_g\sigma_g^2 + N_d\sigma_d^2\sqrt{1 + m_g/m_d})} \tag{3}$$

where N_d is the number of dust particles per c.c., σ_d is the diameter and m_d the mass of a dust particle (assumed the same for all). The g subscripts designate similar symbols for the gas molecules. m_g is negligible compared to m_d, so the final radical reduces to 1. Also, $N_d\sigma_d^2$ is small compared to $N_g\sigma_g^2$, and unless this circumstance can be changed, equation (3) reduces to equation (2). The only way that $N_d\sigma_d^2$ could be made comparable in magnitude to $N_g\sigma_g^2$ for the dust concentrations used in the present experiments is to assume that σ_d is an 'effective' diameter, which might be appreciably larger than the actual diameter of the dust particles. Since σ_d is squared, an effective diameter equal to, say, 50 times the actual diameter, increases $N_d\sigma_d^2$ by a factor of 2,500, and this is sufficient to make its value comparable to $N_g\sigma_g^2$, thus causing equation (3) to indicate a reduction in λ_g of about 50 per cent, which, from (1), would account for a reduction in the viscosity of about 50 per cent, as observed.

Taking the experimental data and reversing the calculation above, one concludes that if the dust particles were all 1μ in diameter, their 'effective' diameter, σ_d must be about 150μ. This suggests that the explanation of the observed effect may be that each dust particle is surrounded by a 'boundary layer' of gas adhering to it. This is not a new concept; indeed, the derivation of Stokes law for the settling of dust particles in a gas[4] presupposes the existence of such a boundary layer. An expression for the approximate magnitude of its thickness is[5]:

$$\delta = \sqrt{\frac{\eta\sigma}{\rho v}} \tag{4}$$

where v, in the case of a suspended dust particle, would be the difference in the gas velocities on opposite sides of the particle. From the known velocity gradient in the viscosimeter annulus, one may calculate v for the case of a 1μ diameter particle, and thus evaluate δ from equation (4). The result is about

100–500μ, thus agreeing reasonably with the value calculated for σ_d.

Thus, one is left with a picture of the suspended dust particles each surrounded by a gaseous boundary layer thick enough to make its 'effective' diameter some 50 or 100 times as great as its actual diameter. This increases the 'cross-section' of the particles sufficiently to cause the gas molecules to collide with these boundary layers just about as often as they collide with unattached molecules (that is, molecules not making up a boundary layer for some dust particle).

A modification of this picture may also be worth considering. The velocity gradient in the viscosimeter annulus causes a force in one direction on one side of any dust particle suspended therein, and a force in the opposite direction on the opposite side of that same particle. This couple should cause the particle and its boundary layer to rotate somewhat like the balls between the races of a ball bearing. For a typical velocity gradient such as 50 cm./sec. per cm., the rate of rotation of the suspended particles should be roughly 8 or 10 rev. per sec. This 'ball bearing' concept may also help account for the observed reduction of viscosity.

The effect discussed in this article may have some significance in meteorological theories of rainstorms, etc., and may even be worth considering in cosmological theories of the evolution of stars and planets from dust-laden gases. It is also possible that this phenomenon might be applied to develop a practical instrument for measuring dust concentration in industrial smoke-stacks and flues.

BIOCHEMICAL CHANGES ACCOMPANYING IMPAIRED RESPIRATION IN STAPHYLOCOCCI

By PROF. G. F. GAUSE, G. V. KOCHETKOVA and G. B. VLADIMIROVA
Institute of Antibiotics, Academy of Medical Sciences, Moscow

IN a recent discussion of the cancer problem[1], mutants of yeasts with impaired respiration have been compared with cancer cells which also have a respiratory deficiency. In this connexion, mutants of staphylococci with oxidation defects which can be observed in cultures of some strains are of great interest[2,3].

A new method has been developed for the isolation of staphylococci with respiration deficiency from parent cultures, which is based on the selective inhibitory action of some fluorinated pyrimidines (Table 1), recently prepared as a new class of tumour-inhibitory compounds. The growth of staphylococci with impaired respiration (mutant *uv*-3) is approximately sixty times more vulnerable to the inhibitory action of 5-fluorouracil than the growth of the initial parent culture (*S. aureus* 209). In both cultures the inhibitory action is reversed by uracil, but not by thymine. On the other hand, 5-fluoro-2-deoxyuridine inhibits growth of the parent culture of staphylococci much more effectively than 5-fluorouracil, and this inhibition is reversed by thymine but not by uracil.

It therefore appears that 5-fluorouracil and 5-fluoro-2-deoxyuridine are blocking different metabolic pathways in staphylococci. In accordance with present views, 5-fluoro-2-deoxyuridine blocks the formation of thymine which is required for the synthesis of deoxyribonucleic acid[4]. It is very significant that 5-fluoro-2-deoxyuridine does not inhibit the growth of mutants with impaired respiration either in liquid or solid media, even at the maximum concentration tested, namely, 1,000 μgm./ml. This points to the possible synthesis of deoxyribonucleic acid thymine by different pathways in mutant and parent strains. Another possible explanation for this phenomenon is that it may reflect the relative impermeability of the mutant cell to 5-fluoro-2-deoxyuridine, so that the drug does not reach the site of its action.

Table 1. CONCENTRATION OF SOME FLUORINATED PYRIMIDINES REQUIRED TO INHIBIT THE GROWTH OF STAPHYLOCOCCI IN LIQUID BROTH

Compound	Micro-organism	μgm./ml.

The observations given above were used for the development of liquid nutrient medium, selectively inhibiting the growth of parent staphylococci and favourable for the multiplication of mutants with impaired respiration. For this purpose a nutrient broth containing peptone (0·5 per cent), glucose (1 per cent), sodium chloride (0·5 per cent), Hottinguer digest (30 ml./l.), corn steep liquor (0·2 per cent), and 5-fluoro-2-deoxyuridine (100 μgm./ml.) was distributed into test-tubes, and seeded with suspensions of the parent cultures of staphylococci (strains 209, *D*, *G*, and 121). The staphylococci were previously grown on meat-peptone agar for 24 hr. at 37° C., washed using physiological saline solution, diluted to a concentration of 2 × 10^8 cells/ml. and added to the selective medium in the amount 0·10–0·05 ml. per 1 ml. of broth. Parent staphylococci did not grow on this medium due to inhibitory action of 5-fluoro-2-deoxyuridine, but any mutants with impaired respiration which were present in the parent inoculum multiplied. If, after 5–7 days of incubation of such tubes at 37° C., their contents were plated on nutrient agar containing 5-fluoro-2-deoxyuridine (25 μgm./ml.), in some cases pure cultures of mutants were observed instead of the parent culture. These mutants were observed more frequently in the strains *D* and 209; in the strains 121 and *G* they were not recorded. Numerous experiments have shown that the quantity of inoculum added to the selective medium is of great importance. If one adds too many parent cells, these acidify the medium and inhibit the growth of mutants, which require a neutral or slightly alkaline medium for their multiplication. If the parent cells are too few, the probability of occurrence of mutants among them is negligible.

Mutant staphylococci isolated by the new technique show the same changes in respiratory activity which have been previously reported[2,5]. The respiratory coefficient is decreased by 40–60 per cent as compared to parent values, while the respiration is less sensitive to cyanide. The cytochrome pattern is also altered in the new mutants. Whereas normal staphylococci reveal three bands of cytochromes, a_2(630 mμ), a_1(600 mμ), and b_1(557 mμ), in mutants the band a_2 is not visible, either under usual conditions of observation or when liquid nitrogen with the subsequent devitrification is employed. Instead of band b_1, two new bands are observed in mutants, at 563 and 553 mμ, which are easily oxidized and reduced in the presence of succinate. In respect of splitting of b_1 band of cytochromes, the mutants of staphylococci with impaired respiration resemble the respiratory-deficient mutants of *E. coli*[5].

Further investigations have shown that mutants with respiratory deficiency in staphylococci differ from the parent culture in a number of important biochemical characters. It may be suggested that respiratory defects, as well as other hereditary metabolic alterations, can be related to some disturbances in the synthesis of deoxyribonucleic acid in mutant staphylococci.

Pigment. A characteristic feature of staphylococci with defective oxidation is their rose-orange intracellular pigment, which is lacking in cells of the parent culture. Mutants were cultivated on the nutrient agar and extracted by ethanol. The absorption spectra of the ethanolic solutions of pigments so obtained from nine different respiratory-deficient mutants of staphylococci were studied, and found to be very similar. Fig. 1 presents the data for pigment from the mutant No. 16, revealing a maximum optical density at 475 mμ. This observation points to the possibility that respiratory defects in mutant staphylococci are accompanied by some disturbances in the metabolism of flavins.

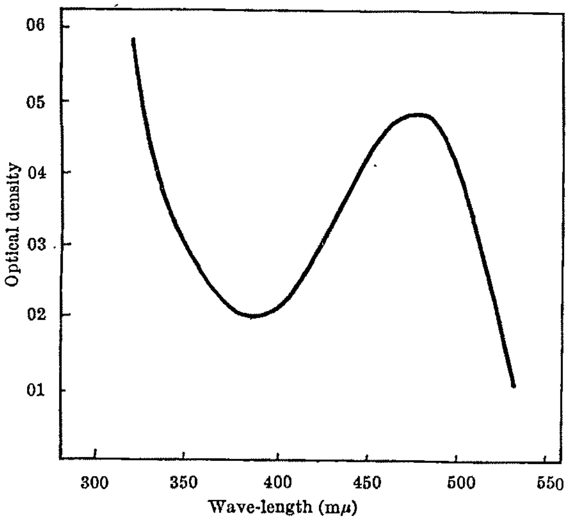

Fig. 1. Absorption spectrum of the intracellular pigment of mutant staphylococci with impaired respiration, strain No. 16

Synthesis of vitamin B_{12}. Theoretical considerations put forward by Woolley[6] suggest that alterations in flavins may affect the biogenesis of vitamin B_{12}. Experimental observations by the same author[7] indicate that respiratory defects and dedifferentiation of cells in some strains of spontaneous tumours of mice are accompanied by the ability of these cells to synthesize vitamin B_{12}.

The content of vitamin B_{12} in the cells of parent staphylococci as well as of a number of respiratory-deficient mutants, which were grown on the liquid medium under identical conditions, was measured with the aid of chromatographic and bioautographic techniques[8,9], using the culture of *E. coli* 113–3. The results of these measurements are presented in Table 2.

Table 2. CONTENTS OF VITAMIN B_{12} IN THE CELLS OF PARENT STAPHYLOCOCCI AS WELL AS IN RESPIRATORY-DEFICIENT MUTANTS

Strain	μgm./gm.	Strain	μgm./gm.
Parent 209	0·3	Mutant 21	18
Mutant 3	18	Mutant 1	26
Mutant 22	20	Mutant 2	17
Mutant 16	28	Mutant 20	23
Mutant 15	18	Mutant 14	16

It can be seen that the content of vitamin B_{12} in the cells of mutants may be increased almost a hundred-fold as compared to parent cells.

Catalase. Suspensions of staphylococci adjusted to 20 mgm./ml. dry weight were disrupted using a Mickle disintegrator at 0° C. and Ballotini glass balls No. 12. The catalase activities of the cell extracts were estimated spectrophotometrically[10]. Table 3 shows that respiratory-defective mutants contain much less catalase activity than the cells of the parent strain.

Table 3. CONTENTS OF CATALASE (IN ARBITRARY UNITS) IN THE CELLS OF PARENT STAPHYLOCOCCI AND IN THE RESPIRATORY-DEFICIENT MUTANTS

Strain	Catalase
Parent 209	4·02
Mutant 2	0·50
Mutant 21	0·56
Mutant 16	0·83

Amino-acid composition of the cell wall. Preliminary experiments carried out in collaboration with Drs. H. Rogers and H. R. Perkins showed a difference in cell wall composition between parent and mutant cells of staphylococci[11]. This observation has been confirmed using the new Park and Hancock[12] procedure, which was found to be very efficient. In hydrolysates of cell wall material of parent staphylococci, in accordance with the published evidence[13], the following components were recorded: alanine, glutamic acid, glycine, glycosamine, muramic acid and lysine. In mutants with impaired respiration (*uv*-2 and *uv*-3) only traces of lysine were recorded while diaminopimelic acid was observed. Since many bacteria possess the capacity to decarboxylate diaminopimelic acid into lysine[14], the substitution of lysine by diaminopimelic acid in the cell wall of respiratory-deficient mutants of staphylococci might indicate the loss by mutants of this specific decarboxylase. In the cell wall material of mutants were recorded also alanine, glutamic acid, glycine, glucosamine, muramic acid and aspartic acid.

Selective inhibition of the growth of mutants. In extension of earlier observations[15], a new series of alkylating agents, antimetabolites of nucleic acids,

Table 4. CONCENTRATIONS OF COMPOUNDS REQUIRED TO INHIBIT THE GROWTH OF PARENT STAPHYLOCOCCI AND RESPIRATORY-DEFICIENT MUTANTS ON NUTRIENT AGAR (μGM./ML.)

Compound	Parents 209	Mutants *uv* 2 and 3
Miracil *D*	500	25

6-Mercaptopurine	> 1,000	30
6-Chloropurine	15,000	1,500
Mitomycin *C*	0·2	0·002
Actinobolin	100	12
Actidione	> 10,000	5,000
Streptomycin	2	10
Chlortetracycline	8	8
Tetracycline	2	2

and antitumour antibiotics was tested in relation to their possible selective inhibition of growth of the respiratory-deficient mutants (Table 4).

It can be seen that antitumour agents (in contrast to the antibiotics streptomycin and tetracyclines) selectively inhibit the growth of mutants with impaired oxidation.

It is interesting to record that the antitumour antibiotic mitomycin C inhibits the growth of mutants a hundred times more effectively than that of parents. The mechanism of action of this inhibitor on bacteria has been related to the selective damage to the synthesis of deoxyribonucleic acid[16].

In view of the fact that respiratory-deficient mutants of staphylococci differ from the parent organisms in a number of biochemical characters, a further analysis of the mechanisms of the selective inhibition of the growth of these mutants by antitumour compounds would be desirable.

Some of the observations reported in this article were started at the time of tenure by one of us (G. F. G.) of the World Health Organization fellowship at the National Institute for Medical Research, London. The senior author is grateful to Sir Charles Harington for hospitality and to Mr. J. W. Lightbown for many helpful discussions.

AN INVESTIGATION OF CLOSELY RELATED GAMMA-MYELOMA PROTEINS AND NORMAL MOUSE GAMMA-GLOBULIN BY PARTIAL ENZYMIC DEGRADATION AND STARCH-GEL ELECTROPHORESIS

By DR. BRIGITTE A. ASKONAS and DR. J. L. FAHEY*
National Institute for Medical Research, London, N.W.7

GAMMA-GLOBULIN as normally found in the serum of mammals is highly heterogeneous in its physico-chemical characteristics. Investigation of its chemical structure is hampered by the difficulty of obtaining γ-globulin fractions consisting of single molecular species. The serum γ-globulin is derived from a large number of cells in many sites throughout the body[1]. The γ-myeloma proteins produced by one of the transplantable plasma cell tumours, by contrast, although very similar to normal γ-globulin in most respects, appear to be limited to a small number of molecular species, probably produced by a single plasma cell clone and may therefore provide a simpler model for structural studies of γ-globulin.

The serum of C_3H mice bearing one of the transplantable plasma cell tumours (*X*5563) contains a high concentration of γ-myeloma protein[2]. By analysis on starch-gel electrophoresis, this γ-myeloma protein was found to consist of five distinct components which are indistinguishable immunologically and had the same molecular size, but varied in electric charge[3]. In an attempt to discover a basis for the difference between these closely related γ-myeloma proteins produced by a single plasma cell tumour and possibly to throw light on the complexity of normal γ-globulin, we had recourse to partial degradation of the proteins with papain and cysteine. Such treatment has been shown by Porter[4] to split rabbit antibody into fragments with sedimentation constants of 3·5 and molecular weights of 50,000–70,000.

Purification of proteins and papain treatment. Normal γ-globulin was prepared from concentrated C_3H mouse serum by zone electrophoresis on blocks of 'Geon 425' (British Geon, Ltd.) by the method described in ref. 5. This preparation contained γ-globulin, migrating more slowly than β-globulin[6]. The 5563 myeloma proteins were prepared from serum of tumour-bearing mice by chromatography on columns of DEAE cellulose[7] using a slow elution gradient from 0·015 *M* to 0·05 *M* potassium phosphate buffer, *p*H 6·5 (ref. 6). Since the components of the myeloma proteins vary by only small differences in charge, only partial separation of the globulin molecules can be achieved and fractions of mainly one component contained also small amounts of adjacent components.

The characteristics of the purified proteins on starch-gel electrophoresis are seen in Fig. 1. The striking spread of the normal γ-globulins over a wide area is an indication of their heterogeneity whereas the γ-myeloma proteins form well-defined bands varying in mobility. Fig. 1 shows the myeloma protein components (*a*–*e*) in serum from a mouse

---

* Present address: National Cancer Institute, Bethesda, Maryland.

Fig. 2. Immunoelectrophoretic analysis of papain-treated proteins. The antiserum used was a mixture of antiserum to normal mouse γ-globulin and the 5563 γ-myeloma protein. The proteins had been treated with papain and cysteine by the method of Porter (ref. 4)

bearing the 5563 tumour and the purified myeloma protein components $c + d$ and $a +$ some b. The myeloma proteins and γ-globulin sedimented at the same rate ($S_{20,w} = 6{\cdot}5$) in the ultracentrifuge.

The purified proteins were treated with papain and cysteine as described by Porter[4], except that incubation with the enzyme at 37° was continued for 1 hr. only. The reaction went to completion in this time with more than 85 per cent, of the protein recovered on weight basis, whereas longer periods of incubation resulted in losses of the split 5563 globulin. Analysis by ultracentrifugation was kindly carried out by Dr. P. Charlwood and showed that, as in the case of rabbit antibody[4], mouse γ-globulin and myeloma proteins were split into smaller molecules of S_{20} around 3·6.

Characterization of fragments in papain digests of purified proteins. The papain digests of normal γ-globulin and 5563 myeloma proteins were examined by immunoelectrophoresis against a mixed rabbit antiserum to normal γ-globulin and 5563 myeloma protein (Fig. 2). Treatment with papain and cysteine results in two types of fragments with distinct antigenic characteristics. Each digest gives two antigen–antibody precipitation arcs which cross. Similar results have been obtained with human γ-globulin (Edelman *et al.*[8]) and, for simplicity, these authors' nomenclature will be followed for the mouse globulin. The slowly migrating fragments (which move towards the cathode from the point of application) and the fast migrating fragments (which move towards the anode) have *S*- and *F*-antigenic grouping respectively. The observation that the precipitin arcs cross without interaction is taken to indicate that the *S* and *F* fragments have different structures and do not share any antigenic groupings.

Analysis by starch-gel electrophoresis revealed marked physicochemical heterogeneity of globulin fragments in the papain digests of these proteins (Fig. 1). The multiple well-defined protein bands, seen in the papain digests of the myeloma protein, are again in sharp contrast to the diffuse heterogeneity of the papain digest of normal γ-globulin. It also can be noted that the different myeloma protein components ($a(+\,b)$, $c + d$) yield fragments, some of which are identical and some of which differ qualitatively or are present in different quantities.

The papain digests were fractionated by chromatography on DEAE cellulose using gradient elution with potassium phosphate buffers of *p*H 8 (Fig. 3). Four protein peaks were obtained. These were concentrated by ultrafiltration and analysed by starch-gel electrophoresis and by gel diffusion in an Ouchterlony plate against antiserum to 5563 myeloma protein. As a result it was possible to classify the chromatographic protein fractions and the many physicochemically different fragments seen on starch-gel electrophoresis into two major groups (*S* and *F*) on the basis of their antigenic characteristics. Peaks S_1, S_2, S_3 (see chromatographic elution pattern, Fig. 3) were found to have the same antigenic groupings, giving reactions of identity when tested in a gel diffusion plate with antiserum to 5563 myeloma protein and normal mouse γ-globulin. This is shown for S_2 and S_3 in Fig. 4. The chromatographic peak *F*, however, had distinct antigenic grouping. Its antibody–antigen precipitation line crossed that of the S_3 fragment on an Ouchterlony diffusion plate (Fig. 4). Starch-gel electrophoresis revealed that chromatographic peaks S_1, S_2 and S_3 contained

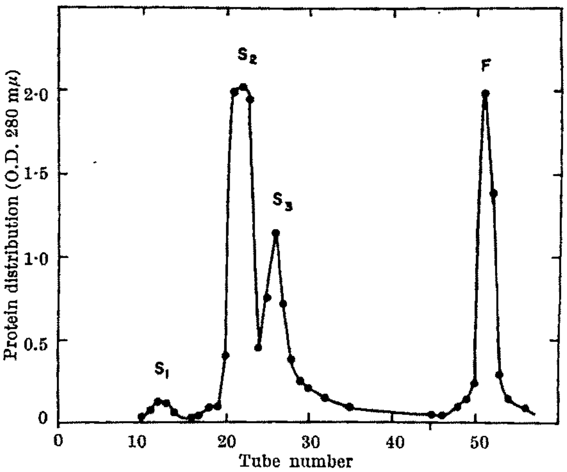

Fig. 3. Chromatography of papain digest of 5563 myeloma protein. Chromatography was carried out on columns of DEAE ion-exchange cellulose (ref. 7), using gradient elution with potassium phosphate buffer *p*H 8 as indicated on the graph. 3-ml. fractions were collected

Table 1. Sedimentation Constants

	S_{20} Whole protein	S_{20} Papain digest
Normal γ-globulin	6·5	3·86
5563 Myeloma protein (components *a–d*)	6·6	3·62
Papain digest 5563 myeloma protein		
S_2		3·73
S_3		3·71
F_5–F_8		3·51

The sedimentation constants were kindly determined by Dr. P. Charlwood on samples extensively dialysed against saline-phosphate buffer, *p*H 7·4 at concentrations of 0·3–0·6 per cent (w/v).

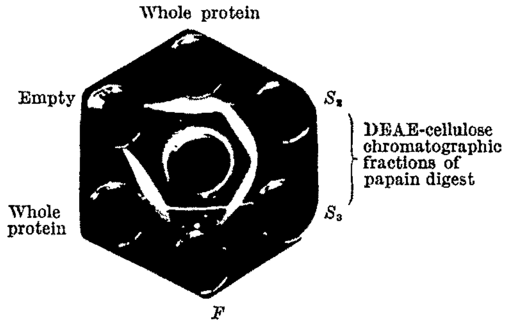

Fig. 4. Antigenic comparison of papain fragments of 5563 myeloma protein by agar diffusion. Centre cup, rabbit antiserum against 5563 myeloma protein; antigen was present at a concentration of 0·2 mgm. protein/ml. Whole protein refers to 5563 myeloma protein purified by DEAE exchange cellulose (ref. 3). Fractions S_2, S_3 + F were prepared from 5563 myeloma protein treated with papain and cysteine by chromatography or DEAE (Fig. 3)

starch-gel bands S_1, S_2 and S_3, respectively. Peak F, however, consisted of a number of fragments in the F_5–F_8 positions on starch-gel electrophoresis. Table I shows that the fragments S_2, S_3 and F had very similar sedimentation constants in the ultracentrifuge (S_{20} = 3·5–3·7).

Comparison of different 5563 *myeloma proteins*. It was mentioned earlier that plasma cell tumour 5563 secretes γ-myeloma proteins consisting of five components (*a–e*) which have slightly different mobilities on starch-gel electrophoresis. The difference in electrical charge between 5563 myeloma molecules *a* and *d* must be at least 3 single or multiple charge units in view of the regularity in increase of mobility. The separated components on treatment with papain and cysteine break down to fragments giving different patterns on starch-gel electrophoresis (Fig. 1). For purposes of discussion only fragments composing more than 5 per cent of the total protein will be considered. Papain digest of 5563 myeloma protein *a* (+ *b*) will be considered first. The starch-gel pattern shows a strong band in position S_2—there is a weak band migrating more slowly than S_3 which is due to contamination of the original myeloma protein with β-globulin. There are four bands, F_4–F_8, with F-antigenic grouping which migrate faster than the S bands. An approximate estimate of the quantity of different fragments may be obtained by making the starch-gel transparent and staining in glycerol by the method in ref. 9. The colour intensity of the bands is measured by a recording microdensitometer. This method tends to under-estimate the relative amount of fragment S_2 present in high concentration and over-estimate the minor components (F_4–F_8). Similar estimates were made by calculating recovery of different protein fragments from the chromatographic elution patterns (Fig. 3). The combined estimations are seen in Table 2. Both methods are very approximate, but indicate that fragment S_2 represents about two-thirds of original globulin molecule and fragments F_5–F_8 one-third. Myeloma protein *a*(+*b*), on treatment with papain and cysteine, thus splits into a single fragment (S_2) with S-antigenic grouping (two-thirds of total protein) and a number (four) of fragments with F-antigenic grouping representing roughly one-third of the original protein.

The papain digest of myeloma proteins *c* + *d* shows a slightly different pattern on starch-gel electrophoresis (Fig. 1) and yields two fragments with S-antigenic grouping, one in the same position as S_2 and a fragment with greater mobility, S_3. In addition, four or five fragments with F-antigenic grouping can be observed. They are present in different quantities from those in the papain digest of myeloma protein *a*(+ *b*). A quantitative estimate of the relative amounts of papain fragments shows that we have about 36 per cent of S_2 and 20 per cent of S_3. Fragment S_2 and fragment S_3 with S-antigenic grouping represent about two-thirds of the original myeloma protein, whereas the F-fragments (F_5–F_8) represent about one-third (Table 2). Table 2 also shows the relative distribution of fragments when myeloma proteins *b* + *c* with intermediary electrophoretic mobilities are treated with papain and cysteine. In this case 15 per cent of fragment S_3 is formed. The ratio S_2/S_3 thus decreases, when myeloma proteins *a*,*b* + *c*, and *c* + *d* are broken down, but the yield of total fragments with S-antigenic groupings stays constant and represents roughly two-thirds of the original protein (65–72 per cent by our estimations). Once more the relative amount of total fragments with F-antigenic grouping stays constant representing 28–35 per cent and being about one-third of the original protein molecule. The relative concentrations of F-fragments with different mobilities vary—when the faster migrating myeloma proteins are degraded higher concentrations of faster migrating F-fragments appear. The mobility of the original myeloma proteins thus appears to depend on variation in electric charge in both the fragments with S- and F-antigenic groupings.

In general these results agree with the results obtained by Porter[4], which suggested that rabbit antibody globulin split into three fragments roughly one-third the size of the original molecule. The 5563 myeloma protein, on treatment with papain and cysteine, appears also to split into thirds, two fragments with S-antigenic grouping and one fragment with F-antigenic grouping. The slowest migrating myeloma protein yields a single S-fragment (S_2) two-thirds of the original protein, but a number

Table 2. Estimate of Relative Amounts of Protein Fragments resulting from Papain and Cysteine Treatment of 5563 Myeloma Proteins

Myeloma proteins treated with cysteine and papain	*a* (+*b*)	*b*+*c*	*c*+*d*
Papain digest fragments	Per cent of total protein		
S_2*	52·5	46·5	33·5
S_3*	5·6	19·5	22
F_5*	21	14·6	7·3
F_6*	10·4	13	13·6
F_7*	7·3	3	14·2
F_8*	2·7	3	9·5
S_2†	67	55	36
S_3†	5	15	29
Total S†	72	70	65
Total F†	28	30	35
Ratio total S/F†	2·5	2·3	1·9
Ratio S_2/S_3†	13·4	3·6	1·2

* Values are approximate and based on measurement of colour intensity of stained protein bands after electrophoresis on a starch-gel block stained in glycerol (ref. 9). This method is known to under-estimate the components present in high concentration compared with those present in smaller amounts.

† Values based on protein elution pattern resulting from chromatography of papain digests on DEAE cellulose (Fig. 3). This method is quantitatively more reliable, but does not distinguish the different F-components.

of *F*-fragments (varying in mobility on starch-gel electrophoresis). Myeloma proteins with increasing electrophoretic mobility yield S_2 and increasing amounts of fragment S_3, which migrates faster than S_2, but the total amount of $S_2 + S_3$ remains constant. A quantitative variation in the *F*-fragments is also observed when myeloma proteins with increasing mobility are degraded. A single difference between S_2 and S_3 could not account for five original myeloma components, and it is therefore likely that there are also variations in the *F*-portion of the molecule. It remains to be seen whether the multiplicity of the *F*-fragments resulting from myeloma protein $a(+b)$ are a consequence of progressive enzymic digestion of a single *F*-fragment or whether a single myeloma protein band can contain different molecular fragments with *F*-antigenic grouping to start with. The gradual loss of fragments with *F*-antigenic grouping, if incubation with cysteine and papain is continued for more than 1 hr., may support the first possibility. This point and the difference between S_2 and S_3 are being investigated further.

We are indebted to Dr. P. Charlwood for determinations of sedimentation coefficients by ultracentrifugation, to Dr. M. Potter for sending us the 5563 plasma cell tumour line, and to Dr. R. R. Porter and Dr. J. W. Goodman for a gift of papain. We should like to thank Dr. R. R. Porter and Dr. J. H. Humphrey for helpful discussions, and Mrs. Marion Perryman for her assistance.

RESPIRATORY EFFECTS OF PHOSPHORYLATION

By Prof. H. LUNDEGÅRDH
Penningby, Sweden

OXIDATIVE phosphorylation is the main mechanism for transfer of energy from the respiratory system by converting adenosine diphosphate (ADP) to adenosine triphosphate (ATP)[1,15]. The reaction

$$\mathrm{ADP} + \mathrm{PO_4} + \text{energy} \rightleftharpoons \mathrm{ATP} \qquad (1)$$

is controlled by a number of enzymes, enabling ATP to transfer energy to many synthetic processes in the protoplasm. In oxidative phosphorylation the supply of energy on the left side of equation (1) is delivered by the stream of electrons moving from an enzyme of lower oxidation potential to an enzyme of higher potential (the difference is 0·17 V. for a two-electron process). ATP and similar compounds are thus serving as the main energy-distributing system, the inhibition of which leads to rapid degradation of the living structure.

The mechanism of oxidative phosphorylation is still incompletely known. It has been claimed that the energy from a flow of electrons between a donor (*B*) and an acceptor (*A*) may be transferred to ATP over an intermediate reaction[2-4,15]. Phosphate may, at a low expense of energy, be combined with one of the enzymes, for example, as $B - \mathrm{PO_4}$, and then, on oxidation by *A*, be transferred to the high-energy state of ATP. Another possibility is phosphorylation by means of an intermediate substance, for example, a quinone[2]. It is postulated in both cases that the electrons are transferred from *B* to *A* through intermediate reactions. Even if other more direct pathways of transfer between *A* and *B* exist, phosphorylation would consequently serve as an accelerator of the stream of electrons through the respiratory system. This suggests the possibility of observing the effect of phosphorylation and the possible sites of this process by measuring the apparent reaction velocities of the enzymes involved.

A suitable technique has been developed on the basis of new spectrophotometric methods for accurate measurement of the time-course of reduction and reoxidation of all respiratory enzymes[7,10,11]. These methods may be applied to live intact tissues or cell suspensions. Owing to the inevitable partial invalidation of the respiratory unit, particulate fractions of homogenates are less suitable for these studies. The present article deals with oxidative phosphorylation in bakers' yeast. The experimental technique was based on the reversibility of the steady-state reaction (1). It was shown[8] that, in wheat-roots, supply of inorganic phosphate promotes an increasing reduction of the cytochromes, whereas the level of oxidation is raised by addition of ATP (ref. 8). These results were interpreted in terms of a displacement of the steady-state equation (1) by an increase or a decrease of concentration of the reactants. Nucleotides penetrate the protoplasm easily. Application of ADP + phosphate or of ATP to a yeast suspension affects the course of electron transfer in less than 3 min.

The experiments were conducted as follows: Bakers' yeast (from Svenska Jästfabriks AB) is thoroughly washed and 16 ml. of a 5–10 per cent suspension is introduced into a quartz circulation vessel[9,11]. The recipient is placed immediately in front of an *EMI* quartz photomultiplier tube 6256 connected to a Philips oscilloscope *GM* 5666. By means of a special electromechanical device[11], which moves the wave-length screw of a Bausch and Lomb grating monochromator rapidly between two end-intervals[11,12], a suitable portion of the spectrum is recorded in a Zeiss Frequentophot camera. The bands of cytochromes *c* (550 mμ) and *b* (562 mμ) are directly visible on the record[12]. Other band-peaks (diphosphopyridine nucleotide (DPNH) 340, flavoprotein (FP) 465, cytochromes a_3 444 and 598, c_1 554, and *a* 604 mμ) are caught by means of a mechanical device which interrupts the oscillographic image at these wave-lengths[11].

Precise measurements of band-heights postulate intimate knowledge of spectral coincidences and of the spectra of purified enzymes[9,11,12]. The time-course of the reduction of the enzymes at stopped aeration (or shifting over to nitrogen) and the reoxidation in air (or oxygen) may be varied, owing to the degree of exhaustion of respiratory substrates in the washed yeast, and the level of temperature, etc. Reduction of the respiratory enzymes is completed in a few seconds at 18° C., but reoxidation may sometimes take only 1–2 sec. Experience has shown that a speed of 4 spectrograms per sec. in all circumstances secures a reliable calculation of the half-times (ht = 50 per cent reaction) of reduction and reoxidation. The apparent velocity is calculated as c/ht (c = reacting portion of the enzyme).

A new technique was introduced for measuring the intensity of respiration during the single experiments. It was shown in this laboratory that the time-lag between turning off the air stream and the start of reduction of the cytochromes $c - a_3$ is inversely proportional to the velocity of respiration, provided that the periods of aeration are held constant. This demand is fulfilled by the introduction of a timer which, by means of electromagnetic valves, regulates the intervals of aeration (15 sec.) and stopped air-flow (mostly 75 sec.). Processes which are not directly linked to the respiratory chain are eliminated by the intermittent aeration.

At the start of the single experiments the apparent velocities of reduction and reoxidation in distilled water were recorded. Immediately following the start, the test substance was added to the recipient. The response was automatically recorded in 4, 6, 10, 16 min.

Results

Addition of ADP, with or without phosphate (the latter is always present in yeast cells), results in an increase of the respiration (Fig. 1), the maximum of which is attained in 3–4 min. As shown in Table 1, the respiratory effect is caused by an acceleration of the stream of electrons, namely, an increased velocity of reduction of the group $a_3 - c$ and of DPN. This increased reduction conveys a corresponding retardation of the reoxidation, because the off-reaction of cytochrome oxidase, namely, the transition $a_3 \xrightarrow{e} O_2$ remains approximately unaffected. Measurements show this to be the case (cf. Figs. 1, 2). As a consequence of the increased internal supply of electrons at constant velocity of the transference $a_3 \xrightarrow{e} O_2$, the cytochromes c and a_3, and flavoprotein are 20–40 per cent more reduced in the aerobic state whereas cytochrome b and DPN remain more unaffected. The balance between oxidized and reduced enzyme is determined by the relation k_1/k_2 in the sequence:

$$\xrightarrow[k_1]{e} \text{enzyme} \xrightarrow[k_2]{e}$$

on-reaction off-reaction

k_1 and k_2 represent the velocities of the on- and off-reactions.

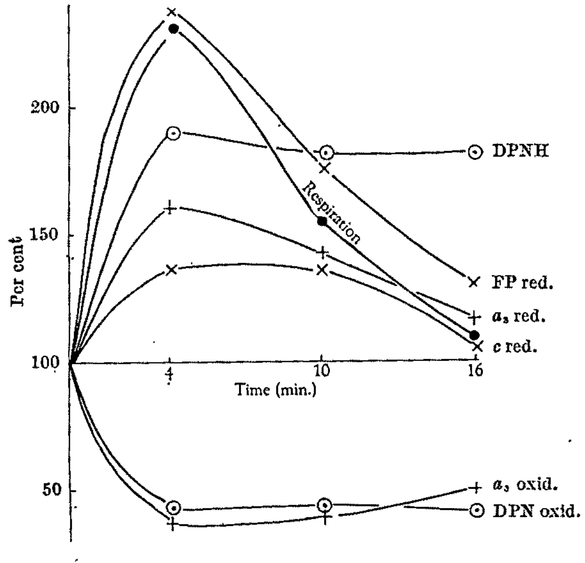

Fig. 1. Response of respiration and apparent velocities ($1/ht$) of reduction and reoxidation on addition of 0·01 M ADP + phosphate to a yeast suspension

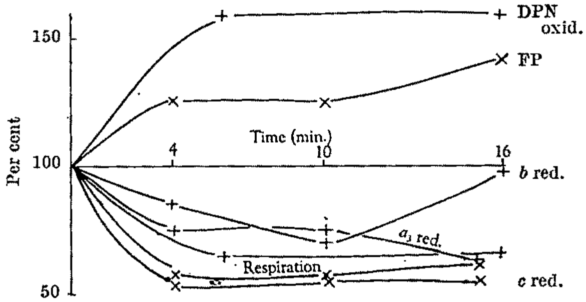

Fig. 2. Response of respiration and apparent velocities ($1/ht$) of reduction and reoxidation on addition of 0·01 M ATP to a yeast suspension

The fact that the step $a_3 \xrightarrow{e} O_2$ does not respond to ADP leads to the conclusion that this step is not involved in phosphorylation. The only known case of an actual acceleration of the stream of electrons from cytochrome oxidase to oxygen is the salt effect, the nature of which has been discussed elsewhere[10,13,14]. Another important difference between the effects of ADP and salts is the response of cytochrome b. In contrast to the uniform response of the total chain of enzymes to salts, glucose and alcohol, ADP reveals a segregation inasmuch as the reduction of cytochrome b is not accelerated.

This individual behaviour of cytochrome b does not mean, however, that it is bypassed by the electrons. An intensification of the stream of electrons between b and $c - a_3$ creates a 'vacuum' at b, appearing as a relatively retarded reduction. The observed facts are leading to the conclusion that the transition $b \xrightarrow{e} c$ is one of the main sites of oxidative phosphorylation. Cytochromes c and a_3 are, as previously shown[12], closely linked together kinetically and the observed identical response of these two enzymes (Table 1) leaves little room for intermediate reactions.

The response of flavoprotein to variations in the ADP/ATP balance is not identical with that of

Table 1. Change of the Relative Velocity of Reduction (at Stopped Aeration) 3–6 min. after Addition of 100 mgm. ADP of ATP (Disodium Salt), corresponding to Concentration of 0·01 mole/l. ht = time of 50 per cent Reaction (sec.)

	Cyt. a_3	Cyt. c	Cyt. b	Flavoprotein	DPN
$1/ht$ in water	0·36	0·38	0·22	0·23	0·06
Response on ADP	0·61 (+ 68 per cent)	0·60 (+ 57 per cent)	0·13 (− 42 per cent)	0·29 (+ 26 per cent)	0·13 (+ 84 per cent)
Response on ATP	0·23 (− 37 per cent)	0·27 (− 30 per cent)	0·20 (− 9 per cent)	0·13 (− 42 per cent)	0·04 (− 31 per cent)

Similar values are obtained 10–12 min. after addition of the reagents.

cytochrome b. It was shown earlier that flavoprotein sometimes acts simultaneously with cytochrome b and that one fraction of it may be linked structurally to the latter[12]. The total flavoprotein is, on the other hand, distributed over at least two enzyme systems, of which one is identical with succinodehydrogenase. This fact may explain the rather varying response of flavoprotein in the present experiments. The results are, however, not opposed to a possible site of phosphorylation near flavoprotein (for the effect of succinate oxidation on phosphorylation see ref. 16).

DPN is known to participate in a large number of enzyme reactions. Table 1 shows a strong acceleration of the step substrate $\xrightarrow{e}$ DPN under the influence of ADP and a corresponding retardation by ATP; these facts illustrate the well-known role of substrate oxidation by DPN in oxidative phosphorylation.

The theoretically expected reversal effect of ATP, as compared with ADP, is illustrated by the steady-state equation (1) (Table 1 and Fig. 2). Addition of ATP retards the transport of electrons from substrates to DPN and from cytochrome b to c. Consequently, the aerobic respiration declines. Values of only 50 per cent of that in distilled water were observed (Fig. 2). The steady-state oxidation – reduction of respiratory enzymes in aerated yeast, treated with ATP, shows an increasing oxidation, primarily, of DPN and the cytochromes b and a_3.

2,4-dinitrophenol (DNP) inhibits phosphorylation, but it acts, nevertheless, similarly to ADP. It accelerates the electron transfer from cytochrome b to the group $c - a_3$ (Table 2 and Fig. 3). This fact indicates a competitive effect of DNP, namely, this substance is obviously capable of transferring electrons between b and $c - a_3$, as a consequence of which the respiration may be raised above the level held in distilled water.

It is interesting to note that the 'vacuum' at cytochrome b is observed also with DNP, a fact emphasizing the probable competitive interaction of this substance in the phosphorylation mechanism. Attention is here again directed to the fundamentally different effect of salts.

Table 2. Effect of 1·3 × 10^{-5} *M* 2,4-Dinitrophenol (DNP) and further addition of 1·3 × 10^{-2} *M* Potassium Chloride (DNP + Potassium Chloride) on Respiration and Kinetics of Enzyme Reactions

A. Reduction at stopped aeration

Medium	Respiration (relative)	Apparent velocities (1/*ht* sec.)		
		a_3	c	b
Water	100	0·36	0·38	0·22
DNP 10 min.	125 (+ 25 per cent)	0·45 (+ 25 per cent)	0·51 (+ 34 per cent)	0·28 (+ 27 per cent)
DNP + potassium chloride 10 min.	167 (+ 67 per cent)	0·63 (+ 75 per cent)	0·57 (+ 50 per cent)	0·39 (+ 77 per cent)

Water	0·63	1·00	1·00
DNP 10 min.	0·78 (+ 23 per cent)	1·07 (+ 7 per cent)	0·85 (– 15 per cent)
DNP + potassium chloride 10 min.	1·30 (+106 per cent)	1·26 (+ 26 per cent)	1·55 (+ 55 per cent)

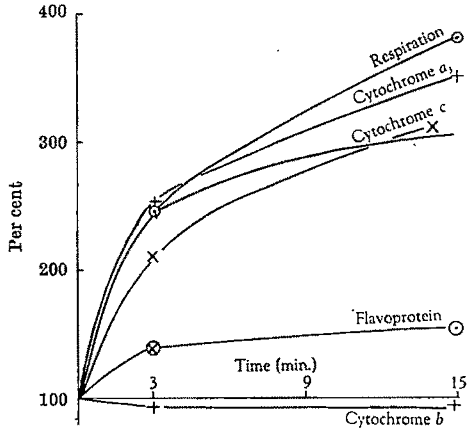

Fig. 3. Response of respiration and apparent velocities of reduction (1/*ht*) on addition of 1·3 × 10^{-5} *M* 2,4-dinitrophenol

Salts are obviously promoting an unspecific electron transference through the respiratory chain, primarily by facilitating the passage of electrons from a_3 to oxygen. Table 2 illustrates the important fact that the salt effect may be superimposed on the DPN effect, resulting in an over-powered electron transfer, which is suggested by a further rise of the respiration.

The unspecific stimulation by salts (electrolytes) produces no vacuum at cytochrome b (Table 3). Salts obviously stimulate both the more direct transfer of electrons and, by indirect stimulation, of $a_3 \xrightarrow{e} O_2$, also the oxidative phosphorylation. This was concluded in previous investigations on the mechanism of absorption and accumulation of salts[10].

Table 3. Effect of Inorganic Phosphate as compared with ADP + Phosphate on the Apparent Velocities of Reduction
Values in percentage of those observed with water (cf. Tables 1 and 2)

Medium	a_3 (per cent)	c (per cent)	b (per cent)	Flavoprotein (per cent)

0·01 *M* ADP + phosphate	+ 68	+ 57	– 42	+ 26

Discussion

The results are in agreement with other work[2-4,15] on phosphorylation by means of intermediate reactions between two respiratory enzymes. Because these reactions are transferring electrons, oxidative phosphorylation acts similarly to a lowering of the internal resistance to the stream of electrons flowing through the system. The organized respiratory unit is envisaged here as a semiconductor, in which electrons are forwarded by means of exchange reactions between atoms and groups of atoms. Reversal of the concentration gradient ADP + phosphate > ATP acts similarly to an increase of the internal resistance, because the intermediate reactions are slowed down according to the law of mass action.

It has sometimes been claimed that two respiratory enzymes which are co-operating in oxidative phosphorylation do not react directly with one another[4]. This idea is at variance with the present experiments.

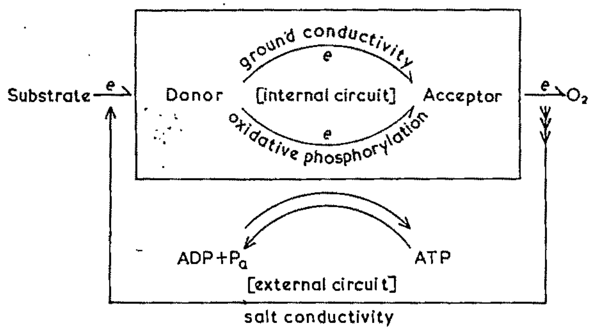

Fig. 4. Scheme of the inner and outer electric circuits in which the flow of electrons is in part controlled by the intensity of oxidative phosphorylation, namely, the activity relations of ADP and ATP, and by the activity of salts in the area surrounding the respiratory unit

My results point to the existence of other eventually more direct pathways, also, which, however, are insufficient for the maintenance of a maximum rate of respiration. There is, of course, a possibility that energy-saving mechanisms other than phosphorylation are co-operating in this 'ground conductivity' of the space between two respiratory enzymes.

The kinetic characteristics of the respiratory unit suggest the conclusion that the enzymes are organized as multimolecular sub-units which, owing to the structurally guided electron transference, are reacting at special points ('reaction centres') or surfaces[12]. This means that the electrons may be sluiced between two enzymes via intermediate processes ('factors') which are mediating the contact. When the supply of oxygen is stopped, the cytochromes c and a_3 start reduction (Table 1). The reduction of cytochrome b starts only after cytochrome c is almost reduced.

It was assumed that the multimolecular sub-unit $c - a_3$ is attached to cytochrome b at only one point or surface and that this area of contact remains oxidized until the $c - a_3$ complex is nearly saturated by electrons[12]. Switching on oxidative phosphorylation accelerates the process. My results convey the conclusion that the transference $b \overset{e}{\rightarrow} c$ is one of the main sites of oxidative phosphorylation, whereas the step $a_3 \overset{e}{\rightarrow} O_2$ does not participate directly.

The characteristic qualities of oxidative phosphorylation and of salts (electrolytes) in promoting the electron transfer through the respiratory system are shown in Fig. 4. Unlike DNP, which to some extent can substitute ADP in the intermediate electron transfer, salts do not compete with phosphorylation. Salts, on the contrary, act indirectly as powerful promoters of phosphorylation, mainly because the step $a_3 \overset{e}{\rightarrow} O_2$, which responds promptly to an total flow of electrons through the system.

The respiratory unit operates similarly to an electric generator[13], built on the basis of semiconductivity. An internal stream of electrons flows from the substrate to oxygen. The overall intensity (electronic density) of the stream is controlled by the electric conductivity of the outer circuit, namely, primarily the concentration (activity) of easily movable salt anions in the surroundings of the system. Salts accelerate non-specifically all internal pathways of electrons, hence the total aerobic respiration. The readiness of the substrate to deliver electrons is, of course, a fundamental regulator of respiration too, but it does not, unlike salts, affect the end-oxidation, namely, the velocity of the step $a_3 \overset{e}{\rightarrow} O_2$.

Salts thus regulate the external resistance to aerobic respiration, and oxidative phosphorylation implies an important regulator of the internal resistance. According to the scheme in Fig. 4, salts also accelerate the electrons which enter the respiratory system from the substrate side. Whereas yeast and animal cells are characterized by only one main exit of electrons, namely, at cytochrome a_3, there are at least two points of admission, but facts as to the biochemical pathways are here still incomplete. We know that the respiratory enzymes are more or less intimately bound to the cell structure, a_3 and b, very firmly, and c and flavoprotein somewhat more loosely. DPN is one of the most versatile co-enzymes. It is possibly synthesized in the nucleus[6] and moves around freely. My results on the acceleration of electrons from the substrate to DPN by ADP + phosphate illustrate the well-known fact that sites of phosphorylation are located between DPN and the substrates.

The investigation has been supported by the Swedish Research Councils of Natural Science and Agriculture.

COLICINE FACTORS AS FERTILITY FACTORS IN BACTERIA

Salmonella typhimurium strain *LT2*

SALMONELLA TYPHIMURIUM strain *LT*2 does not form and is not killed by colicines *E*1, *E*2, *I* or *K*[1,2]. However, it can be made colicinogenic for any of these colicines by growth in mixed culture with an appropriate colicinogenic strain of Enterobacter, presumably as a result of the transfer of a genetic element (colicine factor) controlling the production of a particular colicine. Colicine factor *I* (determining production of colicine *I*), when introduced into *S. typhimurium*, strain *LT*2, can be transmitted by cell contact to other sub-lines of strain *LT*2; and it also potentiates the transmission of colicine factors *E*1, *E*2 and *K* which, in *S. typhimur-*

ium, are not otherwise transmissible by cell contact (or, in the case of factor *E*1, only at a very low frequency). We report here that in *S. typhimurium*, strain *LT*2, factor *I* also makes possible recombination of chromosomal characters following cell conjugation, although the frequency is very low (10^{-6}–10^{-8}) compared with the frequency of transfer of colicinogeny (10^{-1}).

In a broth culture of an *LT*2 sub-line which has carried factor *I* for some time, only a small fraction (1/6,000) of the cells can transmit colicinogeny by cell contact[1]. However, Stocker and Smith[3] found that just after acquiring factor *I*, most cells transmit not only this factor but also any other factors the cell may possess. The increased ability to transmit persists for only 3–7 generations. In recombination experiments, therefore, the bacteria of the parent strain intended as 'donor' of colicinogeny had to be newly infected with factor *I* by growing them with cells possessing this factor. For example, when the donor strain was to be *cys D*–36 (an auxotrophic sub-line of strain *LT*2 requiring cysteine), it was infected with factor *I* by inoculating broth with about 10^6 cells/ml. of *cys D*-36 and about 5×10^4 cells/ml. of *cys D*-36 (*I*), that is, the same strain already carrying factor *I*. After overnight incubation at 37° C., the mixture was diluted 1/10 in fresh broth and incubated for 2 hr. at 37° C.; during this period, about 40 per cent of *cys D*-36 cells newly acquired factor *I* and, consequently, were all able to transmit it.

This 'donor mixture' was then incubated for 1 hr. at 37° C. with an equal number of acceptor cells (for example, *ath C*-5, a sub-line of strain *LT*2 requiring adenine + thiamine) and washed samples plated on unsupplemented glucose–ammonium sulphate medium to detect prototrophic (*cys* D^+ *ath* C^+) recombinants. About one prototrophic colony was formed for 10^8 cells plated, whereas control platings (*cys D*-36 alone; *ath C*-5 alone; and mixture of non-colicinogenic *cys D*-36 and *ath C*–5) gave either no colonies, or a significantly smaller number attributable to reversion. If the *cys D*-36 component of the donor mixture was replaced by the same strain carrying colicine factor *E*1 (*cys D*-36(*E*1)), the yield of recombinants was increased about one hundred-fold. The presence of factor *E*1 in the acceptor strain, however, has little or no effect on the yield of recombinants. Also, factor *E*1 did not permit recombination in the absence of factor *I*. Thus, the presence of factor *E*1 in the donor strain increases the rate of recombination when factor *I* is being transmitted, but does not by itself permit recombination.

The *cys D*-36 (*I*) minority component of the donor mixture, used to introduce factor *I* into the majority component *cys D*-36 (or *cys D*-36 (*E*1)), could be replaced by strain *ath C*-5 (*I*) without reduction of the yield of recombinants. This and other experiments showed that the *ath* C^+ genes of the recombinants came from the strain of the donor mixture initially lacking factor *I*; presumably from bacteria which had just acquired this factor.

Recombinants were obtained, at about the same frequencies, from crosses involving acceptor strains carrying many different contra-selective markers (*ade A*, *B* and *C*; *ath C* and *E*; *ara*; *cys A*, *B*, *C* and *D*; *gly; his; isol; leu; pro; thr; try A* and *D*; *str-s*). In fact, positive results were obtained for all loci tested. Pairs of genes which can be simultaneously transduced by phage *PLT*22, for example, *try D* and *cys B*, remain coupled more frequently than they do during phage-mediated transduction.

Differing donor alleles occupying two or more loci which cannot be simultaneously transduced by phage *PLT*22 are found together in recombinants formed during transfer of colicine factors too frequently for them to have been transferred separately to the same donor cell in different mating events. For example, either *ara* or *isol* occurs separately at a frequency of 10^{-7}, while together, they occur at 10^{-8}. This suggests that long portions of the bacterial chromosome can recombine; perhaps, at least in some cell-pairs, the entire chromosomes of the two pairing bacteria.

Colicine factor *I* was introduced into our sub-lines of *S. typhimurium*, strain *LT*2, by growth with *Shigella sonnei*, strain *P*9, and factor *E*1 by contact with *Escherichia coli*, strain *K*12–30 (both strains were kindly supplied by Prof. P. Fredericq, of Liège). Furness and Rowley[4] found that most wild strains of *E. coli* which produced colicine *I* carried *F* (fertility) factors which, however, could be separated from their colicine factors. We considered the possibility that our colicinogenic *S. typhimurium* strains could recombine because they had acquired *F* factors at the same time as colicine factors; but our colicinogenic *LT*2 strains do not recombine like *LT*2 strains carrying an *F* factor from *E. coli* (Zinder[5] and personal communication).

All the recombinants which have been analysed have been stable, and are thus presumably haploids produced by segregation after chromosomal recombination in a (transient) zygote or merozygote. All the recombinants tested were colicinogenic, nearly all producing colicines *I* and *E*1 in crosses where both factors were present in the donor mixture, whereas only about 25 per cent of acceptor bacteria acquire colicinogeny during the time allowed for mating. We suppose, therefore, that a zygote (or merozygote) results from a conjugation in which colicine factors are transferred.

It is not yet completely certain that gene transfer occurs only from the colicinogenic donor to the acceptor strain, and not also the other way about. However, this is probably so since the result of a cross is affected according to which parent is colicinogenic. For example: (1) in some crosses at least, the unselected markers of the strain accepting colicinogeny are much more frequent in recombinants than are their alleles from the donor strain; (2) colicine factor *E*1 greatly increases the frequency of recombination when it is present in the donor strain, but not when it is present in the acceptor strain; and (3) exposure of the mating mixture to streptomycin for 90 min. much reduces the yield of recombinants when the acceptor strain is streptomycin-sensitive and the donor strain is streptomycin-resistant; but has little effect when the acceptor of colicinogeny is streptomycin-resistant and the donor is sensitive.

Recombination in this system may be fundamentally similar to that mediated by the *F* factor in *Escherichia coli*. The presence of colicine factor *I* in *Salmonella typhimurium*, like that of the *F* factor (in either the *F* + or the *Hfr* form) in *E. coli*, enables the bacteria to pair, although the effect of factor *I* is very small except in bacteria which have recently acquired it; in factor *I*-induced pairing, as in pairing induced by the *F* factor in its *F* + state, chromosomal recombination occurs at a very low rate. The effect of factor *E*1 in raising the rate of recombination in factor *I*-induced pairing is more obscure; one may speculate that it facilitates the opening of the (presumed) closed-loop chromosome of the donor bacterium, so encouraging its transfer, in whole or in part, to the acceptor bacterium (compare the effect of the *F* factor in *E. coli* on passing from the *F* + to the *Hfr* state).

Escherichia coli K-12

THE transfer of genetic material from one strain of *Escherichia coli K*-12 to another is dependent on a fertility factor, termed *F*, which determines the donor state; two *K*-12 strains devoid of *F* (F^--strains) are normally non-fertile when mixed together[6,7]. The *F* factor has been classed as an *episome* by Jacob, *et al.*[8], existing in the autonomous (cytoplasmic) state in the F^+ cell, and in the integrated (chromosomal) state in the *Hfr* cell. The integrated state of *F*, and of other episomes, appears to be related to the ability to promote the genetic transfer of other stably chromosomal characters. Colicinogeny (the heritable ability to produce an antibiotic-like protein called colicin) has also been shown to be determined by factors which have certain episomal characteristics[8].

Two lines of evidence have pointed to the implication of colicinogeny as a genetic vector in *K*-12. Furness and Rowley[9] reported that certain naturally occurring strains of *E. coli*, although showing no direct evidence of fertility with *K*-12 F^- strains, could, nevertheless, transfer to them a fertility factor which rendered these *K*-12 strains fertile with other *K*-12 strains. Unlike *E. coli K*-12, most of these wild-type coliform strains were found to be colicinogenic, the majority for colicin *I*, as were the infected *K*-12 F^- derivatives. However, colicinogeny and fertility do not appear to be determined by the same factor in these strains. This conclusion was reached after treatment with either cobalt chloride[9] or acridine orange, which have been shown to be effective in 'curing' or eliminating the *F* factor from F^+ strains[10,11]. After treatment, the fertile, colicinogenic *K*-12 strains lose their fertility but preserve their colicinogeny.

More recently, Ozeki *et al.*[12] have demonstrated the transfer by conjugation of what appear to be large segments of chromosome from a donor strain to a recipient strain of *Salmonella typhimurium*. The donor state in this case is conferred by the *recent* transfer of colicinogeny from a third strain which is specifically colicinogenic for colicin *I*. If the donor strain is in addition colicinogenic for colicin *E*1, the frequency of transfer is increased about 100-fold, to yield one recombinant/approximately 10^6 recipient cells. These colicinogeny determinants, *I* and *E*1, can be transferred to *E. coli K*-12 by mixing a culture of this strain with a culture of *S. typhimurium* which carries them[13]. An investigation was therefore undertaken of the fertility state of F^- *K*-12 strains subsequent to the transfer of these particular colicinogeny determinants. Two auxotrophic F^- strains of *E. coli K*-12 were employed: 58–161 F^-, which requires methionine, and *W*945 F^-, which requires threonine, leucine and thiamine for growth. In the first experiment, the method of Ozeki *et al.* was followed closely. *S. typhimurium* carrying colicinogeny *I* (col. I^+) and 58–161 F^- were grown overnight in mixed broth culture; the mixture was then diluted 1/50 in fresh broth and reincubated for 2 hr. A culture of the recipient strain *W*945 F^- was then added and the mixture of these three strains incubated for a further hour before washing and plating on minimal medium supplemented with thiamine. After incubation, prototrophic recombinants resulted at the low rate of about one in 10^8 *W*945 F^- cells plated. None of the individual strains, alone, nor in any combination of pairs, gave rise to any prototrophic colonies.

In contrast with the *S. typhimurium* system, the use of the presumptive donor strain 58–161 F^-, made stably colicinogenic for *E*1, failed to increase the frequency of recombinant formation. Another point of difference is that, in *E. coli K*-12, the donor state conferred by colicinogeny *I* is stable and does not depend on recent colicinogenization. When a strain of 58–161 F^-, stably colicinogenic for *I* (isolated from mixed culture with *S. typhimurium* (col. I^+)), was used in a simple bi-parental cross with *W*945 F^-, prototrophic recombinants again arose at the same low rate as before. All the recombinants tested from these experiments were colicinogenic, and fertile as donors in crosses with F^- recipients. It is, therefore, concluded that colicinogeny *I* confers on *K*-12 F^- strains the capacity for concomitant chromosomal and colicinogeny transfer to other F^- strains. Since *Salmonella* apparently cannot readily harbour *F*, it seems possible that in this system, as distinct from that reported by Furness and Rowley, the fertility factor is the colicinogeny determinant itself. This is supported by the fact that no recombinants arose when *Salmonella* strains, differing only in harbouring colicinogeny *E*1 or *E*2 instead of *I*, were used in experiments similar to those reported above.

A comparison was made of unselected marker transfer among a number of recombinants from a *col I*-mediated cross, and the comparable *F*-mediated cross, using 58–161 in the colicinogenic or F^+ state respectively as the donor parent with *W*945 F^- as the recipient (Table 1). Crosses were plated on minimal medium supplemented with thiamine so that selection was made for the ability to synthesize threonine (thr^+) and leucine (leu^+) from 58–161, and methionine (met^+) from *W*945. The two strains differed in seven other markers; the ability to synthesize thiamine (*thi*); to ferment the sugars arabinose (*ara*), lactose (*lac*), galactose (*gal*) and xylose (*xyl*); and resistance to the drug, sodium azide (*azi*) and the coliphage T6 (*T*6), A variety of recombinant types

Table 1. FREQUENCY OF RECOMBINANTS CARRYING GENETIC MARKERS OF *E. coli* STRAIN 58–161 WHEN CROSSED WITH *W*945 F^-

resulted, as indicated in Table 1. Although the *col I*-mediated cross was only one-hundredth the fertility of the *F*-mediated cross, the table shows similarities in marker transfer from both types of crosses. Assuming a one-way transfer of genetic material (the colicinogenic strain acting as a donor as in the case of the F^+ strain), and assuming the order of markers on the *K*-12 chromosome as determined by *Hfr* or F^+ crosses[14], the recombinants from both types of crosses can be accounted for by a double crossing over in more than 90 per cent of the recombinants. It appears, therefore, that the genetic fragments transferred in the *col I* cross are of the same order of size as those involved in the F^+ cross, in which, for example, the distance between *thr-gal* has been shown to be about 15 per cent of the total chromosomal length[14].

Episomal systems determining certain types of colicinogeny appear, therefore, to resemble other episomal systems such as temperate phage and more particularly *F*, in the ability to mediate genetic transfer. It is tempting to imagine that if mutation were to occur in such colicinogenic strains so as to remove the lethal effect of the colicin, it would be difficult to distinguish them readily from F^+ strains. Other possible similarities of the colicinogenic and *F* systems are being examined.

ANALYSIS OF IRRADIATED *DROSOPHILA* POPULATIONS FOR MEIOTIC DRIVE

By PROF. E. NOVITSKI[*] and G. D. HANKS[*]

Biology Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee[†]

THE existence of chromosomes or alleles that are represented in the gametes of a heterozygote with a frequency greater than the expected 50 per cent is now well established for a variety of species. The immediate population result of introducing such a chromosome or allele must be a sharp increase in its frequency, along with any other genes associated by linkage, independent of or, indeed, in spite of, their phenotypic effects[1,2]. For this reason such phenomena have been referred to as cases of 'drive' and, more specifically, as 'meiotic drive' when the basis is found in some aberration of meiosis[3]. Such instances would seem to provide an unparalleled opportunity for the study of population dynamics, for example, the efficacy of response of natural selection to unfavourable genes. It seemed worth while, therefore, to determine whether such chromosomes or alleles characterized by drive might be induced in the laboratory.

We expected that such an event would occur with a very low frequency, and would probably not be detectable in an X-ray experiment conventionally designed. Instead, chromosomes were tested that had received light doses of radiation each generation for about 200 generations. These chromosomes had been derived from the population cages kept at the Long Island Biological Laboratory at Cold Spring Harbor by Dr. Bruce Wallace, to whom we are indebted for making samples of these populations available to us.

The genetic tests consisted simply of back-crossing heterozygotes for chromosomes derived from the irradiated populations and for stock chromosomes carrying mutant genes to the mutant stock in order to detect any deviation in the progeny from the expected 50 per cent of each type. Seven different populations were tested, and the standard mutants chosen marked the distal ends and centromere regions of the three major chromosomes. Furthermore, since it could not be anticipated in which sex any disturbances of segregation might be effective, both male and female heterozygotes were tested. Of 1,654 tests there were two instances in which the chromosomes derived from the irradiated population were recovered in significantly more than half the progeny, and where this deviation persisted after repeated testing.

One of these cases involved an irradiated second chromosome, which appeared in the F_1 of male heterozygotes, with frequencies ranging from 53 to 80 per cent (Table 1). The second chromosome showed this peculiarity over six consecutive generations and in combination with a variety of different

stock second chromosomes. The bottle stock carrying this chromosome was left unattended for a period of several months, and subsequent re-testing failed to uncover it again. In the meantime the population from which this was originally derived was unfortunately discarded. It is not clear why we should not have been able to recover it again in the unselected population if it were in fact a bona fide case of drive.

In the second case, an irradiated X chromosome when present in a parental male, appears in 56–64 per cent of his progeny (Table 2). This has persisted over 20 consecutive generations; in fact, the mean recovery is now 67 per cent, presumably because of the persistent selection exercised in each generation for genes which accentuate the discrepancy. As in the preceding case, this chromosome behaves normally in the heterozygous female.

Evidence that inequality of recovery of the two homologues (in this case the X and Y chromosomes) is not simply differential mortality of the male progeny caused by this particular X chromosome may be found in the following observations:

(1) When matings are made to attached-X females instead of ordinary females with free-X chromosomes, the deviation persists but with reversed direction, as one might expect if more eggs were being fertilized by X- than by Y-bearing sperm.

(2) Pair matings were made of females with males which carried the irradiated X chromosome. After eggs were collected and carefully counted, the sex of the adults emerging was scored. The overall mortality was simply the difference between the eggs laid and the total emerging adults. A χ-square test was made of the deviation in sex ratio, but to ensure the most conservative test, the overall mortality was added to the least frequent class, the male class. Even with this correction, which would tend to minimize the magnitude of the difference between the two classes, the P value was less than 0·005. This refutes the possibility that the difference between the numbers of the two sexes recovered may be explained by mortality and supports the alternative that it is caused by some pre-zygotic mechanism, as meiotic drive.

(3) At lower temperatures (18° C.) the magnitude of the effect is depressed, 56 per cent recovery, as opposed to 67 per cent at 25° C. However, if a male develops at 18° C. and is then mated in a culture bottle at 25°, which is then kept at the higher temperature during the development of the progeny, the resulting ratio in the progeny is that characteristic of the low temperature, not the higher, as would be expected if zygote mortality were responsible.

Those three lines of evidence speak strongly for an action before fertilization and possibly during meiosis, which would qualify this case for inclusion under the heading of meiotic drive. Preliminary cytological examination has revealed nothing unusual, but unless the basis for this effect were something quite obvious (as, for example, the formation of anaphase bridges as in 'segregation-distorter'[4]), one would not hope to have much success in this effort with a species the meiosis of which is as intractable cytologically as is that of *Drosophila melanogaster*.

We wish to acknowledge the contribution of technical assistance of Mrs. R. D. Wilkerson, the innumerable helpful suggestions of the genetics group at the Oak Ridge National Laboratory, and the invaluable assistance of Dr. Allyn Kimball, who constructed criteria based on sequential analysis, which expedited the testing enormously.

CHROMOSOME FRAGMENTS AND MUTATION OF THE INCOMPATIBILITY GENE

By PROF. D. LEWIS, F.R.S.
Department of Botany, University College, London

IN a study in *Petunia inflata* of changes in the self-incompatibility system, Brewbaker and Natarajan[1] found self-compatible plants among the selfed generation after X-radiation of the pollen mother cells. This is similar to results obtained in *Oenothera organensis*, *Prunus avium*[2] and *Trifolium* species[3], which have been interpreted on a basis of mutation of the self-incompatibility S gene. Brewbaker and Natarajan discovered, however, that their self-fertile plants had a small centric chromosome fragment extra to the normal diploid set of chromosomes. Their analysis supports very fully their interpretation that the fragment carries the S gene, and that a self-compatible plant has two alleles, say S_1 and S_2, in the normal pair of chromosomes, and either S_1 or S_2 in the fragment. Such a plant will produce 50 per cent pollen grains with one normal S chromosome, and the fragment. Half these fragment-carrying pollen grains have a different S allele in normal and fragment chromosomes.

It has long been known that a diploid pollen grain with two different, but not two like, S alleles has a weakened incompatibility reaction or has lost it altogether. This effect has been called competitive interaction between the S alleles so that neither allele produces its specific protein, which is responsible for the incompatibility reaction[4]. When the incompatibility reaction has been completely lost by competitive interaction, a plant with diploid pollen grains is fully self-compatible. When the incompatibility is only weakened, then the pollen tubes are less inhibited, but they are still unable to effect fertilization and produce seed when growing on their own style. The plant is therefore still self-incompatible.

This competitive interaction is the basis of Brewbaker and Natarajan's interpretation of the fragment and self-compatibility in *Petunia*. A plant which produces pollen grains with a normal chromosome with S_1 and a fragment with S_2 will exhibit competitive interaction between the alleles, and will be self-compatible.

The finding of a chromosome fragment and the behaviour of the self-compatible plants both as male and female parents in *Petunia inflata* proves conclusively that the change to self-compatibility induced by the X-rays and the selective method of self-pollination is due to the presence of two competing alleles in disomic pollen grain and not to mutation of the *S* gene itself. This is certainly true of the five self-compatible plants analysed. It may or may not be the explanation for the remaining 16 self-fertile plants which have not been reported in detail.

The extra *S* fragment in these self-compatible plants is precisely what would have been expected on the hypothesis of competitive interaction in a genus such as *Petunia*, where competitive interaction results in a complete loss of the pollen incompatibility reaction. This was shown by the data of Stout and Chandler[5] and interpreted by Lewis[4].

Brewbaker and Natarajan claim that a chromosome fragment and competitive interaction can explain results obtained by me in mutation studies in *Oenothera organensis*.

I propose to dispose of the *S* fragment explanation of self-compatible plants in *Oenothera* only. The arguments and findings given apply also to many of the self-compatible plants in *Prunus* and *Trifolium*, but these will not be discussed.

First, the competitive interaction in diploid pollen grains with two different *S* alleles in *Oenothera* has been analysed in detail in the combinations between *S* alleles used in the mutation studies. None of the pairs of different alleles showed competition strong enough to result in self-compatibility. Longer pollen tubes on selfing tetraploids were produced, but there were no seeds except in a tetraallelic plant $S_{2\cdot3\cdot4\cdot6}$ which gave only eleven seeds from 15 flowers pollinated, which is less than 1 per cent of the compatible seed set. The plants are therefore not self-compatible[4].

In *Oenothera organensis* the progeny obtained after X-ray treatment and self-pollination contained two classes: 50 per cent of heterozygotes S_1S_2' and 50 per cent of 'homozygotes' S_2S_2', where S_2' is a mutated form of S_2. This S_2' mutant confers full self-compatibility on the plant. These two genotypes can be unambiguously identified by their reaction as female parent in test crosses. The S_1S_2' plants as female inhibit both S_1 and S_2 pollen, S_2S_2' plants inhibit only S_2 pollen. Homozygotes of the type $S_2'S_2'$ were found in the progeny from selfing the S_2S_2' plants.

In *Petunia*, on the other hand, all the progeny from X-ray treatment and self-pollination were identical, and reacted in the same way as the parent, that is, as S_1S_2 when used as females in test crosses. Furthermore, the progeny from selfing again the self-fertile plants contained only the one class.

In *Oenothera*, even if competitive interaction were strong enough to have resulted in self-compatibility, the presence of homozygotes of the types S_2S_2' and $S_2'S_2'$ in their expected proportions on a stable gene mutation hypothesis excludes the possibility of an *S* fragment and competition as a basis for the self-compatibility. Such homozygous plants could not produce pollen grains with two different alleles as required by the fragment explanation.

Further evidence for the mutational origin of the self-compatible plants is not necessary, but it has been found recently in the reaction of diploid pollen grains in artificially produced tetraploids[6]. Not all pairs of *S* alleles show competitive interaction; some show dominance and some show independence. In a diploid pollen grain, S_2 and S_4 are independent in their action so that both are expressed. A diploid pollen grain with a normal S_2 and a mutant S_4' is incompatible on a style with S_4' or S_4, whereas a pollen grain with S_4' alone is not incompatible on such styles. In this case the activity of S_4' in the pollen, which has been lost by mutation, has been restored by the presence of S_2', so that S_4 protein is produced. The allele S_4' has not been permanently changed by the presence of S_2, but only its activity. Such a result cannot be explained on a fragment basis.

Accepting that a class of self-compatible plants in *Petunia* after X-ray treatment is due to the presence of a fragment bearing an *S* gene, this explanation does not apply to *Oenothera organensis*, and it would be surprising if all self-compatible plants found in *Petunia* could be explained on this basis. In *Petunia*, where competitive interaction is strong enough, and the fragment is transmitted by the pollen, both *S* fragmental, *S* mutational or *S* recombinational and possibly *S* trisomic self-compatible plants should be found. In *Oenothera* only mutational or recombinational *S* plants are expected.

The sieve operating in the incompatibility system will allow different classes of mutations to pass in different species. In *Oenothera* the sieve is more discriminating than in *Petunia*. In *Petunia* a wider spectrum of mutational changes will be recovered. It is possible that, if more pollen grain were tested for mutation in *Petunia* then the S_2' type of mutant in *Oenothera* may still not be found in *Petunia*. The tests in *Petunia* were on 3,100 pollinations and this represents about 3×10^6 viable pollen grains. If the X-ray induced mutation-rate is the same in *Petunia* and *Oenothera*, only 3 self-fertile mutants of the S_2' type would be expected.

A further point of interest is that in *Petunia* self-fertile plants were not obtained after X-ray treatment and self-pollination of homozygotes of the type S_1S_1. This has led to the suggestion that the self-fertility may be due to some rare equal or unequal gene recombination[7]. In *Oenothera* this is a possible explanation in some cases but not in all, because self-fertile mutants of the S_2' type have been obtained from *S* homozygotes (Lewis and Dowrick, unpublished).

In two of the most completely analysed self-compatible mutants induced in *Oenothera* the explanation rests on the mutation of an activator part of the gene or of a separate activator gene contiguous with the *S* specificity gene[6].

PHYSICS

A Notable Growth Spiral on Synthetic Diamond

IN previous communications[1] it was reported that a few growth spirals of step height of some 100 Å. were observed on what were otherwise very smooth cubic faces of synthetic diamonds. These spirals were found only among one batch of crystals (1958) made by General Electric (U.S.A.). Of several thousand faces examined only two very clear-cut single-step spirals were found, together with another eight irregular, shallow, imperfect examples.

A stock of selected (1960) General Electric crystals was secured later, and, despite careful search, which indeed uncovered many smooth cubic faces, no spirals were detected, although a considerable number of crystals were studied.

I have been engaged for some time past in examining microcrystal diamonds recently made by de Beers of Johannesburg. These crystals are of interest in that they show numerous highly perfect faces, both octahedral and cubic. They are being examined with a high-sensitive phase-contrast microscope and with two-beam interferometry, using, for both techniques, a 4-mm. objective, with magnification × 750. The crystals are tiny, the largest being 0·1 mm. across, and on these some thousands of faces have already been examined.

Among them another single growth spiral has been found, but it is indeed striking. It appears on an irregular face, which must be an incompleted cubic face. The phase-contrast picture (× 500) is shown in Fig. 1. Although of an apparent partial triangular outline, this face is certainly not octahedral (no angles of either 60° or 120° occur between edges). It is an incompleted cubic face.

The beautifully defined spiral is clearly of cube face origin, sweeping round with marked rectangular outline. Thus once again our original finding is confirmed in that this too fits the observation that all spirals found to date on diamond appear only on smooth cubic faces of synthetic diamonds and nowhere else.

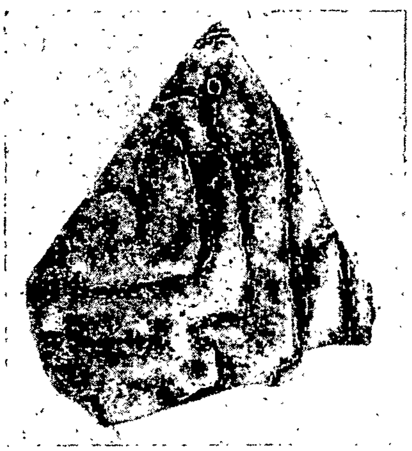

Fig. 1

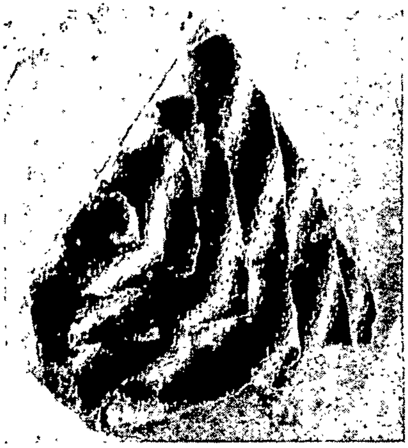

Fig. 2

This spiral is much more perfectly defined than any yet seen by us, and that it is one of considerable step height is shown by the two-beam interferogram (Fig. 2, × 500), taken with green mercury light. The height of the spiral step is about 1300 Å., which is surprisingly large.

The definition of the micrograph of Fig. 1 is so good on the original that it can be clearly seen that the spiral edge is double, and this can be detected too on the interferogram. It is worthy of note that on both the best of our earlier examples as well as on this one the complete face is covered by one single spiral.

It is once more re-emphasized that spiral growth is a quite rare phenomenon in diamond. It is certainly not the normal method of growth, either of synthetic or natural diamond, as the rarity of appearance proves.

The phase-contrast technique in use in this laboratory is capable of revealing spiral step edges as shallow as 2½ Å., and it is unlikely that any spirals have been missed on the thousands of faces studied by us.

An Upper Limit for the Resistivity of a Superconducting Film

SEVERAL experiments have been carried out to check whether the resistance of a bulk metal in the superconducting state is truly zero. The best known is that carried out by Collins[1], in which a persistent current of several hundred amperes was maintained in a lead ring for two and a half years. At the end of this time there was no measurable decrease in the

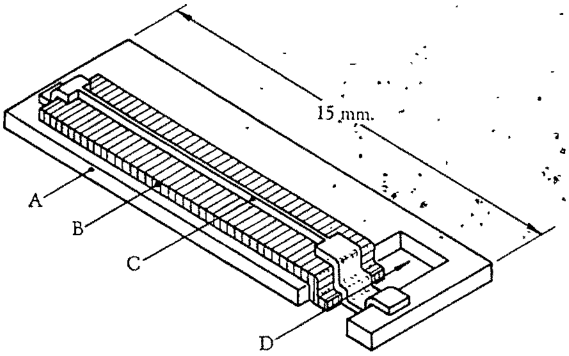

Fig. 1. Arrangement of superconducting films. Vertical dimensions not shown to scale

magnitude of the current. The resistance of the ring is quoted by Crowe[1] as less than 10^{-21} ohm, but no figure for the resistivity of the lead is given.

The question of whether the resistance of a superconducting film of thickness comparable with the depth of penetration is truly zero is of interest both from a fundamental point of view and because of the possibility of using persistent currents for storing information in computers. The present experiment was carried out to investigate this problem.

In principle, the experiment consisted of inducing a persistent current in a superconducting film, then measuring the resultant magnetic field with a bismuth Hall-effect probe of the type described by Kronick[2]. The presence of any resistance in the film would be indicated by a decay in the magnetic field. To increase the sensitivity of the measurement the L/R time-constant of the film in the normal state was made as short as possible by adopting the arrangement shown in Fig. 1. A lead film A, 1000 Å. thick, was evaporated on to a glass substrate, and a silicon monoxide insulating layer B, 2500 Å. thick, deposited on the lead in the position shown. A third film C, 800 Å. thick, composed of an alloy of lead containing 2 per cent indium, was deposited over the insulation, making contact with the lead film A at each end. The narrow section of C had a resistance of 50 ohms at a temperature just above the critical temperature ($\simeq 7°$ K.), which is about ten times higher than if the film had been made of pure lead. However, because of the small separation between it and the 'ground plane' A, its contribution to the inductance of the loop is quite small. Measurements on a scale-model showed that the total inductance of the loop was 5×10^{-9} H., and hence the time constant $L/R_N = 10^{-10}$ sec. The bismuth Hall-effect probe was placed near the centre of the area D enclosed by the films and the arrangement immersed in liquid helium at a temperature of 2·10° K. A persistent current was induced in the loop by means of an electromagnet and the magnitude of the magnetic field produced as a result of that current was measured before and after an interval of 3 hr. ($\simeq 10^4$ sec.). The accuracy of measurement of the magnetic field was limited by noise in the probe to 1 part in 50, but no decay in the persistent current outside this limit could be observed. Therefore the time constant in the superconducting state must be greater than 50×10^4 sec. and the ratio $R_S/R_N = (L/R_N)/(L/R_S)$ is less than 2×10^{-16}. The corresponding resistivity in the superconducting state is less than 10^{-21} ohm cm. This is quite close to the upper limit obtained by Collins, but due to the use of an alloy my figure for the ratio R_S/R_N is probably about one order of magnitude smaller.

I thank Dr. E. H. Rhoderick of this Laboratory for suggesting the experiment and for his helpful advice, and also the Admiralty for permission to publish this communication.

Flow of Visco-Elastic Liquids from Tubes

It is frequently observed that when a visco-elastic fluid issues from a tube that the diameter increases as the fluid moves away from the tube exit.

To eliminate gravitational effects, consider the fluid flowing horizontally from a tube. It may be shown that if horizontal momentum is conserved, the diameter of the emerging jet should decrease as the material moves away from the tube exit. Since the diameter often increases with a visco-elastic liquid, it is deduced that momentum is not conserved and that there should be a force acting on the fluid. If this is the case, there should be an equal and opposite force acting on the apparatus from which the fluid flows.

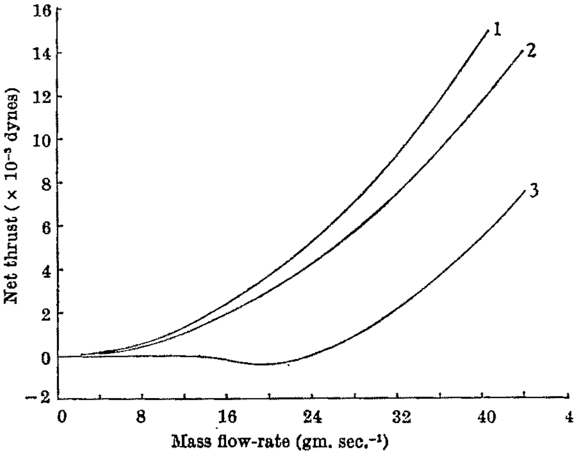

Fig. 1. Graphs of net thrust versus mass flow-rate for octal in paraffin 3/16-in. diam. tubes. Curve 1, calculated from cone and plate viscometer data; curve 2, calculated for flat velocity profile; curve 3, observed experimental results

Results of some experiments to test these ideas are shown on Fig. 1, on which is plotted the net thrust exerted by the flowing liquid on the apparatus versus the mass flow-rate. Curve 3, the observed net thrust, is unusual in that no net thrust is noted below a certain mass flow-rate. The net thrust then becomes negative and finally positive, but is much less than the calculated value.

It is well known that these fluids have a non-Newtonian distribution of normal stresses, and the results appear to show a measurable tensile force acting along the stream lines.

The same type of force seems to be present in the flow of solutions of aluminium laurate.

It was interesting to note that the apparatus moved in the same direction as the motion of the fluid when the net thrust was negative.

Inelastic Scattering of Conduction Electrons in Dilute Silver–Manganese Alloys at Low Temperatures

THE method of Gruneisen–De Haas was recently employed by me[1] for the analysis of our thermal and electrical resistivity data at helium temperatures[2] on dilute silver–manganese rods (containing, respectively, 0·55, 0·32 and 0·14 atoms per cent of manganese in random solid solution) in transverse magnetic fields ranging from 0 to 25 kilogauss. This method of analysis yielded information regarding the variation of the electronic Lorenz parameter L_e with the magnetic field and the temperature, while, at the same time, effecting the separation of the measured thermal conductivity into its electronic and lattice components.

I wish to direct special attention to a result of that analysis: namely, that L_e, at liquid helium temperatures, dipped below the normal Sommerfeld value L_n ($= 2{\cdot}45 \times 10^{-8}$ watt-ohm-deg.$^{-2}$), attained a minimum, and approached the value L_n at temperatures close to 0° K.

In order to explain their own results (following those of Gerritsen and Linde[3]) on the electrical resistivity maximum in the case of dilute alloys of a noble metal with a small amount of a transition metal, Schmitt and Jacobs[4] discussed the effects of inelastic impurity scattering of the conduction electrons[5,6]. Since a co-operative magnetic transition is known to occur[7–9] in such alloys, in this temperature region, the spin degeneracy of the impurity ion is thereby removed and the scattering process involving the spin flips of the conduction electron and the ion becomes inelastic[4,10].

The critical test for the existence of such an inelastic scattering would be in the thermal resistivity[11]. The 'vertical' transitions of the electrons, to which heat conductivity is very sensitive, would result in an anomalous contribution to the electronic thermal resistivity. My results for the electronic thermal resistivity (w_e) of these alloys do exhibit this behaviour. The plots of w_eT against T show this in the form of a pronounced 'peak'.

Taking $f = [(\rho_m/\rho_0) - 1]$, (where ρ_m stands for the value of the electrical resistivity maximum and ρ_0 for the value at $T \rightarrow 0$), as a measure of the maximum fractional contribution of inelastic impurity scattering, I obtain an estimated $f \approx 0{\cdot}1$, in my silver–manganese rod specimens. This ignores any temperature-dependent contribution from elastic scattering by the impurity ions[10].

For making the corresponding estimates in the case of the electronic thermal resistivity in these specimens, I write, $f' = [\{(w_eT)_m/(w_eT)_0\} - 1]$. Here, $(w_eT)_m$ and $(w_eT)_0$ stand for the values at the 'peak' and at $T \rightarrow 0$, respectively. From my plots of w_eT versus T, we obtain $f' \approx 0{\cdot}5$, $0{\cdot}6_5$ and $0{\cdot}8$, in the order of decreasing manganese content.

The fact that inelastic impurity scattering makes such a large contribution to the electronic thermal resistivity of these alloys, while making only a small contribution to the electrical resistivity, accounts for the 'dip' in the value of L_e with respect to the normal value L_n. The further result that L_e seems to approach L_n at temperatures close to absolute zero (below $\approx$ 1° K.) is explained by the fact that this inelastic scattering cannot occur at 0° K. Scattering, which would involve loss of energy by the electron, is not permitted since there are no lower electronic states available; scattering which would involve gain of energy by the electron is also not possible since there are no ions in the excited states at 0° K. to transfer energy to the electron.

Full details will be published elsewhere.

Grateful acknowledgment is made of the benefit of discussions with Sir K. S. Krishnan, Director of the National Physical Laboratory of India.

Breakdown Strength of Cæsium Iodide

Two crystal structures, both cubic, are found in the alkali halide group of compounds: (1) the 'sodium chloride type' of interpenetrating face-centred cubes, and (2) the 'cæsium chloride type' of interpenetrating simple cubes. All the group except cæsium chloride, cæsium bromide and cæsium iodide resemble sodium chloride at ordinary temperatures and pressures[1]. Measurements of the breakdown strength of halides of the sodium chloride type have shown[2] that there exists a simple relationship between the breakdown field strength, F, and the interionic distance, a, given by $Fa^3 = 28(\pm 25$ per cent) where F is measured in MV./cm. and a in Å. No previous work on the cæsium chloride type of halide has come to our notice.

In the course of some work on electro- and photo-luminescence of crystals, the opportunity was taken to establish whether cæsium iodide obeyed this relationship. The crystals used contained about 0·1 per cent thallium (to make them better scintillators). This presence of foreign ions may raise the breakdown strength slightly above that of the pure crystal[3], but it is unlikely that the increase will be greater than experimental error.

Two single crystals of cæsium iodide were used, each approximately 0·01 cm. thick. For this thickness, it is to be expected that 'intrinsic' breakdown will take place[4]. In one method of procedure, an aluminium point contact was used as one electrode and a metal plate the other, while in a second method a metal sphere of diameter 3 mm. was used as the first electrode. A film of water usually forms on cæsium iodide crystals and results in discharges around the edges. This was prevented by polishing the crystals in oil and keeping an oil film on the crystals during the experiments.

Over a series of experiments at room temperature using the first method, breakdowns occurred at fields which varied from experiment to experiment, due probably to the presence of local flaws in the crystal structure, the minimum and maximum fields at which breakdown occurred being 0·29 and 0·36 MV./cm.

With the second method, the corresponding limits were 0·20 and 0·40 MV./cm., and the average value was 0·32 (±0·05) MV./cm.

The interionic distance for cæsium iodide is 3·95 Å. (ref. 5). Then for this crystal $Fa^3 = 20 \pm 3$, in reasonable agreement with the value found for the sodium chloride type of crystal structure.

ASTROPHYSICS

Trajectories of Chromospheric Disk Surges

As a result of the use of rapid sequence *H*-alpha cinematography, Lockheed Solar Observatory has collected a large quantity of data on disk surges during 1959 and 1960. Since January 1960, the band pass of the birefringent filter has been displaced 0·5 Å. to the blue or red of *H*-alpha. The increased contrast between active absorption features and the background in the wings of *H*-alpha has resulted in a greater ability to detect disk surges. The percentage of flares of all classes associated with observed surges increased from 11·4 per cent in 1959 to 20·4 per cent in 1960. Approximately 94 per cent of the total flares were sub-flares. During the two years, a total of 953 flare surge events were photographed at the Observatory.

The study of surges observed in the wings of *H*-alpha has permitted the identification of a new class of disk surges which are characterized by extremely intricate structures. Unlike the 'classical' disk surges which appear as straight brush-like extensions from flares[1], these dark surges, which we term 'complex surges', appear on single frames as irregular, dark mottles. Although material is clearly being ejected with typical velocities of 100 km./sec., the complex surges show little preferential direction of flow and have trajectories seemingly dominated by local force fields. Table 1 lists three large complex surges observed in 1960.

Table 1

Date 1960	Time Start (U.T.)	Time Max.	Extension	Mean velocity (km./sec.)	Associated position	Flare importance
May 9	0030	0052	0·13 R	69	S. 11 E. 04	1
Sept. 25	1817	1855	0·30 R	92	S. 18 W. 22	1
Nov. 20	1640	1655	0.19 R	77	N. 23 W. 45	1–

While viewing the off-band films of these events, particular attention was paid to the motion of the complex surges relative to the neighbouring bright coarse mottling. It was found that whenever the direction of flow was altered the dark surge material appeared to avoid the bright mottling. The surges with very complex structure were deflected many times as the surge material appeared to flow along the lanes between the bright mottling.

The complicated trajectories of these surges may perhaps be understood in terms of magnetic fields in the coarse mottling. The kinetic pressure of surge material moving with a speed of 100 km./sec. with a density of 10^{11} protons per cm.[3] would be balanced by the magnetic pressure of a field of about 20 gauss. The correspondence between magnetic fields of such magnitude and CaII plages was first established by the Babcocks[2], and has recently been corroborated by Howard[3] and Leighton[4]. The boundaries of CaII plages appear to be contained by 10 gauss contours and the fields in such plages may reach as high as 200 gauss. The wings of *H*-alpha are not formed at the same height of the chromosphere as the centre of the CaII *K* line; however, bright mottling in the wings of *H*-alpha and CaII plages may well correspond to different heights in the chromosphere along continuous vertical magnetic columns.

Detailed work on the association between magnetic fields and the coarse mottling in the wings of *H*-alpha is needed; but it does appear that bright mottling is adjacent to large field gradients. Chromospheric filaments apparently lie between regions of opposite polarity[2], and when filaments are visible in the wings of *H*-alpha, they are generally bordered by bright mottling apparently identical to that which deflects the surges. Further work on the trajectories of disk surges is continuing as the observations reported here suggest that surges may be utilized as 'test particles' for the mapping of chromospheric and coronal magnetic fields.

GEOLOGY and MINERALOGY

Origin of Ignimbrites

A FIELD and laboratory study of the Ordovician ignimbrites of North Wales that has been in progress since 1953[1–3] has revealed certain limitations in Marshall's original hypothesis[4] regarding the origin of this interesting category of rocks. These limitations have been apparent to workers elsewhere[5–8]. The evidence from North Wales, and much of the published evidence from North and South America, is categorically opposed, however, to the hypothesis of origin now proposed by Steiner[9]. As this new hypothesis is based on a petrological study of the type ignimbrites from the North Island of New Zealand, and involves the far-reaching conclusion that liquid immiscibility plays a large part in the petrogenesis of acid igneous rocks, a critical appreciation of Steiner's views is urgently required. A detailed petrological criticism is in preparation, and will be published in full elsewhere. In the meantime, it is appropriate to state that Steiner's conclusions appear to be based on a misinterpretation of the evidence afforded by the New Zealand rocks.

Steiner correctly observed the presence of two contrasting glasses in fresh New Zealand ignimbrites—a feature of certain ignimbrites mentioned by other authors[10,11]. Ancient ignimbrites, such as those from North Wales, cannot contain unaltered glass, but they do retain, in many instances, the textural evidence of its former presence. It is on the textural evidence derived from a comparison of North Welsh rocks with unaltered New Zealand specimens that Steiner's hypothesis of liquid immiscibility is rejected. The presence of two, and, rarely, of three, distinct glasses appears to be an accidental feature of certain ignimbrites, and not of universal importance. In some fresh New Zealand ignimbrites, fragments and shreds of juvenile glass can be seen to enclose rounded and partly resorbed xenoliths of earlier glassy ignimbrites and vitric tuffs, along with globular masses of a similar shape and size of another glass of higher refractive index. The conclusion that this second glass did not originate by liquid immiscibility, but is present as small xenoliths, is amply confirmed by the occasional presence of much larger angular xenoliths of the same glass, containing resorbed phenocrysts. In other instances the accessory xenolithic origin of the small globular masses of the second glass is not so readily obvious, but, once its characteristic features have been defined by study of unambiguous examples, the general identity of origin of the second glass can be confidently accepted. The peculiar groupings and matching shapes, within patches of small globules of this second glass, are clearly related to the partial resorption and separation of the perlitic fragments of an earlier obsidian. Vent-rocks from North Wales, and large fragments contained within ignimbrites, both from New Zealand and North Wales, often have very intricate textural patterns, produced by the plastic distortion of hot obsidian containing numerous gas vesicles and dissolving xenoliths of earlier glass. It is the texture shown by rocks of this type that has misled Steiner.

Steiner observed that the second glass has a higher refractive index than the juvenile glass. This can be confirmed, and indeed is to be expected, if the second glass were present as reheated and partially dissolved fragments of an earlier obsidian that consolidated within or below the volcanic vent, for this would be derived from either an earlier volatile-poor fraction of the present magmatic phase, or from a magma less advanced along the differentiation sequence.

Much of the textural evidence described by Steiner from New Zealand ignimbrites can be studied equally well in North Welsh rocks. The phenocrysts of ignimbrites, for example, cannot be described as generally showing multiple resorption features. The vast majority of the felspar phenocrysts are obviously broken and abraded by gas-generated expansion, and only the rare quartz phenocrysts preserved within xenolithic obsidian lumps show that intricate resorption outline regarded by Steiner as evidence for gentle flow rather than a violent expansion of gas. Any resorption of phenocrysts occurred mainly before eruption.

The conclusion of Hausen that ignimbrites are more akin to lavas in their mode of origin than to pyroclast-showers is one that most workers in the field would support, but the field and petrographic evidence is definitely opposed to the view that they are true lavas. There may be, in fact, every gradation from the

Skiddaw Slates proved in t Inlier

The small inlier of Lower Palæoz
Teesdale crops out beneath Carbo
the banks of the River Tees below C
the hamlet of Langdon Beck, Co
inlier is poorly exposed, but consis
belt of soft greenish and light-colour
slates, until recently regarded as co
liferous, and a western area in w
lava occur. The slates are best e
workings near the Pencil Mill (*NY*

at one time the softer beds were worked up into slate-pencils.

The Teesdale Inlier was discovered in the latter part of the last century when the highly cleaved slates were described as probably Skiddaw Slates, Lower Ordovician, by Dakyns[1] in 1877. A further account of the inlier in 1878 by Gunn and Clough[2] referred the slates tentatively to the Silurian Stockdale Shales. Later authors followed Gunn and Clough in regarding the slates as probably Silurian until Kendall and Wroot[3] revived the view that they were better placed in the Skiddaw Slate Series, and this latter view was supported by Dunham[4]. Five mica-lamprophyre dykes are intruded into the slates in the vicinity of the Pencil Mill and have been described by Williams[5]. The lavas at the western end of the Inlier are tentatively referred to the Borrowdale Volcanic Series.

The first fossils to be found in the slates of the inlier were collected near Pencil Mill by Mr. G. F. Lea during a Durham undergraduate geological mapping exercise in the spring of 1959. The specimens consisted of poorly preserved graptolites which were not found *in situ*. Several subsequent visits to the inlier in search of further graptolites were unsuccessful, but some small elongated thin-shelled fossils were obtained which are believed to be phyllocarid crustacean carapaces and tentatively referred to ? *Caryocaris* sp. On a further recent visit to the inlier three more graptolites were obtained from slate scree in the Pencil Mill workings and the preservation of these specimens is more definite. It is noteworthy that all the fossils found in the slates of the inlier are inconspicuous to the naked eye, and it is undoubtedly owing to this that they have remained undiscovered until the last few years.

The graptolites found in the Teesdale Inlier have been examined by Prof. O. M. B. Bulman, who has made tentative identification of the specimens as follows: ? *Cryptograptus* sp.; *Glyptograptus dentatus* (Brongn.); *Didymograptus* sp., the proximal end of a pendent didymograptid, possibly *D. climacograptoides* Holm MS. (Bulman).

This fauna, particularly the presence of pendent didymograptid in association with *G. dentatus*, is sound evidence of Lower Ordovician age and shows that the beds belong to the upper part of the Skiddaw Slate Series. Prof. Bulman suggests that the slates of the Teesdale Inlier may in fact be an easterly extension of the Ellergill Beds, the central division of the Skiddaw Slates of the Cross Fell Inlier. The presence of ? *Caryocaris* sp. in the Teesdale slates is supporting evidence for Skiddaw Slates Series age. Thus the long-disputed question of the age of the slates of the Teesdale Inlier is finally solved by the discovery of a graptolite fauna.

The advice and assistance of Prof. O. M. B. Bulman and Mr. J. D. D. Smith, who kindly examined the graptolites and other fossils from the Teesdale Inlier, are gratefully acknowledged.

breakdown occurs. The energy
e breakdown is sufficient to evapo-
rtion of the particle. The puff of
l can initiate an arc if of sufficient
size and if the electric field is of sufficient strength. If, however, these requirements are not met, a simple loss of impurity occurs at the surface. Thermal cycling will, however, tend to replenish the depleted surface layer by diffusion of impurities from the interior. This hypothesis is supported by experiments on molybdenum at less-severe electrical conditions than those mentioned above. Thus at 1·7 kV., 8 amp./cm.[2], the arcing-rate passes through a maximum at about 1,050° C., during heating and again on cooling. At low temperature, therefore, the competition between surface depletion and precipitation is won by the former due to low diffusion-rates.

We have made use of the depletion process to prepare molybdenum wires which are virtually non-arcing at any temperature in the range 700–1,800° C. The procedure adopted is to cool the wire slowly from 1,800° C. while at the same time exposing it to an uninterrupted series of discharges at the maximum electrical conditions of 2 kV., 16 amp./cm.[2]. Very little arcing occurs during this process if the cooling-rate is sufficiently slow; the surface particles are therefore evaporated before they grow big enough to start an arc. After several such operations no arcing can be induced by extended heat treatment aimed at homogenizing the wire to encourage surface precipitation. It seems likely therefore that the wire is depleted throughout its volume by this method.

These observations suggest that the conditioning of various metals against arcing at room temperature observed by Craston *et al.*[1] is due to the depletion at the surface of insulating inclusions.

A detailed report is to be published elsewhere.

CHEMISTRY

Prevention by Cysteamine of Radical Formation in Bovine Serum Albumin by γ-Rays

CYSTEAMINE is one of the most effective substances for the protection of animals against ionizing radiations, and *in vitro* has been shown to reduce radiation damage of macromolecules by energy transfer in solid polymethylmethacrylate[1], by capture of OH· radicals for serum albumin in dilute solution[2], and by hydrogen transfer to an organic radical for polymers in aqueous solution[3,4]. Gordy and Miyagawa[5] have found that the electron spin resonance spectrum of the protein zein is altered in magnitude and character if cysteamine is present, and have ascribed this to the combination of cysteamine with the protein by a disulphide exchange reaction. Earlier experiments[1] led us to believe that an energy-transfer process is a more probable mechanism of protection, and to test this hypothesis we studied the effect of cysteamine on the electron spin resonance spectrum of bovine serum albumin irradiated with cobalt-60 γ-rays at room temperature and at 77° K. (dose, 5 Mrads, dose-rate = 750 krads/hr.). The mixture of 90 per cent bovine serum albumin + 10 per cent cysteamine was produced by freeze-drying a solution. Although bovine serum albumin contains 17 disulphide groups per molecule, none of these reacts with cysteamine under isoelectric conditions because they are sterically inaccessible[6,7] and the possibility of protection by disulphide exchange is therefore excluded (human serum albumin combines with cysteamine at the isoelectric point because one disulphide bond is reactive[7]).

A 400 kc./s. magnetic field modulation X-band spectrometer was used. The samples were placed in an H_{014} transmission-type cavity. The source of microwave power was a low-voltage reflex $K302$ klystron, and crystal detection employing a $CV2154$ crystal was used. A maximum linear sweep amplitude of about 200 gauss was obtained using an electronic 'bootstrap' type linear sawtooth generator. Thus all spectra were recorded as the first derivative of the absorption intensity as a function of variation in magnetic field with the microwave frequency held constant. At maximum usable sensitivity, 7×10^{14} radicals in α,α-diphenyl β-picryl hydrazyl could be detected at room temperature.

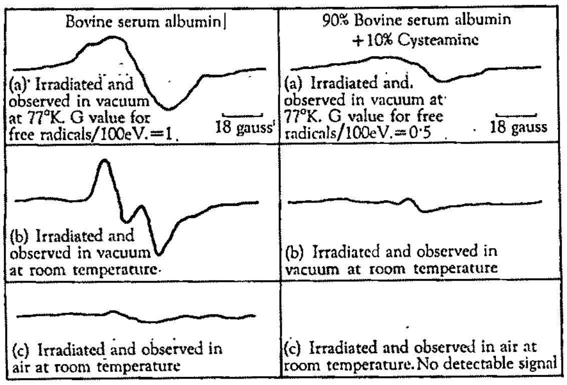

Fig. 1. Electron spin resonance spectra of bovine serum albumin and a mixture of 90 per cent bovine serum albumin + 10 per cent cysteamine under various conditions. All spectra recorded at the same spectrometer sensitivity

Fig. 1 shows that the presence of 10 per cent of cysteamine reduces the intensity of the electron spin resonance spectrum of bovine serum albumin whether the irradiation is carried out at 77° K., at room temperature *in vacuo*, or at room temperature in air. The nature of the electron spin resonance spectrum is different under these three conditions, but in every case cysteamine has the same effect, namely, to reduce to half or less than half the number of radicals that are formed. In each case the same weight of cysteamine on its own gives no signal. Measurements at 77° K. presumably reveal all the radicals that are produced on irradiation, while electron spin resonance at room temperature measures those radicals that for steric reasons have been unable to recombine.

The protection by cysteamine seen in the room-temperature measurements could be due either to energy transfer from the proteins to the cysteamine before a radiochemical reaction occurs, or due to hydrogen transfer leading to a reconstitution of the protein radical ($R^{\cdot}$) :

$$R^{\cdot} + \text{SH}\text{—} \rightarrow R\text{H} + \text{S}^{\cdot}\text{—}\ (2\ \text{S}^{\cdot}\text{—} \rightarrow \text{—S.S—})$$

The electron spin resonance signal of the mixture at room temperature is small and a choice between the two mechanisms is not possible.

This hydrogen transfer 'repair' mechanism (cf. refs. 3 and 4) cannot, however, apply at 77° K., since the radicals are effectively frozen and prevented from reacting, and the observed protection must therefore be ascribed to an energy-transfer process similar to that originally observed in synthetic polymers. Moreover, the electron spin resonance spectrum of the mixture at 77° K. is qualitatively the same as that of bovine serum albumin alone. This confirms that the bovine serum albumin has been protected by transfer of energy to the cysteamine rather than by a chemical reaction, which would probably give rise to a signal in the mixture different from that for bovine serum albumin alone. There seems to be no reason for limiting this interpretation to bovine serum albumin and we feel that the disulphide exchange reaction need not be involved in the protection of other proteins by sulphydryl compounds, in particular since our electron spin resonance experiments with irradiated cystine and bovine serum albumin (Libby, D., Ormerod, M. G., and Alexander, P., unpublished work) do not lead us to the conclusion of Gordy, Ard and Shields[8] that radicals induced by irradiation are chiefly associated with the sulphur atoms to which the energy deposited in other parts of the protein molecule migrate. The electron spin resonance pattern of bovine serum albumin irradiated at 77° K., when all the radicals are still present, bears no resemblance to that of irradiated cystine.

Our experiments lead us to question the hypothesis[9] that disulphide exchange plays a part in the protection of animals against radiation by cysteamine, since this mechanism need not be invoked to account for the protection of proteins *in vitro*, whether this occurs directly or by capture of OH· radicals formed in water[2].

Behaviour of Magnesium Impurity in Gallium Arsenide

Anomalous behaviour of magnesium in gallium arsenide has been reported by Edmond[1] and Weisberg *et al.*[2], who found that magnesium behaves as a donor impurity, differing in this respect from zinc, cadmium and mercury. Edmond incorporated $5 \cdot 7 \times 10^{19}$ atoms/cm.^{3} of magnesium in his specimens and found it to be a donor impurity ; however, Weisberg found magnesium to be a donor when present at low concentration, but an acceptor at levels higher than $4 \cdot 4 \times 10^{18}$ atoms/cm.^{3}. The experimental methods employed by Weisberg are not known to me; however, Edmond prepared his specimens by heating gallium arsenide and magnesium together in sealed silica tubes for 1 hr. at 1,551° K., a small quantity of arsenic being added to prevent decomposition.

Two specimens were prepared in these Laboratories by the method described above. As they had similar properties, the calculations and work reported here relate to one of these samples only.

After cooling, a light grey stain was observed on the inner surface of the tube. This stain, which appeared over a small area only, was not removable by aqua regia and indicated reaction between the tube and its contents. The specimen was carefully etched to remove surface oxides and was compared spectrographically with the pure gallium arsenide from which it was prepared. The most sensitive lines of magnesium and silicon, barely visible for the pure arsenide, showed up strongly for the specimen. The ratio of silicon to magnesium was estimated to be somewhat greater than unity.

In order to determine the true behaviour of magnesium, a further specimen was prepared in a different manner. Gallium arsenide and magnesium were placed in a carbon container with a well-fitting lid. This container, together with the correct quantity of arsenic, was sealed within a silica tube and heated to 1,551° K. for a short time.

Spectrographic examination indicated a much smaller silicon content than in the other specimens. This specimen was p-type with $6 \cdot 1 \times 10^{18}$ acceptors/cm.^{3} compared with $5 \cdot 6 \times 10^{19}$ magnesium atoms/cm.^{3} which were incorporated by weighing. Magnesium, therefore, is an acceptor in gallium arsenide and probably occupies gallium lattice sites.

Reaction between magnesium and silica proceeds according to the general equation :

$$2Mg + SiO_2 = 2MgO + Si \qquad (1)$$

This implies that in experiments of this kind, a thin layer of magnesium oxide forms on the inner surface of the tube. The rate of reaction is limited by the rate at which fresh silica can reach the surface (by solid state diffusion), and the final ratio of silicon to magnesium in the melt is determined by the composition of the oxide phase in equilibrium with the melt.

At 1,551° K., the system $MgO - SiO_2$ has one stable intermediate phase Mg_2SiO_4, and another phase $MgSiO_3$ of marginal stability. The extra stability of Mg_2SiO_4 is − 15,120 cal./mole and large variations in the activities of MgO and SiO_2 are to be expected for $MgO : SiO_2$ ratios close to 2 : 1 (compare the treatment of system CaO–SiO_2 [4]).

For equilibrium with oxide phases having $MgO : SiO_2$ ratios less than 2, it is best to use the equation :

$$2Mg(l) + 2SiO_2(s) \rightleftharpoons Mg_2SiO_4(s) + Si(l) \qquad (2)$$

$$\Delta G^0 = -83{,}980 + 2 \cdot 52\, T \log T - 4 \cdot 99 T$$

$$= -79{,}250 \text{ cal. at } 1{,}551° \text{ K.}$$

For equilibrium with oxide phases having $MgO : SiO_2$ ratios greater than 2, it is best to use :

$$2Mg(l) + Mg_2SiO_4(s) \rightleftharpoons 4MgO(s) + Si(l) \qquad (3)$$

$$\Delta G^0 = -53{,}740 + 2 \cdot 52\, T \log T - 4 \cdot 99 T$$

$$= -49{,}000 \text{ cal. at } 1{,}551° \text{ K.}$$

In order to proceed further, it is necessary to know values of the activity coefficients of silicon and magnesium in gallium arsenide. These are not available and, as this is only an approximate treatment, ideal solution behaviour has been assumed for the purpose of these calculations. Liquid magnesium and undercooled liquid silicon are adopted as the standard states.

In the experiment carried out in these Laboratories, the amount of magnesium incorporated in the specimen was $5 \cdot 25 \times 10^{19}$ atoms/cm.^{3}.

Combining this information with a ΔG^0 value of − 79,250 cal. and, using the expression :

$$\Delta G^0 = -RT \log_e \frac{x_{\text{silicon}}}{x^2_{\text{magnesium}}}$$

we obtain :

$$x_{\text{silicon}} = 1 \cdot 18 \times 10^{-3}$$

$$\text{ratio } \frac{x_{\text{silicon}}}{x_{\text{magnesium}}} = 1 \cdot 32 \times 10^4$$

$$x_{\text{magnesium}} = 8 \cdot 9 \times 10^{-8}$$

(where x is the mole fraction).

Alternatively, using a ΔG^0 value of − 49,000 cal. we obtain:

$$x_{\text{silicon}} = 1 \cdot 17 \times 10^{-3}$$

$$\text{ratio } \frac{x_{\text{silicon}}}{x_{\text{magnesium}}} = 95$$

$$x_{\text{magnesium}} = 1 \cdot 24 \times 10^{-5}$$

As silicon is a donor impurity in gallium arsenide, electrical behaviour, previously attributed to magnesium, may be explained by the process of chemical replacement described here. The specimens prepared in contact with silica were shown by thermal E.M.F. measurements to be n-type but the ratio $x_{\text{silicon}}/x_{\text{magnesium}}$ appeared to be less than the estimated value of 95.

Taking into account electronegativities of the atoms involved, and the stabilities of their compounds, it appears that the assumption of ideal behaviour is reasonably accurate for silicon but not for magnesium. Silicon has a structure similar to that of gallium arsenide and can substitute on either lattice site[5]. Each magnesium atom, by analogy with zinc or cadmium, should substitute on a gallium site and be surrounded tetrahedrally by four arsenic atoms. Magnesium also forms a stable arsenide, Mg_3As_2 (estimated heat of formation, − 90,000 cal./mole), in which each magnesium atom is bounded by four arsenic atoms as nearest neighbours. For this reason, the activity coefficient of magnesium in gallium arsenide should be considerably less than unity.

Equations (2) and (3) represent the limiting conditions likely to be encountered in experimental work. Ratios of $x_{\text{silicon}}/x_{\text{magnesium}}$ derived from them need to be reduced to allow for the non-ideality of magnesium. The extent of this reduction is not easy to estimate.

This work is being carried out under Admiralty contract *CP.4D*(2) 5298/58/60.2.

Crystal Growth of Gallium Arsenide using Carbon Boats

GALLIUM arsenide is a semiconductor of great interest from the purely scientific point of view and as a device material. It is therefore desirable to be able to prepare single crystals of high purity. Because of the reactive nature of gallium liquid and arsenic vapour at high temperature, only a limited number of refractories may be used as boat materials for gallium arsenide (melting point, 1,511° K.). Among these are carbon, vitreous silica and alumina. In addition a sealed envelope of vitreous silica is generally employed to prevent the escape of arsenic vapour from the system.

It is observed that, in general, the use of carbon or carbonized silica boats facilitates single crystal growth, whereas ingots grown in silica boats exhibit various degrees of wetting and subsequent polycrystallinity. On the other hand, despite reduced wetting, material grown in carbon boats is the more strongly *n*-type. Typically, a crystal grown in a carbon boat yields an electron concentration of $1{\cdot}3 \times 10^{18}$/cm.^{3} and Hall mobility, $\mu_n = 2{,}500$ cm.^{2}/V./sec., compared with the usual 3×10^{16}/cm.^{3} and 5,000 cm.^{2}/V./sec. obtained for crystals grown in silica. It is worth adding that in all cases the observed mobility is less than that to be expected from the carrier concentration[1], implying a fair degree of compensation. There is, therefore, a considerable gain to be achieved by the removal of residual impurities.

Although the results above indicate that the presence of carbon increases the donor concentration in gallium arsenide, the absence of wetting suggests that this is not due to carbon being dissolved in the melt. It is suggested, therefore, that the prime effect of carbon is to bring about reduction of the silica envelope according to the equation:

$$\mathrm{SiO_2(s) + 2C(s) \rightleftharpoons Si(s) + 2CO(g)} \qquad (1)$$

Spectrographic examination indicates that silicon is present in fair amounts in gallium arsenide grown in carbon boats.

At the melting point of gallium arsenide, the standard free energy change for reaction (1) is $\Delta G^0 =$ 26,000 cal.[2]. Using the relation:

$$\Delta G^0 = -RT \log_e Kp = -2RT \log_e p_{\mathrm{CO}}$$

where p_{CO} is partial pressure of carbon monoxide, we obtain $p_{\mathrm{CO}} = 1{\cdot}3 \times 10^{-2}$ atmosphere. We can see, therefore, that starting with carbon and silica in a closed system, free silicon is produced until the pressure of carbon monoxide reaches the above value. In addition, the free silicon is able to dissolve in molten gallium arsenide to form a dilute solution; its activity is thereby reduced and the reaction can proceed further from left to right.

Since similar results are obtained for carbon as for carbonized silica boats, it seems that silicon must enter the melt from the vapour phase. The following reactions are reversible and provide mechanisms for the transport of carbon and silicon from one part of the system to another:

$$\mathrm{C(s) + CO_2(g) \rightleftharpoons 2CO(g)} \qquad (2)$$

$$\mathrm{Si(s) + SiO_2(s) \rightleftharpoons 2SiO(g)} \qquad (3)$$

At 1,511° K., the partial pressure of silicon monoxide is $9{\cdot}55 \times 10^{-4}$ atmosphere.

In practice, the equilibrium vapour pressure of carbon monoxide is not attained. It seems likely that since the partial pressure of arsenic in the system is high (0·9 atmosphere), the rate at which silicon enters the melt is mainly limited by gaseous diffusion and convection.

Carbon should be a satisfactory crucible material for gallium arsenide under conditions where it is unable to react with reducible oxides such as silica. Recent chemical analysis of gallium arsenide grown in contact with carbon has shown the carbon content to be less than $2{\cdot}7 \times 10^{17}$ atoms/cm.^{3}, which is the limit of detection of the method. One would expect the solubility of carbon in gallium arsenide to be comparable with that in germanium at the same temperature (about 10^{13} atoms/cm.^{3} at 1,511° K.).

This work is being carried out under Admiralty contract *CP.4D*(2) 5298/58/60.2.

Methane Oxidation initiated by Electrical Discharge

AN apparatus for the mass-spectrometric study of free radicals occurring in gas-phase reactions has recently been completed in this Laboratory. While testing the equipment we have investigated the reactions in a methane–oxygen mixture, subsequent to electrical discharge in one of the gases.

The apparatus, which is illustrated in Fig. 1, is essentially similar to that of Foner and Hudson[1]. A flow of gas is maintained through a silica discharge tube, the discharge products being swept into the 'Pyrex' reaction vessel, where they may mix with another gas entering down a side tube. The mixing zone is sampled by a pinhole in platinum foil leading to the ion source of a Metropolitan-Vickers *M.S.*2 mass spectrometer. The ion source was modified by the makers to provide a higher pumping speed, differential pumping from the filament region, and line-of-sight access from the pinhole leak to the ionization chamber.

The electrical discharges were maintained by a 200-watt radio transmitter, working at 13,560 kc./s., which supplied a coil wound around the discharge tube, 2 ft. above the sampling pinhole. Pressures of 500–750μ and flow-rates of 500–700 ml./sec. were used in this work.

The detectable products from a discharge in methane were mainly ethane and hydrogen, with some acetylene and ethylene; approximately one-third of the methane was removed, but the $\mathrm{C_2}$ hydrocarbons detected could only account for 60 per cent of this. When oxygen was added (through the side tube) to the products of a discharge in methane the detectable products were scarcely affected; there was a slight decrease in the amount of ethane formed, and some water and carbon dioxide were detected, but 40 per cent of the carbon was still unaccounted for.

If the oxygen is submitted to the electrical discharge and the products mixed with undissociated

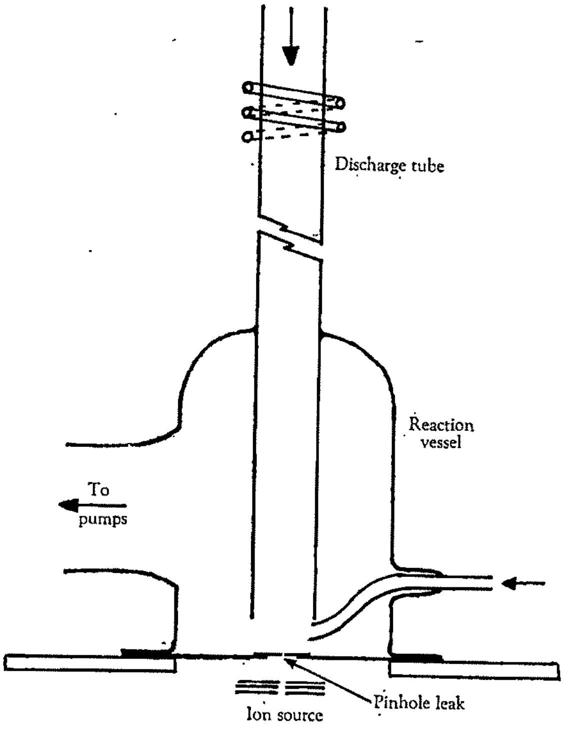

Fig. 1

methane, the detectable products of the reaction are very different. Within the limits of the present work there is a carbon balance, 80 per cent of that lost as methane appearing as ethane, and the remainder equally divided between ethylene and carbon dioxide; no acetylene is detectable. The remaining hydrogen appears mainly as water, only about 10 per cent being H_2.

A large residual peak exists at a mass/charge ratio of 17, its height being two and a half times that of the water peak at $m./e. = 18$. We are unable to explain this peak, except by assuming the presence of hydroxyl radicals.

Since we were not able to use low electron energies to confirm the presence of free radicals[2], the above conclusions must be regarded as tentative. Work is now in progress to use the low electron energy method, and also to coat the surface of the platinum foil so as to reduce the rate of recombination of radicals thereon; further results will be reported in due course.

We wish to thank Mr. G. Wilkinson for glass-blowing, and Dr. J. W. Linnett for the use of the mass spectrometer, which was provided by grants from the Department of Scientific and Industrial Research and Esso Research, Ltd. One of us (M. B.) is the holder of a Department of Scientific and Industrial Research maintenance grant, and the other (J. C.) is an Imperial Chemical Industries, Ltd., Research Fellow.

Internuclear Distances of Methyl and Methylene Radicals

The experimental determination of the geometry of the methyl and methylene radicals is very difficult[1,2]. Hence it may be of some interest to report estimates of the internuclear distances of the methyl and methylene radicals. Comparisons were made of several hydride radicals and molecules of the first row of the Periodic Table as shown in Table 1 and Fig. 1. The arrangement indicates regularity in the differences of the internuclear distances of these structures.

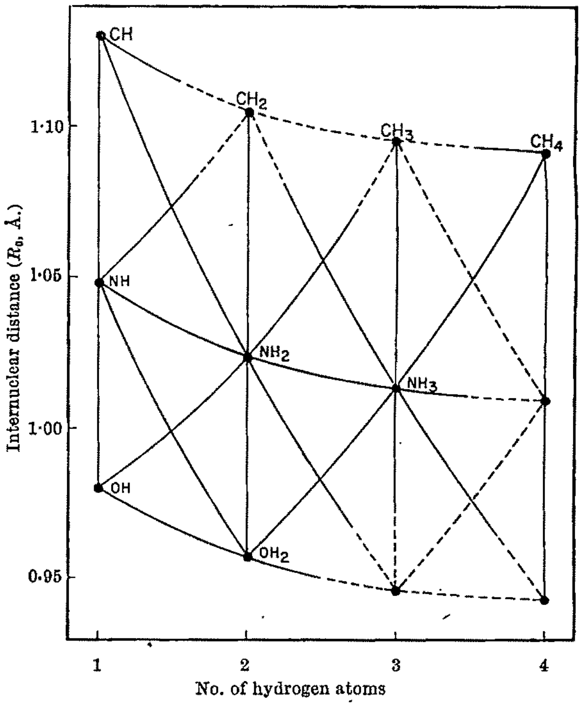

Fig. 1. Relation between internuclear distances of the hydrides of elements of the first row of the Periodic Table as a function of the number of hydrogen atoms

The internuclear distances of methyl and methylene radicals are estimated to be respectively 1·096 and 1·105 Å. It is interesting to point out the general utility of networks of the type shown in Fig. 1. A large grid of which Fig. 1 is a part has been used in another connexion[3]. A physically significant point of such a network must lie at the juncture of four lines as indicated in the diagram. The structures shown in Fig. 1 are both radicals and saturated molecules. Since the nitrogen hydrides fit into this simple scheme,

Table 1. Comparison of Internuclear Distances of First-Row Hydrides

	R_0		R_0		R_0		R_0

Table 2. GEOMETRY OF THE HYBRID METHYLENE RADICAL

CH or CD Å.	Fig. angle	I (CHD) × 10^{-40} gm. cm.^{2}	Deviation from y-axis
1·105	137° 20′	5·262	6° 50′
1·095	140°	5·252	6° 15′
1·071	147° 54′	5·230	4° 46′

it may be expected that the corresponding carbon hydrides should also be located within the same framework in similar manner.

From the rotational constants[2] $B''(CD_2) = 3{\cdot}96$ and $B''(CHD) = 5{\cdot}33$ cm.$^{-1}$, the principal moments of inertia of the CHD radical are found to be: $I(CD_2) = 7{\cdot}084 \times 10^{-40}$ gm. × cm.^{2} and $I(CHD) = 5{\cdot}247 \times 10^{-40}$ gm. × cm.^{2}. In the latter case, the figure axis inclines slightly from the y-axis of the co-ordinate system. The comparison shown in Table 2 indicates that neither the measured distance (1·071 Å.) nor the predicted value (1·105 Å.) is satisfactory. It can also be seen that a carbon–hydrogen distance of 1·095 Å. yields $I(CHD) = 5{\cdot}252 \times 10^{-40}$ gm. × cm.^{2}, which checks the experimental value. However, the results rest on the assumption that the experimentally determined rotation constants are correct. Unless the two radicals under discussion show some extraordinary electron configurations, it is expected that the present prediction and final experiment must ultimately agree. No detailed calculations have been made for the methyl radical.

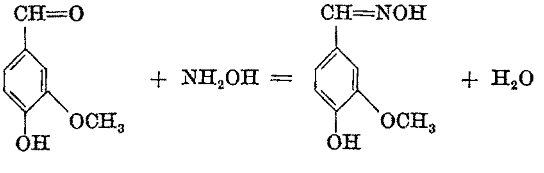
Polarographic Determination of Vanillin

VARIOUS physico-chemical and chemical methods have been used for the determination of vanillin. Of the volumetric methods[1], the oxime method has been modified in many ways, whereby either the quantity of the hydrochloric acid set free in the reaction of hydroxylamine hydrochloride with vanillin, or the quantity of the unreacted hydroxylamine, is titrated visually or potentiometrically. Colorimetric methods are based on the slight reducing capacity of phenols[2], the polarographic methods[3] on the reduction of the aldehydic group of vanillin.

I have devised a new method for the determination of vanillin by utilizing the condensation of the aldehydic group with hydroxylamine with formation of the oxime, according to the following scheme:



The resulting oxime is polarographically active. The condensation of the aldehydic group proceeds quantitatively and the resulting oxime is reduced at more positive potentials. The sensitivity of the method is twice that of the direct polarographic determination. The condensation as well as the reduction of vanillin oxime proceed best in a phosphate buffer of pH 5·9. Under these conditions, the height of the oxime wave is precisely double that of vanillin before condensation (Fig. 1).

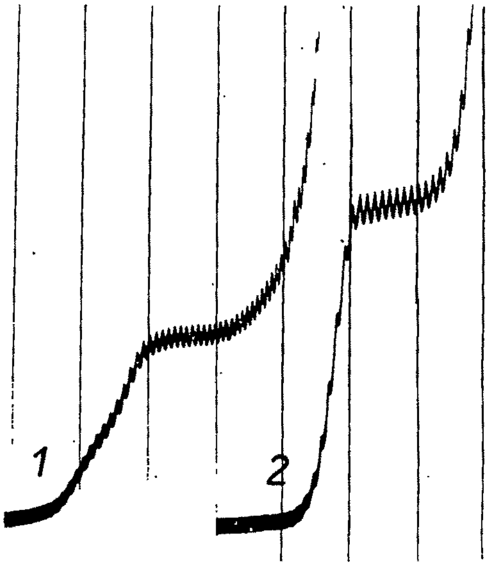


Fig. 1. Condensation of vanillin with hydroxylamine. Curve 1: 5 ml. 0·1 M ammonium chloride + 5 ml. 1 × 10^{-3} M vanillin solution, from −1·30 V. Curve 2: 4 ml. phosphate buffer, pH 5·9 + 5 ml. 1 × 10^{-3} M vanillin solution + 1 ml. 1 M hydroxylamine hydrochloride, from −0·78 V. Saturated mercurous sulphate electrode, sensitivity 1: 30, 195 mV./absc.

In phosphate buffer of pH 5·9, vanillin is reduced at a half-wave potential of − 0·93 V. (sat. calomel electrode) in a single well-developed four-electron wave. The dependence of the height of the oxime wave is a linear function of the concentration of vanillin. The wave shows a diffuse character, is easy to read and suitable for analytical use.

A detailed account of the reaction conditions and of the utilization of the method for the analysis of vanillin, both in the pure state and in foods, will be described elsewhere.

Spectrophotometric Determination of the Electron Affinities of Some Diatomic Molecules

THE purpose of this communication is to present a calculation of the electron affinities of some molecules from charge transfer spectra. Mulliken's[1] theory for a charge-transfer process leads to the expression:

$$h\nu_{\text{max.}} = I_D - E_A - \Delta \qquad (1)$$

where $h\nu_{\text{max.}}$ is the energy corresponding to the most probable electronic transition, I_D and E_A are the vertical ionization potential of the electron donor and the vertical electron affinity of the electron acceptor. Δ represents the stabilization energy, relative to the ground-state, of the excited state in the nuclear configuration corresponding to the ground-state. This relation has been confirmed for some series of various donors with one acceptor[2,3] and for series of a particular donor with various acceptors[4].

By using spectroscopic data for charge transfer from one electron donor to various electron acceptors the electron affinities of these acceptors may be evaluated, provided that one absolute value of E_A is accurately known. It is assumed that the value of Δ is independent of the nature of the electron acceptor[4]. Thus, equation (1) leads to the relation:

$$h\nu_{\text{max.}}^{(1)} - h\nu_{\text{max.}}^{(2)} = E_{(2)} - E_{(1)} \qquad (2)$$

The magnitude of the vertical electron affinities of molecular halogens have not yet been established. These data were calculated by using the recent experimental results for the absorption spectra of iodine atom and aromatic hydrocarbon complexes[5] (Table 1).

Table 1. ELECTRON AFFINITIES OF MOLECULAR HALOGEN COMPOUNDS FROM CHARGE TRANSFER SPECTRA OF BENZENE COMPLEXES

Electron acceptor A	$\lambda_{\text{max.}}$	$h\nu_{\text{max.}}$	E_I—E_A	E_A	E_X—D_{X_2} (refs. 8 and 9)	E_A (previous estimation)
I	495 (ref. 5)	57·8	0	74·6 ± 1·5 (ref. 8)		
I_2	297 (ref. 6)	96·3	38·5	36	40 ± 1·5	41·5 (ref. 1)
Br_2	292 (ref. 7)	98·0	40·2	34	35·6 ± 1·5	
Cl_2	278 (ref. 7)	102·9	45·1	30	30·7 ± 1·5	≤39 (ref. 8)
ICl	287 (ref. 7)	99·6	41·8	33		

Wave-lengths given in mμ. Energetic data in kcal.

The lower limit for the equilibrium values of the electron affinities $E^e_{X_2}$ of the homonuclear molecules X_2 can be obtained from the relation:

$$E^e_{X_2} \geqslant E_X - D_{X_2} \qquad (3)$$

where D_{X_2} is the dissociation energy of the molecule. The values obtained for the vertical electron affinities of the halogens are smaller than the lower limits for $E^e_{X_2}$. As the stabilization energy of the excited state of the atomic iodine complex may be slightly higher compared with the corresponding state of the molecular iodine complex, the data of Table 1 present the lower limits for the vertical electron affinities of the halogen molecules. The vertical electron affinity of I_2 is expected to be lower than the corresponding equilibrium value[10]. However, our results indicate that in the benzene–iodine complex the repulsive part of I_2^- curve does not cross the I_2 curve at its minimum, as was indicated by the results of the dissociative attachments of the electrons in free iodine[10].

The same method was applied for the evaluation of the electron affinities of oxygen and of nitric oxide. Ultra-violet absorption spectra of oxygen in aromatic and aliphatic hydrocarbons[11-14] and of nitric oxide in alcohols[14] were observed. The continuous bands were assigned to charge transfer spectra[13,14], the oxygen and nitric oxide molecules acting as electron acceptors. The band onset energy $h\nu_0$ (arbitrarily chosen for $\varepsilon = 10$ litre mole^{-1} cm.$^{-1}$) was used for the specification of the transition energy. It is assumed that the vibrational broadening is independent of the electron acceptor. This relation is quite well fulfilled for the series of the I_2 aromatic complexes. The energetic data for oxygen and nitric oxide complexes are presented in Table 2.

Using the value of E_{I_2} we obtain $E_{O_2} = 17 \pm 4$ kcal. and $E_{NO} = 20 \pm 4$ kcal.

A recent theoretical estimation of the equilibrium electron affinity of oxygen[16] leads to a much lower value of 3·5 kcal. However, the result obtained for E_{O_2} from charge transfer spectra is in agreement with the equilibrium electron affinity of oxygen estimated from thermochemical data[8].

Electron attachment experiments in nitric oxide indicate that the electron affinity of this molecule is positive[8].

BIOCHEMISTRY

Structure of Collagen

A TRIPLE helical structure for collagen with two systematic hydrogen bonds for every three residues was put forward from this laboratory in 1955 [1]. This structure was criticized by Rich and Crick[2] on the basis of a few short interatomic contacts occurring in it; they suggested that only structures with one hydrogen bond for every three residues will be free of bad contacts. Recently, we have examined the whole question carefully, and it has been found that

Table 2. DETERMINATION OF THE ELECTRON AFFINITIES OF OXYGEN AND NITRIC OXIDE

D \ A	I_2		O_2		NO		E_{I_2}—E_{O_2}	E_{NO}—E_{O_2}
	λ_0	$h\nu_0$	λ_0	$h\nu_0$	λ_0	$h\nu_0$		
Benzene	380 (ref. 6)	76	301 (ref. 14)	95	252 (ref. 14)	112	19	3
Cyclohexane	280 (ref. 3)	102	242 (ref. 12)	118			16	
Methanol	300 (ref. 15)	95	248 (ref. 14)	115·3			20	
Ethanol	300 (ref. 15)	95	251 (ref. 14)	114			21	

Wave-lengths given in mμ. Energetic data in kcal.

it is possible to build up a two-bonded structure (two hydrogen bonds for three residues) while retaining all contacts within permissible values. This has been possible mainly because a study of the observed interatomic contacts in various reported organic structures showed that contact distances actually occur which are much shorter than those mentioned by Rich and Crick[2], namely, C . . . C = 3·6 – 4·0 Å. and C . . . O = 3·2 – 3·4 Å. In fact, if Rich and Crick's criteria were adopted, some of the accepted structures like the α-helix will become unacceptable. Secondly, the study of the relation between the NH . . . O hydrogen bond distance and the infra-red frequency showed that the observed frequency (Ramachandran, G. N., Sasisekharan, V., and Thathachari, Y. T., unpublished work) in collagen, which is higher than that observed in other proteins, should correspond to a value of the order of 3·0 Å. The actual parameters of the minor helix of the collagen structure have also been re-determined. These gave a value of 2·95 Å. for the residue height and 3·28, rather than 3·33 (10/3), for the number of residues per turn. As a consequence, the twist for three residues in the triple helical structure should be 30° rather than 36°.

On the basis of these results, a satisfactory two-bonded structure has been worked out, and its co-ordinates are given in Table 1. The two hydrogen bonds which are formed, namely, $N_1H_1 \ldots O_2$ and $N_3H_3 \ldots O_3$, are of the same type as in the earlier structure proposed by Ramachandran and Kartha[1]. They are of the order of 3·00–3·05 Å. and the hydrogen-bond angles are less than 30°. The primary bond distances, bond angles and the deviation from planarity of the amide group are all well within the ranges observed in organic structures. Denoting the three chains by *A*, *B* and *C*, the only short contacts which occur are: (1) $O_2(A) \ldots O_3(A) = 2{\cdot}73$ Å.; (2) $C_1(B) \ldots O_2(A) = 2{\cdot}90$ Å.; (3) $C_4(A) \ldots O_2(B) = 3{\cdot}10$ Å.; (4) $C_4(A) \ldots O_3(B) = 3{\cdot}03$ Å.; and (5) $C_1(A) \ldots C_1(B) = 3{\cdot}50$ Å. The structure is thus seen to be satisfactory in every respect.

Table 1. ATOMIC CO-ORDINATES OF THE ATOMS IN ONE SET OF THREE RESIDUES OF THE PROPOSED STRUCTURE OF COLLAGEN

The cylindrical polar co-ordinates given are with respect to the axis of the major helix

Atom	*r* (Å.)	Degrees	*z* (Å.)
C_1	1·15	0·0	0·00
C_1'	2·27	12·0	1·00
O_1	3·26	–3·6	1·15
N_1	2·43	38·8	1·70
H_1	2·15	63·1	1·71
C_2	3·52	35·4	2·72
C_2'	2·93	23·0	3·96
O_2	1·75	17·5	4·16
N_2	3·79	15·8	4·82
H_2	4·78	18·1	4·70
C_3	3·47	2·0	6·00
C_3'	2·50	18·7	6·86
O_3	2·68	45·5	6·50
N_3	1·95	1·8	7·87
H_3	2·29	–24·4	8·04
C_4	1·15	30·0	8·85

The two-bonded structure is found to be highly specific and is satisfactory only for a coiled-coil structure with a twist close to 30° for three residues, and is definitely unsatisfactory for twists of 10° and 50°. It is also satisfactory only for a residue-height close to 3·00 Å. Thus, it is possible to explain stereochemically why collagen occurs with the particular structure actually found and why the parameters are the same for collagen obtained from widely different sources. The inextensibility of the collagen structure can also be explained on the basis of the steric hindrance produced by the proline and hydroxyproline residues.

Although, when the sequence gly-pro-hypro occurs, two bonds cannot occur systematically, the above structure can be slightly modified locally to incorporate this sequence. The detailed co-ordinates for such a modified structure have also been worked out.

Finally, it may be mentioned that the calculated Fourier transform of the new structure is in good agreement with observation, and its expected infrared dichroism is also consistent with the observations.

Thus we would expect that most of the residues in the regular collagen structure would take up a two-bonded configuration, which is highly specific. It should, however, be mentioned that other types of linkages such as ester linkages and gamma-peptide linkages have been reported for collagen, but the number of these is so small that the main structure is not likely to be affected by these.

We wish to thank Messrs. Y. T. Thathachari, B. R. Lakshmanan, and C. Ramakrishnan, who also collaborated in this project. The detailed results are to be published elsewhere.

Effect of Temperature on the Concentration of Free Radicals in Melanins from *Allium cepa*

IN a previous communication we reported the presence of free radicals in the seeds of the onion *Allium cepa*[1]. Further investigations have shown that these free radicals are attributable to the melanins present in the black seed-coats.

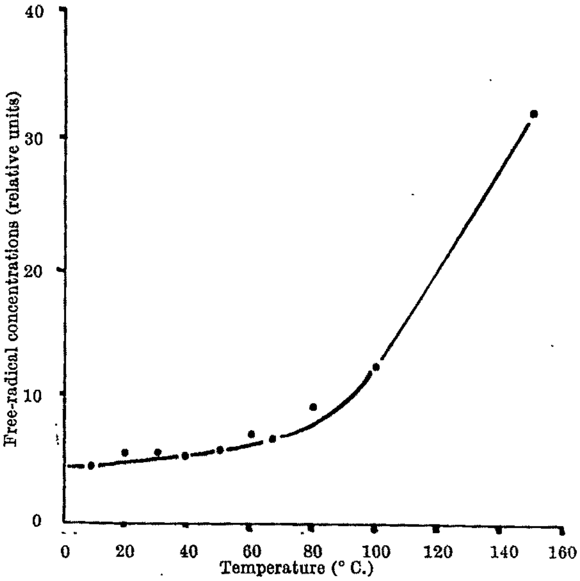

Fig. 1. Variation with temperature of free radical concentrations in onion seeds

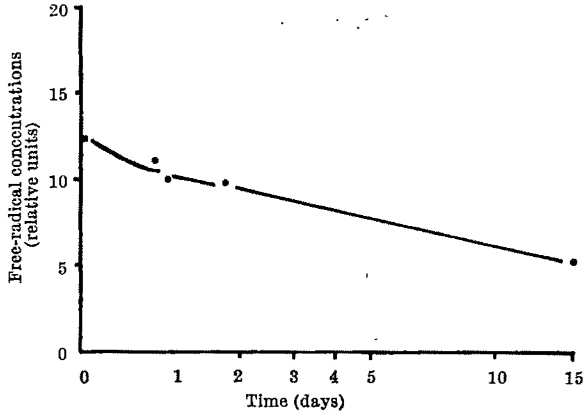

Fig. 2. Rate of decay in liquid oxygen (seeds heated to 100° C.)

Batches of 10 similar seeds were kept at a specified temperature for 15 min. and then placed in the liquid oxygen-surrounded cavity of a microwave spectrometer (125 kc./s. field modulation; x-band model, with automatic locking of klystron frequency to that of the cavity).

Fig. 1 shows the effect of temperature on the relative free-radical concentration, there being a marked increase in the seeds kept at 60° C. and above. The signal diminished in strength with time (the seeds being kept in liquid oxygen throughout the experiment). The fall was quite rapid over the first 3 hr. and slower thereafter. A similar effect of temperature on the signal strength was found to occur with seed-coats alone, or with melanin extracted from seeds by refluxing with concentrated potassium hydroxide. Melanins extracted from such widely different sources as *Calliphora* adults, *Rana* tadpoles, human hair and dark-coated seeds of *Dianthus barbatus*, *Delphinium* sp. and *Aesculus hippocastanum* gave results essentially similar to those described for onion seeds. Barley, marrow and French beans seeds without melanin in their seed coats gave no appreciable signal. Ingram, Allen and Mason[2] have described the presence of unpaired electrons in melanin extracted from *Sepia* ink and *Calliphora* pupæ.

Adenosine Triphosphate- and Coenzyme *A*-dependent Decarboxylation of Oxalate by Extracts of Peas

Despite the wide distribution of oxalic acid in plants, and its high concentration in certain tissues[1], very little is known of its metabolism. Investigations with whole plants indicate that the acid is either metabolically inert[2,3] or metabolized slowly to glycollic acid[4]. Work with cell-free extracts, on the other hand, has demonstrated that the enzyme oxalate oxidase is widely distributed in higher plants. This enzyme has been shown to be associated with the 'particulate fraction' of sugar beet leaves[5,6] and roots[7].

The following report provides evidence for the presence, in extracts of germinating pea cotyledons, of an enzyme system which catalyses an adenosine triphosphate (ATP)- and coenzyme *A*-dependent conversion of oxalate to formate and carbon dioxide. The enzyme system is associated with the supernatant fraction obtained after centrifugation of a homogenate at 10,000g for 30 min., and does not require oxygen for activity.

Pea seeds (*Pisum sativum*, var. Telephone) were germinated in moist peat moss for five days. The cotyledons were homogenized with twice their weight of a solution containing 0·45 M sucrose, 0·2 M *tris* buffer of pH 7·2, and $5 \times 10^{-4} M$ 2,3-dimercapto-1-propanol. The homogenate was squeezed through cheese cloth, the filtrate centrifuged at 1,200g for 7 min., and the supernatant so obtained centrifuged at 10,000g for 30 min. This crude supernatant was used as a source of the enzyme system. To demonstrate co-factor requirements, the crude supernatant was adjusted to pH 6·0 with 1 M acetic acid and centrifuged at 10,000g for 10 min. The clear supernatant solution was brought to pH 7·2 with 1 M potassium hydroxide, and dialysed for 3 hr. against 0·01 M *tris* buffer at pH 7·2. All operations were carried out at 0–3° C.

Table 1 shows the co-factor requirements for the decarboxylation of oxalate-1,2-^{14}C. The reaction was carried out in a conventional Warburg vessel, $^{14}CO_2$ being absorbed by 0·2 ml. 20 per cent potassium hydroxide in the centre well. After 30 min. incubation at 30° C., the reaction was stopped by tipping saturated potassium bisulphate from the side arm. Carbon-14 labelled carbon dioxide was precipitated as barium carbonate and the counts/min. determined with a Geiger–Müller tube. The results demonstrate an absolute requirement for ATP and coenzyme *A*. Omission of glutathione or magnesium ions causes a significant decrease in the rate of decarboxylation. Omission of phosphate causes a slight stimulation in the rate, while omission of thiamine pyrophosphate has little effect. By treatment of the enzyme system with 'Deacidite *FF*' in the chloride form, it is possible to demonstrate a stimulation in the rate of decarboxylation by the addition of thiamine pyrophosphate.

Table 1. Co-factor Requirements for the Decarboxylation of Oxalate-1,2-^{14}C

Components	$^{14}CO_2$ Counts/min.
Complete	1,012
Minus ATP	8
,, coenzyme *A*	7
,, glutathione	888
,, thiamine pyrophosphate	929
,, magnesium chloride	570
,, phosphate	1,255

The complete reaction mixture contained 1 μmole oxalate-1,2-^{14}C (12,200 counts/min.); 0·5 ml. enzyme (approx. 5 mgm. protein); 100 μmoles phosphate buffer pH 7·2; 5 μmoles glutathione; 0·1 μmole thiamine pyrophosphate; 0·1 μmole coenzyme *A*; 5 μmoles magnesium chloride; 5 μmoles ATP. Final volume 2·0 ml., pH 7·2

The stoichiometry of the reaction was demonstrated by incubating 1·14 μmoles of oxalate-^{14}C (100,000 counts/min.) with the enzyme system under the conditions shown in Fig. 1. At fixed times the reaction was stopped and $^{14}CO_2$ was determined as described here. Each reaction mixture was then extracted continuously with ether for approximately 20 hr., the ether extract so obtained evaporated to a small volume under a flow of ammonia gas, and the concentrated extract made up to a known volume. An aliquot of each of the extracts was chromatographed in 95 per cent ethanol/concentrated ammonia, 100:1 (v/v)[8]. A radio-autograph of the chromatogram

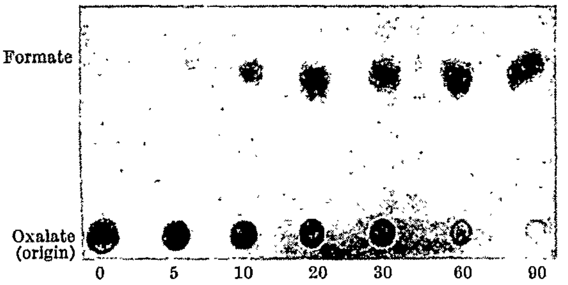

Fig. 1. Formation of formate-^{14}C during decarboxylation of oxalate-^{14}C. To each reaction vessel was added 1·14 μmoles oxalate-1,2-^{14}C (100,000 counts/min.); 1·0 ml. crude supernatant (approx. 27 mgm. protein); 5 μmoles glutathione; 0·1 μmole thiamine pyrophosphate; 0·1 μmole coenzyme *A*; 5 μmoles magnesium chloride; 10 μmoles ATP; 0·2 ml. 20 per cent potassium hydroxide in the centre well of a conventional Warburg vessel. Final volume 2·0 ml., *p*H 7·2. Temperature, 30° C.

(shown in Fig. 1) illustrates that the decarboxylation of oxalate-^{14}C is accompanied by the formation of a radioactive compound migrating ahead of oxalate-^{14}C. This compound was identified as formate-^{14}C by (*a*) two-dimensional co-chromatography with authentic formate, using 95 per cent ethanol/concentrated ammonia, 100:1 (v/v)[8], in the first dimension (R_F, 0·37), and absolute ethanol/16 per cent ethylamine, 4:1 (v/v)[9], in the second dimension (R_F, 0·65); (*b*) steam volatility under acid conditions; (*c*) degradation to $^{14}CO_2$ by mercuric acetate[10].

Aliquots of the above extracts were assayed for formate-^{14}C and oxalate-^{14}C. Formate-^{14}C was first estimated by degradation to $^{14}CO_2$ by mercuric acetate. Oxalate-^{14}C was then estimated by degradation to $^{14}CO_2$ by ceric sulphate[11]. This procedure was found to give satisfactory quantitative recoveries using mixtures of authentic oxalate-^{14}C and formate-^{14}C. The results shown in Table 2 demonstrate that the decarboxylation of each mole of oxalate-^{14}C results in the formation of one mole of formate-^{14}C and one mole of $^{14}CO_2$.

Table 2. STOICHIOMETRY OF OXALATE DECARBOXYLATION

Incubation time (min.)	Oxalate-1,2-^{14}C decarboxylated (μmoles)	Formate-^{14}C formed (μmoles)	$^{14}CO_2$ formed (μmoles)
0	0·00	0·02*	0·00
5	0·14	0·12	0·10
10	0·25	0·28	0·29
20	0·58	0·55	0·57
30	0·73	0·71	0·70
60	1·09	1·11	0·96
90	1·11	0·97	1·05

Conditions were the same as those described for Fig. 1. All samples were counted as barium carbonate. Each figure represents the mean of two determinations. The maximum deviation from the mean was ± 0·04 μmole.

* Separate experiments showed that up to 2 per cent of oxalate-^{14}C was consistently degraded to carbon-14 labelled carbon dioxide by mercuric acetate. The error is not known exactly for each estimation, but in every case represents a potential error less than the maximum deviation of ± 0·04 μmole.

It has not been possible to determine the stoichiometry of ATP in the reaction, since the enzyme system is quite crude. Coenzyme *A* is required only in catalytic quantities.

On the basis of the above evidence, the following scheme for decarboxylation of oxalate is suggested:

$$\text{Oxalate} + \text{coenzyme } A \xrightarrow{\text{Mg}^{++}\text{, ATP}} \text{oxalyl coenzyme } A$$
$$\text{Oxalyl coenzyme } A \longrightarrow CO_2 + \text{formyl coenzyme } A$$
$$\text{Formyl coenzyme } A \longrightarrow \text{formate} + \text{coenzyme } A$$

The reaction sequence is similar to that demonstrated by Jakoby *et al.*[12] for extracts of *Pseudomonas* grown on oxalate, and by Quayle *et al.*[13] for *P. oxalaticus* extracts. However, in both these systems oxalate was not activated directly, but required catalytic quantities of acetate[12] or succinate[13]. Treatment of the pea enzyme system with 'Deacidite *FF*' in the fluoride form failed to reveal a requirement for either acetate or succinate.

At present it is difficult to suggest a physiological role for this enzyme system in plants. The participation of ATP and coenzyme *A* suggests that the reaction may have some significance in the energetics of intermediary metabolism.

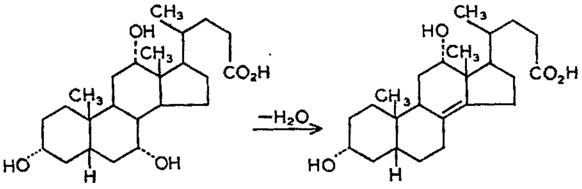
Carcinogenic Activity of Apocholic Acid

THE production of cancer by bile acids is a topic of far-reaching interest, because of the natural occurrence and biosynthesis of these substances in the body and of their molecular structure, which places them in the biologically essential family of steroids. In view of this, the two main bile acids, namely, cholic acid and deoxycholic acid, have often been tested for carcinogenicity, but results have so far been either negative or controversial. Thus, while both Ghiron[1], and Cook *et al.*[2], were able to produce sarcomas in mice by subcutaneous injection of deoxycholic acid, Shear *et al.* recorded negative results with both cholic and deoxycholic acid and attributed the sarcomas described in the literature to the possible influence of the solvent used[3]; more recently, Klein also reported negative results using the intramuscular route[4]. It was, therefore, evident that if these acids were carcinogenic, their activity was weak in degree and not constantly reproducible.

This communication reports experiments made with apocholic acid (II), a product of mild dehydration of cholic acid (I), and the results indicate a definite carcinogenic activity for this compound.

Forty-two 3-month-old male mice of strain *XVII nc/Z* (Radium Institute) were given subcutaneous injections in the right flank (10 times with 10-day intervals between each injection) of 0·5 mgm. of apocholic acid dissolved in 0·2 c.c. sterile neutralized olive oil. Fourteen mice which died between the 120th and 217th day following the start of our



(I) (II)

experiment showed no tumour at the site of injection. The first sarcoma to be observed *in situ* occurred on the 204th day, and the animal died on the 227th day; three other mice developed sarcomas on the 230th, 241st, and 370th day, respectively.

Spontaneous sarcomas of the soft parts have never been observed in our strain of mice; nor could the excipient be held responsible for the production of the tumours: every year since 1955 a control group of some 40–60 mice are given 10 injections of 0·2 c.c. of the oil referred to above, and in similar conditions, and out of a total of 350 animals thus treated (120 of which survived over 500 days and 66 over 700 days) none has ever shown a tumour at the site of injection.

It is worth mentioning that both deoxycholic and apocholic acid are powerful complexing and enolizing agents, giving stable addition-compounds ('choleic acids') with numerous organic molecules[5]. The present work adds experimental evidence to the proposition that certain steroids with an appropriate molecular structure are able to produce tumours *in situ*[6]; it also lends support to the theory which postulates an enolization of proteins through van der Waals forces as an early step in certain mechanisms of chemical carcinogenesis[7].

We thank the National Cancer Institute, U.S. Public Health Service, for a grant, and Dr. E. Mosettig for a sample of pure apocholic acid.

Interaction of Proteins and Nucleotides in Buffered Aqueous Solutions

A NUMBER of reports have appeared in the literature on the binding of organic ions by proteins. Klotz and Luborsky[1] have discussed the influence of various solvents on the binding of such ions and the nature of the complexes which are formed. Kakuliya[2], studying the interaction of proteins with electrolytes, noted a decreased rate of specific conductivity and an increased *p*H when adenosine triphosphate (ATP) was added to a protein solution. Tonomura and Morita[3] observed the binding of pyrophosphate by myosin *A* and myosin *B*.

During the preparation of solutions containing ATP and albumin, Katz (personal communication) noted the formation of a precipitate. Since the solutions were not well buffered, we assumed that the precipitate was due simply to the formation of an insoluble un-ionized salt similar to protein precipitates formed by the action of trichloroacetic or phosphotungstic acid on aqueous solutions of proteins.

We have investigated this precipitation of nucleotides and proteins under rigorously controlled conditions of *p*H and of nucleotide and protein concentration and wish to report the results of our preliminary experiments.

In our first experiment the precipitation of albumin by ATP was investigated. All reactions were carried out in 7·0 ml. of McIlwain buffer at the *p*H's and concentrations shown in Table 1. All mixtures were centrifuged at 2,500 r.p.m. The supernatants were analysed for protein by a modification of the biuret reaction[4] and for ATP by measuring the optical density at 260 mμ in a Beckman *DU* spectrophotometer.

It may be seen from Table 1 that there is complete precipitation of albumin at *p*H's below the isoelectric point of the protein and virtually no precipitation at *p*H's above this point.

Similar investigations were carried out using lysozyme, hæmoglobin, and human globulins. All these proteins were found to interact with ATP when the *p*H was on the acid side of the isoelectric point of the protein, but not when it was on the alkaline side. This could also be demonstrated when ATP was replaced by triphosphates of other purine or pyrimidine ribosides, but not when the corresponding diphosphates or monophosphates were used. We are at present trying to establish the quantitative nature of these reactions.

In another series of investigations the behaviour of the precipitate was examined. The precipitate formed by ATP and albumin was centrifuged and redissolved in distilled water. It was then lyophilized and dissolved in 0·05 ionic strength veronal buffer, *p*H 8·6. Paper electrophoresis of this solution yielded a single spot, the mobility of which was the same as that of the original albumin from which the precipitate was formed.

Similar results were obtained when albumin was replaced with hæmoglobin, lysozyme, and human globulins. In the case of lysozyme the enzymatic activity was found to be unaltered when the precipitate was redissolved.

The ability of ATP to react with serum proteins was also examined. To 0·5 ml. of human serum (dialysed against isotonic saline, *p*H 4·6) was added a solution of ATP buffered at *p*H 4·6. The precipitate was obtained by centrifuging and redissolved in isotonic saline at an alkaline *p*H. Paper electrophoresis of this solution yielded spots with mobilities equal to those of human globulins, but no spots with the mobility of albumin. Paper electrophoresis of the supernatant of the original precipitate resulted in a single spot which migrated with human albumin at *p*H 8·6 and *p*H 7·4.

Selective precipitation has been of limited value as a preparative tool because of possible alterations of the proteins, both those precipitated and those remaining in solution. However, our results indicate that little, if any, alterations occur when ATP is used as the precipitating agent. This may have some limited application in the separation of proteins. Furthermore, it is felt that this reaction may have a bearing on the transport and storage of high-energy phosphate compounds.

Electrophoretic Mobility of Cultured Mesodermal Tissue Cells

AMBROSE *et al.*[1] have shown that individual tumour cells from hamster kidney possess a significantly greater electrophoretic mobility than normal homologous kidney cells. Later, Purdom *et al.*[2] obtained a correlation between the development of a mouse sarcoma and the progressive increase in the negative electrophoretic mobility of individual cells obtained from this sarcoma at various stages of its development. As the tumour cell acquired more malignant properties, evinced by the formation of early metastases, the negative electrophoretic mobility of individual cells was observed to have increased.

Recently, Ben-Or *et al.*[3] observed that the electrophoretic mobility of individual cells from adult rat liver during regeneration was appreciably greater than that of homologous non-regenerating liver cells. They suggested that the raised electrophoretic mobility of the former was an expression of growth in general rather than of malignancy in particular.

We have found that mouse fibroblasts cultured by conventional methods from embryonic tissue, mouse subcutaneous fibroblasts[4] strain *L*, clone 929 (obtained from Mrs. A. A. Newton, Department of Biochemistry, The University, Cambridge) and fibroblasts cultured from the hearts of adult mice show reproducible microelectrophoretic mobilities, which are the same for fibroblast cultures freed from the glass either mechanically (policemen) or enzymically (trypsin).

The embryonic fibroblasts possess a mobility significantly greater than the adult fibroblasts, with the *L*-strain fibroblasts exhibiting an intermediate electrophoretic mobility (Table 1).

All tissue cells were prepared for microelectrophoresis by the procedure used for human erythrocytes[5]. The electrophoretic mobility measurements on the cells were made in a cylindrical microelectrophoresis chamber at 37·0 ± 0·1° as described previously[6]. A mobility determination was based on the migration of about one hundred individual cells. No appreciable divergence in the electrophoretic mobility of individual batches of cells has been observed from one culture to another. Human erythrocytes washed in the same 0·145 *M* aqueous sodium chloride system were used as a reference standard[5].

Table 1. MOBILITIES OF VARIOUS CELLS IN 0·145 *M* SODIUM CHLORIDE: 3×10^{-4} *M* SODIUM BICARBONATE, at 37·0 ± 0·1°

System	*p*H	Mobility (μsec.$^{-1}$ V.$^{-1}$ cm.)
Embryonic mouse fibroblasts	6·0–8·0	−0·97 ± 0·05
Adult mouse fibroblasts	6·0–8·0	−0.82 ± 0·05
L-strain mouse fibroblasts	6·0–8·0	−0·88 ± 0·05

The *L*-strain fibroblasts, originally derived from Earle's 20-methylcholanthrene-treated strain *L* which produced sarcomata on injection into *C3H* strain mice, can probably be considered to be malignant. However, sub-lines of the *L*-strain may differ from the original in a number of ways, as a result of transformations during the long period since the initial cloning[7]. Any direct comparisons between the *L*-strain and the embryonic and adult fibroblasts (cultured only for about 100 hr.) may be misleading. The *L*-strain, however, does exhibit an electrophoretic mobility greater than that of the adult fibroblasts in keeping with the observations in ref. 1. Though any electrophoretic mobility measurements made on tissue cells after washing and removal from a natural or a culture medium must be viewed with caution in relation to the behaviour *in vivo*, it is probably permissible to compare the mobility of the adult and embryonic fibroblasts cultured *in vitro* (Table 1).

The higher electrophoretic mobilities of the embryonic fibroblasts as compared with the adult fibroblasts support the views expressed in ref. 3. A raised electrophoretic mobility is therefore probably associated with growth in general and thus it is not simply the higher net negative electrokinetic charge of malignant cells which is the significant factor in their invasiveness.

Identification of 20β-Hydroxy-pregn-4-ene-3-one in Luteal Tissue from Pregnant Whales

USING biological methods of assay, several authors have reported gestogen activity in extracts of whale corpora lutea[1–4]. Prelog and Meister[5] were the first to isolate progesterone from this source by a chemical method and reported amounts of 3 mgm. per 100 gm. tissue. In addition to progesterone the biologically inactive 5α-pregnane-3β-ol-20-one was also found. These two substances seem to be the only steroids isolated from the reproductive organs of the whale.

Since either 20α- or 20β-hydroxy-pregn-4-ene-3-one, or both, have been shown recently to be naturally occurring gestogens in several mammalian species, it seemed of interest to make a search for these compounds in the whale as well.

In this investigation a combination of chromatographic and spectrophotometric methods was applied to extracts of luteal tissue from pregnant fin-whales (*Balaenoptera physialus* L.). The tissues were collected in the Antarctic and kept frozen until processed.

Portions of tissue were homogenized and extracted with ethanol/ethyl ether (3 : 1). After removal of fatty material by repeated precipitations in cold 70 per cent methanol, the methanolic solution was shaken with three times its volume of petroleum ether (boiling point 40–60° C.) and collected. The petroleum ether was then extracted with five additional volumes of 70 per cent methanol, the pooled extracts evaporated, the residue taken up in a small volume of absolute methanol and chromatographed on paper. Evaporations were made at reduced pressure below 60° C. For chromatography the ligroin–80 per cent methanol system of Zander and Simmer[6] (system 1), and the heptane–formamide system of Zaffaroni (system 2) were used.

Three compounds were easily detected by contact photography of chromatograms using light of 253 mμ. Their ultra-violet absorption spectra in methanol with a distinct maximum at 240 mμ and the positive soda fluorescence reactions indicated the presence of the Δ^4-3-keto-grouping in the steroid molecule. After rechromatography in system 1, one compound moved like progesterone. It was present in large amounts, and its infra-red absorption spectrum was shown to be identical with that of progesterone. The second compound showed chromatographic behaviour like 20β-hydroxy-pregn-4-ene-3-one in both system 1 and 2, both as the free and acetylated compound. More material was processed, and the substance was isolated in quantities sufficient for registration of the infra-red absorption spectrum, which was found to be identical with that of the authentic 20β-hydroxy-pregn-4-ene-3-one.

The third substance was chromatographically similar to 20α-hydroxy-pregn-4-ene-3-one in both the free and acetylated form in system 1. However, in system 2 it moved faster than this substance, both free and acetylated. Moreover, it showed a negative reaction to the iodine test, which is considered to be rather specific for the 20α-grouping. The identity of this substance remains to be established.

From the observations reported, it seems safe to conclude that both progesterone as well as 20β-hydroxy-pregn-4-ene-3-one are naturally occurring gestogens in the whale. This corresponds to those found in the horse[7] and the cow[8], while in man both the 20α- and 20β-hydroxy compounds are present in addition to progesterone[9]. In rat ovarian tissue 20α-hydroxy-pregn-4-ene-3-one and progesterone have recently been found to be reversibly interrelated[10]. Species variations in stereospecific enzymes in gestogen metabolism therefore seem to occur. The observations reported here for the whale add to our knowledge about such variations.

We are indebted to Prof. Å. Jonsgård, University of Oslo, for his aid in obtaining material from whales, to Prof. W. Klyne, London, for generous gifts of reference compounds, and to S. Veige, chemical engineer, AB Leo, Hälsingborg, Sweden, for recording and interpretation of infra-red absorption spectra.

Antibodies blocking Neutralization of Penicillinase by the Homologous Antiserum

Immunization of rabbits with purified exopenicillinase of *Bacillus cereus* results in the appearance of antibodies which neutralize approximately 90 per cent of the activity of the enzyme[1,2]. The present communication describes the preparation and some of the properties of neutralization-blocking antibodies, evoked by injection of penicillinase-producing cells. Immune serum containing neutralization blocking antibodies will be referred to as 'blocking antiserum'.

The strains of *B. cereus* used in this work were the wild-strain 569, which forms penicillinase following induction with penicillin, and the mutant-strain 569/*H*, derived from strain 569, which forms penicillinase constitutively.

Neutralizing antiserum was prepared by immunizing rabbits with a highly purified preparation of exopenicillinase produced by strain 569/*H* of *B. cereus*[3]. 20 mgm. of the enzyme were administered with Freund's adjuvant in 3 intramuscular injections at 10-day intervals.

Blocking antiserum was prepared by immunizing rabbits with intact cells of *B. cereus* 569/*H*. The cells were collected from a 12-hr. old broth culture, washed with, and resuspended in, physiological saline. The immunization consisted of 7 subcutaneous injections over a period of 40 days. Each dose contained 100 mgm. bacterial dry weight.

Absorption of antibodies was carried out by mixing equal volumes of sera and packed bacterial cells and incubating for 2 hr. at 37° C. The mixture was kept for 20 hr. at 4° C. before cells were removed by centrifuging.

The effect of the blocking antiserum on the interaction of penicillinase with the neutralizing antiserum was assayed in the following way. 0·2 ml. aliquots of a purified penicillinase preparation (575 units/ml.) were incubated (30 min. at 28° C.) with 0·2 ml. of the appropriate dilutions of the blocking antiserum. A quantity of neutralizing antiserum in excess of that required for maximal neutralization (1,000 neutralization units in 0·2 ml.) was added and the mixture incubated for another 30 min. Normal rabbit serum replaced blocking antiserum, neutralizing antiserum or both in the respective control tubes. The activity of penicillinase was assayed by the iodometric method[4].

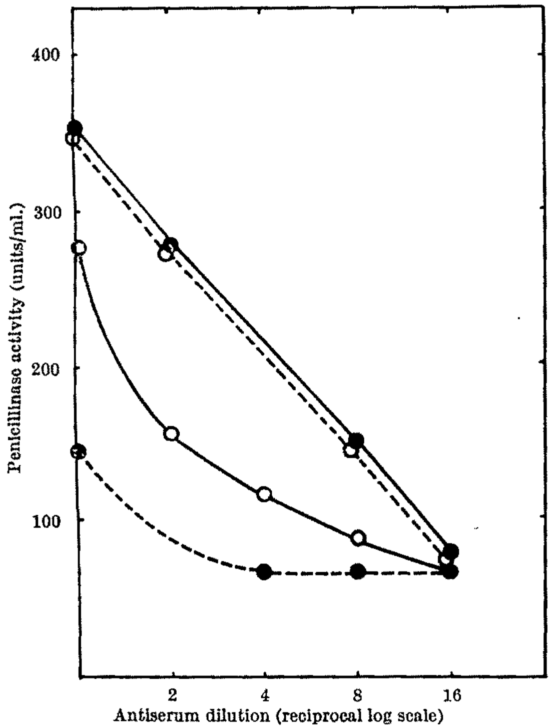

Fig. 1. Activity of penicillinase incubated with neutralizing serum, following exposure to serial dilutions of 'blocking antiserum'. The 'blocking antiserum' was treated as follows: ● - - - - ●, Absorbed with constitutive cells; ○——○, absorbed with induced cells; ○ – – – ○, absorbed with non-induced cells; ●——●, untreated

The results, presented in Fig. 1, are expressed as residual enzyme activity following incubation with varying dilutions of the blocking antiserum and excess of neutralizing antiserum. Also shown in Fig. 1 is the effect of absorption of the blocking antiserum by the homologous (569/*H*) cell suspension, and by both induced (that is, penicillinase forming) and non-induced cells of the parent strain 569.

It will be noted that the undiluted non-absorbed blocking antiserum interferes strongly with inhibition of penicillinase by the neutralizing antiserum. The inhibition decreases as the blocking antiserum is diluted. Blocking antibodies are removed largely by absorption with the homologous cells, and, to a lesser extent, by absorption with induced 569 cells. Absorption with non-induced 569 cells has no effect on the blocking titre of the antiserum.

The blocking antiserum agglutinates cells of the constitutive (569/*H*) strain and, to a lesser degree, induced cells of the adaptive strain 569. The agglutinating titre for non-induced cells is very low. Thus the susceptibility to agglutination by the blocking antiserum appears to be related to the level of penicillinase formed by the cell. A similar correlation has been found in cross-absorption experiments. Absorption of the antiserum with constitutive cells resulted in complete removal of agglutinins, whereas absorption with non-induced cells had no effect on the titre of agglutination of constitutive cells. Induction of penicillinase imparted to the adaptive cells a limited ability to absorb agglutinins. The results are summarized in Table 1.

The close correlation between the blocking and agglutinating properties of the antiserum suggests that both activities may be due to a single species of antibody, directed to cell-bound penicillinase.

Table 1. AGGLUTINATING TITRE OF THE 'BLOCKING ANTISERUM'

Serum absorbed with	Cell suspension agglutinated		
	Constitutive	Induced	Non-induced
(*a*) Constitutive cells	0	0	0
(*b*) Induced cells	1 : 640	1 : 40	0
(*c*) Non-induced cells	1 : 1,280	1 : 80	0
(*d*) Not absorbed	1 : 1,280	1 : 80	1 : 20

A difference in the immunological response to cell-bound and to extracellular penicillinase was to be expected on the basis of established antigenic differences between the two states of the enzyme[4,5].

Quite apart from the structural aspects of the bound and free forms of bacterial penicillinase, the present observations may bear on the problem of *in vivo* resistance to penicillin. The acquired resistance to penicillin of clinically important micro-organisms depends in most cases on their ability to form penicillinase[6]. Formation of penicillinase-neutralizing antibodies could thus be regarded as a specific component of the acquired defence mechanism of the host. Modification of the host response, along the lines described, might have a distinct survival value for the infecting agent.

PHYSIOLOGY

Effect of Temperature on the Retinal Slow Potential of the Horseshoe Crab

IN a previous paper[1] we indicated that the retinal slow potential, a generator potential, of the horseshoe crab (*Tachypleus tridentatus*) decreased in its amplitude as the time in darkness before illumination is reduced, even if stimuli of equal intensity and duration were applied. This depressive effect of the short time-interval is compatible with the 'depression'[2] or 'refractoriness'[3] of the receptor potential of the Pacinian corpuscles. It was found that the grade of 'depression' as well as the amplitude of the retinal slow potential is affected by changes in temperature, though the resting potential seems to be little influenced.

The retinal slow potentials were recorded intracellularly from single ommatidia of the horseshoe crab by the same procedure as that described by another author[4]. The temperature of the bathing solution could be varied between 6° C. and 23° C. by controlling the inflow of the cold or warm oxygenated physiological solution for the horseshoe crab[5] or sea-water which was stored in a cylinder, and was measured by employing a thermocouple which was placed by the preparation.

The records illustrated in Fig. 1 are responses obtained after 60 (column *A*) and 15 (column *B*) sec. in darkness at various temperatures. As shown in

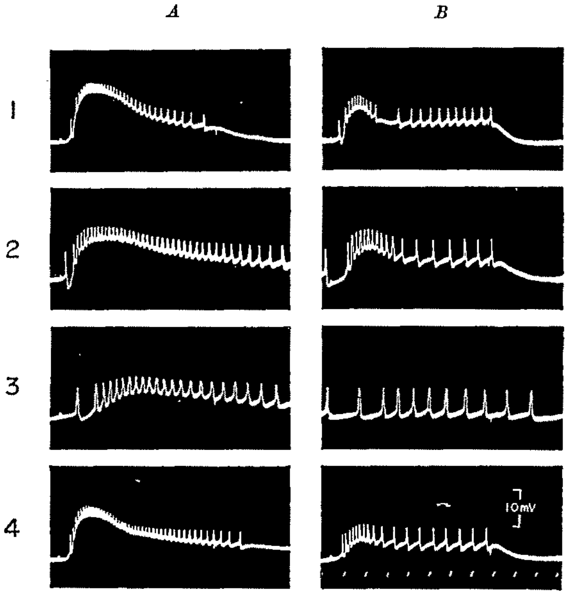

Fig. 1. Effect of temperature on the action potentials arising within a single ommatidium of the horseshoe crab. Records in column *A* and *B* were obtained by the same stimuli after 60 and 15 sec. in darkness at various temperatures. From the top records downwards, 12, 9, 6 and 12° C. The onset and turn-off of illumination are indicated as pips. Note the reverse effect of temperature on the amplitude of the slow potential and the spike potential. Time, 0·1 sec.

Fig. 1, differences in the shape of the slow potential due to its time in darkness before illumination were also found at different temperatures. In addition, the separation of the initial maximal and the decreased, sustained depolarization, which is usually clearer in the responses obtained by illumination of high intensity and after a shorter time in darkness or at high temperature, became indistinct at low temperature (records 3 in column *A* and *B*) as the result of the prolongation of the falling phase of the initial maximal depolarization. In most other experiments, flashes which are short enough to obtain simple responses without any additional decreased depolarization were applied to make the measurement of the falling phase of the slow potential easier.

The temperature coefficient of the amplitude of the maximal depolarization of the slow potential was much larger than that reported in the propagated action potential of nerve[6] and muscle[7] fibres. Its Q_{10} was positive and ranged from about 3 to 5 in the responses obtained after 60 sec. in darkness. It should be mentioned that the temperature coefficient of the duration of the rising phase was larger than that of the falling phase, being negative. On the other hand, the temperature coefficient of the amplitude of the spike potential generated by the retinal slow potential was negative, as it is in the giant axon of the squid[6].

The records of the bottom row of Fig. 1 were taken after the temperature had been raised once more to that of the top records. The amplitudes of the slow potentials were both smaller than their initial figures. This after-effect of cooling was often observed under our experimental conditions in which temperature was lowered at the rate of about 0·5° C./min., and raised at about 1° C./min. This seems not to be due to the depolarization of the membrane potential during the temperature run, since it could appear without any significant change in the resting potential in most cases. Thus the after-effect can be explained by saying that when the temperature is changed it takes time for the new functional level to establish itself.

These effects of temperature on the slow potential indicate that some chemical processes are probably involved in the generation of the retinal slow potential, one of them being suggested by Fuortes[8]. A detailed report on the effect of temperature on the electrical activity of the sensory cell in the lateral eye of the horseshoe crab is being prepared for publication.

Binding of Calcium Ions by the Aorta

PREVIOUS work[1] has shown that the aorta has an inherent ability to bind calcium ions *in vitro*. This binding in turn had a marked influence on the stability of emulsions, causing precipitation. The distribution and solubility characteristics of the primary substance suggested that collagen was responsible for the calcium binding, although other possibilities were recognized. Because of the importance attributed to binding of calcium ions by the aorta in plaque formation[1], further work is reported here to add to the information concerning the identity of the binding agent(s). This was accomplished by noting the effect of various enzymes and extractive procedures on the aortic binding of calcium chloride labelled with calcium-45 which could be followed autoradiographically.

All experiments were conducted with human thoracic aortas of adult males. These were prepared as described previously[1], and used in the form of pieces 6 cm.^{2} in order to conserve material. Following decalcification with ethylenediaminetetraacetate at *p*H 7·2 in the cold and subsequent washing and extraction with acetone–petroleum ether[1], the strips were incubated overnight with the appropriate enzyme at 37° C. at optional *p*H. They were then washed free of enzyme, and incubated overnight with 3–4 μc. labelled calcium chloride in sealed vials. After washing and drying, the strips were exposed to dental film for 17 hr. within a plastic cassette. Conditions for radioautography were strictly controlled to permit comparison with control strips which were not enzymatically treated. All experiments were repeated at least twice and in duplicate. Summarized in Table 1 are the results of various treatments on the calcium-binding of the aorta. In all cases the physical appearance of the aorta strip remained intact following the experimental procedure.

These results indicate that several factors may be responsible for calcium-binding by the aorta. These are protein in nature as made evident by the fact that

Table 1

Treatment	Effect on calcium binding
(1) Hyaluronidase[2], bovine testes, 300 U.S.P. units/mgm. per 15 ml. saline-acetate, *p*H 6·0	None
(2) Elastase[3], 100 units/5 mgm., 15 ml. saline, *p*H 8·0	None
(3) Collagenase, 10 mgm./15 ml. distilled water, *p*H 7·2	Very slight reduction
(4) Alkaline phosphatase, intestinal, 180,000 Bodansky units/15 ml. saline, *p*H 8·4	Marked reduction
(5) Trypsin, twice crystallized, 10 mgm./15 ml. distilled water, *p*H 8·0	Complete elimination
(6) Extraction of soluble proteins with 0·25 *M* glucose[4]	None
(7) Extraction of chondroitin sulphate with 30 per cent KCl–1 per cent K_2CO_3[5,6]	Marked enhancement

they are completely eliminated by trypsin digestion. The present evidence would indicate that the factors are not hyaluronic acid, elastin or collagen, but probably an insoluble protein-phospholipid complex. Phospholipids, in particular the sphingomyelins, have been reported to increase in atherosclerotic aortas[7,8]. The extraction with potassium chloride–potassium carbonate appears to remove an inhibitor of the calcium binding which has the properties of a chondroitin sulphate.

Effects of Certain Androgenic Steroids on the Increase of Endometrial Carbonic Anhydrase caused by Progesterone

IT has previously been demonstrated by Lutwak-Mann[1] that, as a result of treatment of œstrogen-primed rabbits with methyltestosterone, an appreciable increase in endometrial carbonic anhydrase occurred, and that when methyltestosterone and progesterone were given simultaneously, methyltestosterone appeared to prevent the activating effect of progesterone on the endometrial enzyme. The present investigation dealt with the question of how other androgenic steroids affect the endometrial carbonic anhydrase response to progesterone. The following steroids were tested: methyltestosterone, androstenedione, androstanolone, Δ^5-androsten-3β, 17β-diol and stigmasterol.

All experiments were performed on immature albino rabbits, weighing approximately 1·5 kgm. at the beginning of the experiments. Following Clauberg's method[2], the rabbits were injected subcutaneously once daily with 5 μgm. of œstradiol for six days. After this period, progesterone and androgen were given simultaneously in five divided doses at daily intervals by subcutaneous injection into the neck of the animal. The standard dose of progesterone was 2·0 mgm. and the androgen doses varied as indicated in Table 1. On the second day after the last injection, the rabbits were killed by breaking the neck and cutting the carotid artery. The uteri were isolated and rinsed with cold saline. The endometrium was dissected and homogenized with cold distilled water. The homogenate was centrifuged and the supernatant was used for the determination of enzyme activity. The enzyme activity of the extract was estimated colorimetrically by modifying the Philpot and Philpot method[3], one enzyme unit being defined as $(T_0 - T)/T$, where 'T_0' is the reaction time without enzyme and T is the same with enzyme.

As can be seen in Table 1, a dose of 2 mgm. of progesterone caused a marked increase in the activity of endometrial carbonic anhydrase. However, when various doses of androgen were given with 2 mgm. of progesterone, the combined effect of the two steroids on the enzyme activation was rather lower than that due to 2 mgm. of progesterone alone. In a dose of 0·02 mgm., considerable lowering of endometrial enzyme activity was demonstrated in methyltestosterone, androstenedione and androstanolone. There was significant difference between the endometrial enzymes with and without androgen. Percentage inhibition of carbonic anhydrase was 42 by methyltestosterone, 52 by androstenedione and 49 by androstanolone. However, 0·02 mgm. of Δ^5-androsten-3β,17β-diol and stigmasterol were not so pronounced as the other androgens, an inhibition of 34 per cent each being observed. A total of 0·2 mgm. proved exceedingly effective for the inhibition of the effect of 2 mgm. of progesterone, causing a 47 per cent inhibition by Δ^5-androsten-3β,17β-diol and a 42 per cent by stigmasterol.

The androgens used caused a significant fall in the increased enzyme activity produced by progesterone. It seems that the anti-progestational ability is practically the same for methyltestosterone, androstenedione and androstanolone, but somewhat weaker than the others in Δ^5-androsten-3β,17β-diol and stigmasterol.

We wish to thank Dr. W. O. Nelson, of the Population Council, Inc., and Dr. G. Pincus, of the Worcester Foundation for Experimental Biology, for supporting this work. This investigation was carried

Effect of Allyl*iso*propylacetamide on Liver Metabolism

THE administration of allyl*iso*propylacetamide (AIA) causes porphobilinogenuria in rabbits[1], but it is not known whether this is caused by an increased synthesis of porphobilinogen (PBG) or a decreased utilization. PBG is synthesized in the liver via δ-aminolævulinic acid (ALA) from glycine and acetate or succinate and it seemed possible that a study of the effect of AIA on the metabolism of carbon-14-labelled glycine, acetate and succinate by rabbit liver might throw a light on the problem.

Four male rabbits (2·5–3·0 kgm.) each received 300 mgm. of AIA by stomach tube twice daily for 6 days. The urine from each animal then contained about 14 mgm./100 ml. of porphobilinogen (24 mgm./24 hr.) and 7·5 mgm./100 ml. of ALA (13 mgm./24 hr.). Four rabbits not treated with AIA were controls. The animals were killed, and chopped preparations[2] of the livers incubated with substrates labelled with carbon-14 as indicated in Table 1. The tissue was incubated for 3 hr. at 37° in air, killed and extracted with ethanol, and the ethanol-aqueous extracts chromatographed in two dimensions using phenol–water as the first solvent and *n*-butanol–propionic acid–water as the second. Radioactive substances on the chromatograms were located by radioautography and counted directly on the paper with an end-window counter[2]. The carbon-14 contained in each compound was expressed as a percentage of the total carbon-14 in the cell extract.

There was a decreased total incorporation of the isotope into the soluble intermediaries. Nevertheless, with labelled acetate and succinate as substrates considerably more carbon-14 was present in glutamic acid in the AIA-treated animals compared with the controls; this was also true for alanine when labelled succinate was used as substrate. When [2 : 3-^{14}C] succinic acid was the substrate, the radioactivity in glutamic acid and alanine was about twice as great in both groups of animals as with [1 : 4-^{14}C] succinate as substrate (Table 1). This is to be expected if these two amino-acids were derived from succinate via the tricarboxylic acid cycle and transamination. No other obvious differences in distribution of carbon-14 were seen between the tissues from AIA-treated and the control animals in the incorporation of carbon-14 into aspartic acid, glucose, proline, γ-aminobutyric acid, valine, lactic, malic and fumaric or citric acids. The lack of increased incorporation from labelled acetate and succinate into aspartate in the AIA-treated animals compared with the controls suggests that there was no increased passage of carbon atoms from the keto-acids into the corresponding amino-acids derived from them by transamination. The preferential incorporation of carbon-14 into the alanine and glutamic acid may indicate that there is an abnormality of the further metabolism of these amino-acids in the AIA-treated animals, but it seems unlikely that this is directly related to the mechanism responsible for the porphobilinogenuria.

It was impossible to interpret the experiments using [2-^{14}C] glycine because the material decomposed to a variable extent during the purification and chromatographic procedures.

We thank the Mental Health Research Fund for a personal grant to one of us (M. K.).

Inhibition of Emotional Reactions by Phenothiazine Tranquillizers

PHENOTHIAZINE tranquillizers inhibit conditioned responses of various laboratory animals. Since this action can be demonstrated by means of a great variety of methods, it is generally considered to be characteristic of these compounds. Some tranquillizers also diminish 'emotional reactions'[1–4]; but these effects have not been studied so much, mainly due to a lack of simple and adequate methods. Thus, views are still divided whether depression of the emotional reaction is a primary effect or an effect secondary to the sedative action of such drugs[3,4]. Any new technical procedure which permits the study of the influence of a drug on emotional behaviour independent of its general depressive effect, therefore, appears interesting.

Table 1. TOTAL INCORPORATION AND DISTRIBUTION OF CARBON-14 IN ALANINE AND GLUTAMIC ACID

Group of animals	Control			AIA-treated		
Substrate	[2-^{14}C]acetate	[1: 4-^{14}C]succinate	[2: 3-^{14}C]succinate	[2-^{14}C]acetate	[1: 4-^{14}C]succinate	[2: 3-^{14}C]succinate
Glutamic acid	11·1 ± 2·0 (6·7–16·3)	0·19 ± 0·05 (0·12–0·31)	0·39 ± 0·10 (0·30–0·67)	20 ± 3·7 (13–27)	0·73 ± 0·17 (0·50–1·2)	1·5 ± 0·30 (1·1–2·4)
Alanine	4·0 ± 0·75 (1·7–5·1)	2·6 ± 0·44 (1·4–3·4)	4·2 ± 0·6 (2·4–5·0)	5·2 ± 0·67 (0–1·7	4·6 ± 0·67 (2·8–5·8)	8·5 ± 2·0 (4·2–13)
Total carbon-14	95 ± 48 (35–240)	1,700 ± 280 (1,100–2,300)	1,600 ± 250 (900–2,000)	65 ± 9·2 (40–79)	1,500 ± 320 (990–2,400)	1,400 ± 270 (900–2,200)

Samples of rabbit liver (containing about 10 mgm. dry weight of tissue in a vol. of 0·25 ml.), derived from four control animals and from four animals treated with AIA, were incubated in air for 3 hr. at 37° with 5 μc. of either 1·01 μmoles [2-^{14}C]acetate, 0·46 μmole [1:4-^{14}C]succinate or 0·46 μmole [2: 3-^{14}C]succinate. The total carbon-14 incorporated into the sum of the soluble metabolic intermediates is expressed as 10^{-3} × counts/min./25 mgm. dry wt. of tissue. The radioactivity found in glutamic acid and alanine is expressed as a percentage of the total carbon-14 in the sum of the soluble metabolites. All results are given as the mean of 4 observations ± *S.E.* (range).

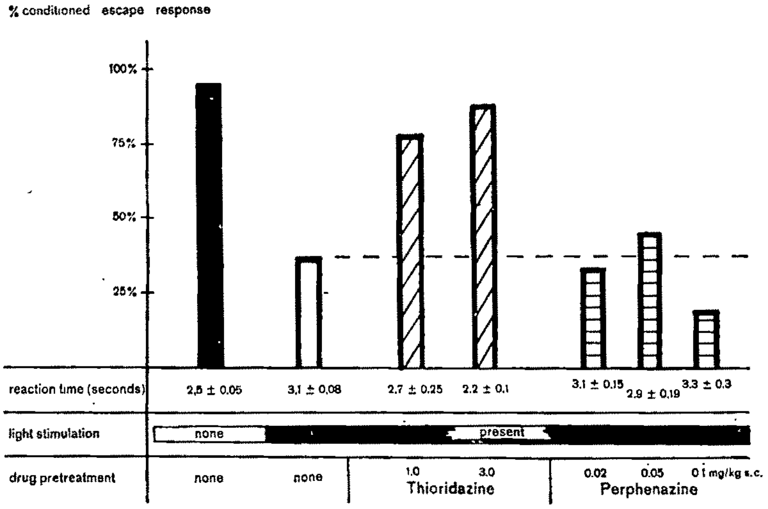

Fig. 1. An intense light stimulus prevents the normal course of a conditioned escape response in rats in a non-reinforced procedure. Thioridazine inhibits this disturbing influence. Perphenazine is ineffective in this respect, but depresses further the conditioned response

Based on frequent observations that novel stimuli which elicit an emotional reaction in rats regularly interfere with the correct performance of a conditioned response, the following test was devised: rats were trained to climb a vertical pole as soon as an acoustic signal (conditioned stimulus—tone of 500 c./s.) was sounded. The animals could thus avoid an electric shock delivered 5 sec. later through the grilled floor of the cage (conditioned escape response)[5]. Each rat was trained daily for 10 successive trials with a 1-min. interval between each trial. After an adequate training period, all rats performed the conditioned escape response correctly in 94 ± 1·1 per cent of all trials, the average reaction time being 2·4 ± 0·07 sec. During the subsequent trials, an intense light stimulus (100 W.) was applied 2 sec. prior to each acoustic signal. This stimulus terminated simultaneously with the acoustic signal either at escape or after 5 sec., that is, at the onset of the electric shock. The rats exposed to the light stimulus performed the conditioned escape response in only 63 ± 2·5 per cent of all trials with an average reaction time of 2·5 ± 0·08 sec. These results demonstrate that the light stimulus interferes partially with the conditioned escape response. Light stimulation elicited a higher degree of disturbance in a non-reinforced procedure in which no electric shock was applied, that is, conditioned escape response in only 37 ± 2·4 per cent of all trials within 3·1 ± 0·08 sec. (In control trials without light stimulation, the conditioned escape response was performed in 95 ± 0·9 per cent of all non-reinforced trials with an average reaction time of 2·5 ± 0·05 sec.)

In the circumstances, it appeared more suitable to study drug action on this disturbing influence by means of the non-reinforced procedure. In order to avoid any accommodation to the interfering light stimulus, this test was carried out only once a week, reinforced training procedure being followed on the other days. Each group alternately underwent the non-reinforced procedure alone and the non-reinforced procedure with prior light stimulation under drug therapy and saline. At least 20 trials in 10 rats were required to assess the action of one dose of drug. The compounds were administered subcutaneously 2 hr. before the test, controls receiving saline. Two phenothiazines were selected which were found in previous studies[4] to possess an opposite activity pattern: perphenazine and thioridazine. The results of these experiments are summarized in Fig. 1. Rats pretreated with thioridazine (1 and 3 mgm./kgm.) perform the conditioned escape response correctly despite the disturbing light stimulus (78 ± 7·2 per cent and 88 ± 1·9 per cent). Their reaction time is normalized or even slightly shorter than in rats not exposed to the light stimulus. Thioridazine, therefore, inhibits the disturbing influence of the light stimulus. Perphenazine, on the other hand, does not prevent the disturbing influence of the light stimulation; a minimal effect is noted with a low dose of 0·05 mgm./kgm. (45 ± 5·9 per cent), whereas higher doses (0·1 mgm./kgm.) further depress the conditioned escape response (19 ± 3·3 per cent).

It is generally assumed that an intense light stimulation elicits an emotional response in rats[6]; such emotional reactions (confusion, stupor, anxiety, etc.) can interfere with the normal operant behaviour of the animals[7] or—as shown in these experiments—with the performance of a conditioned response. The degree of depression of the motor behaviour serves as a measure of the extent of the emotional reaction. The finding that the thioridazine-treated rats perform the conditioned escape response correctly despite the disturbing light stimulus points to a primary action of this drug on the emotional response. This anti-emotive property is apparently not due to general sedation, as it is demonstrable in doses which do not inhibit the conditioned response. On the other hand, perphenazine does not inhibit the emotional reaction. However, this compound further inhibits, in relatively low doses (0·1 mgm./kgm.), the conditioned escape response.

These findings are in accord with those obtained in previous work[4,5] when it was found that thioridazine depresses selectively emotional defecation and has relatively little effect on the conditioned escape response in rats, whereas perphenazine inhibits predominantly the conditioned response and depresses emotional defecation only in higher doses. Apparently, the depression of emotional reactions on one hand, and inhibition of a conditioned escape response on the other, are, to a certain degree, two independent properties of the phenothiazine tranquillizers.

Further Evidence for Phosphatidic Acid as the Sodium Carrier

We have presented evidence[1,2] before that phosphatidic acid acts as the Na^+ carrier in the membrane of the avian salt gland. The proposed scheme for Na^+ transport involves a cycle in which disodium phosphatidate is formed at the inner surface of the membrane from diglyceride, adenosine triphosphate (ATP), and 2 Na^+, and is hydrolysed to diglyceride, orthophosphate and 2 Na^+ near the outer surface of the membrane. One of the more important questions which we would like to test in relation to this scheme is whether the rate of renewal of phosphate in phosphatidic acid is compatible with the expected rate of Na^+ transfer across the membrane.

The time-courses of the responses in this tissue can give some indication as to whether this rate is compatible with the proposed scheme. Initially, albatross salt gland slices were incubated for 90 min. in the presence of orthophosphate-phosphorus-32; various concentrations of acetylcholine (plus eserine) were then added to the medium. With each concentration of acetylcholine, samples taken at 10-min. and 20-min. intervals after the addition of acetylcholine showed the same amount of radioactivity in the phosphatidic acid with respect to the radioactivity of the orthophosphate (and the ATP) of the tissue (Table 1). The radioactivity levelled off at different and successively higher values with increasing concentrations of acetylcholine. The incorporation of phosphorus-32 into phosphatidic acid was measured at shorter intervals of time after the addition of acetylcholine in goose salt gland slices. After addition of acetylcholine, the radioactivity of the phosphatidic acid showed a rapid increase; this radioactivity reached a maximum value 1–2 min. after the addition of acetylcholine to the medium, and then levelled off and maintained this same value relative to the specific activity of the precursor for the remainder of the period tested, which was up to 20 min. after the addition of acetylcholine (Fig. 1).

To test that the levelling off of the radioactivity in phosphatidic acid was not due to a cessation of response to acetylcholine, albatross salt-gland slices were incubated with acetylcholine (10^{-4} *M*) plus eserine (10^{-4} *M*) for 90 min. before addition of phosphorus-32 to the medium; the slices were removed from the incubation bath 30 min. after the addition of phosphorus-32. Five times as much radioactivity was found in the phosphatidic acid from stimulated slices as compared with the controls. These results show that whatever the mechanism responsible for the increased incorporation of phosphorus-32 into phosphatidic acid in response to acetylcholine, this mechanism was still operating in response to acetylcholine even after 90 min. of exposure to this agent.

Table 1. The Response of Albatross Salt-Gland Slices to Different Concentrations of Acetylcholine

Additions (molar concentration) Acetylcholine	Eserine	Radioactivity of phosphatidic acid (c.p.m. per milligram fresh weight of tissue)	
0	0	50	
		10 min. after acetylcholine added	20 min. after acetylcholine added
10^{-7}	10^{-4} *M*	107	109
10^{-6}	10^{-4} *M*	150	176
10^{-5}	10^{-4} *M*	200	217
10^{-4}	10^{-4} *M*	228	224

Slices of albatross salt gland were incubated in bicarbonate saline with glucose (1 mgm. per ml.) and phosphorus-32 for 90 min. before the addition of acetylcholine and eserine. The radioactivity is expressed as total counts per min. (c.p.m.) in the phosphatidic acid from 1 mgm. fresh weight of tissue, corrected to a radioactivity of 10^4 c.p.m. per mgm. fresh weight of tissue for the orthophosphate of the tissue. Under these conditions of pre-incubation the specific activity of the 7-min. acid hydrolysable-phosphate of the ATP of the tissue was the same as that of the orthophosphate of the tissue. The values for phosphatidic acid radioactivity given are the averages from two experiments.

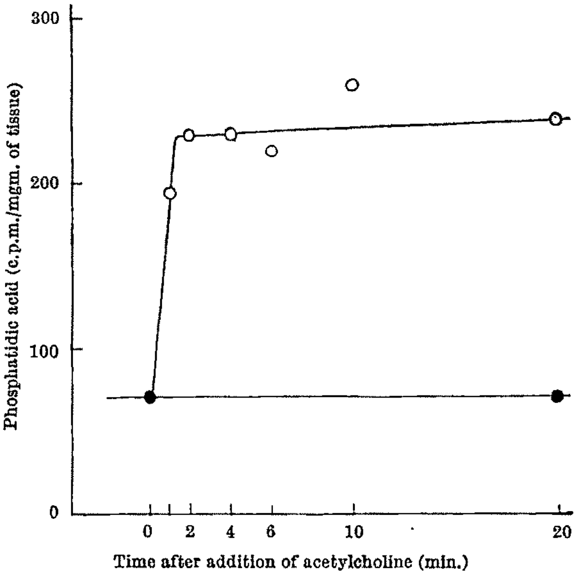

Fig. 1. Time-course of the incorporation of phosphorus-32 into phosphatidic acid on addition of acetylcholine in goose salt-gland slices. The slices were incubated with orthophosphate-phosphorus-32 for approximately 2 hr. before the addition of acetylcholine (10^{-4} *M*) and eserine (10^{-4} *M*). The radioactivity is expressed as in Table 1. The experiment was carried out three times; in each experiment slices from the same animal were incubated in triplicate for each point. Each value given is therefore the average of nine separate estimations on slices from three animals. ○, samples to which acetylcholine was added; ●, control samples incubated over a comparable time without the addition of acetylcholine

Since the renewal of phosphate in phosphatidic acid in response to acetylcholine is taking place throughout this time of exposure to acetylcholine, the maintenance of a constant level of radioactivity in the presence of a given concentration of acetylcholine must mean that a fraction of the phosphatidic acid of the cell has reached equilibrium with the precursor ATP and that this fraction is turning over without any mixing with the other phosphatidic acid of the slice. The step-wise activation in the presence of increasing amounts of acetylcholine presumably indicates the presence in the membrane of receptor sites associated with the turnover of phosphatidic acid which have different threshold values for activation by acetylcholine.

When all the activated phosphatidic acid is in equilibration with its precursor (that is, the specific activity of the activated phosphatidic acid fraction is the same as that of the ATP from which its phosphate is derived), it is not possible to calculate the rate of renewal of phosphate in the relevant phosphatidic acid fraction. This could be very great. Theoretically, the rate of renewal might be obtained from the time taken for the active fraction to reach equilibration with the ATP. However, in order for this to be related to the amount of Na^+ transported during this time, the measurement must be made under conditions in which there is instantaneous and simultaneous activation of all the sites which respond to a given concentration of acetylcholine. Approximate calculations indicate that, under such ideal conditions, equilibration would be expected to take place within a few seconds of activation. Experimentally, however, these conditions cannot be achieved in salt gland slices. It takes an appreciable time for the added acetylcholine to completely permeate the slice and to activate all the possible sites. Some lag in response can therefore be anticipated in this type of experiment due to non-synchronous activation of all the responsive sites. In view of this, the fact that an activated fraction of the phosphatidic acid reaches the specific activity of its precursor within 2 min. after the addition of acetylcholine to the medium is encouraging. It indicates that the rate of renewal of phosphate in the relevant phosphatidic acid could be sufficiently great to account for Na^+ transport by the mechanism which we have proposed.

This work was aided by grants from the United Cerebral Palsy Research and Educational Foundation, the National Institute of Neurological Diseases and Blindness, and the Wisconsin Alumni Research Foundation. It will be published in detail elsewhere.

Impairment of Erythropoiesis by Irradiation

THERE is much evidence that erythropoiesis is regulated by at least one humoral factor, erythropoietin[1], the chemical composition of which is considered to be that of a glycoprotein[2]. Investigations indicate that this hormone induces erythrocyte production by stimulating differentiation of primitive cells of the reticulum[3-5].

The ideal nature of the transfusion-induced polycythæmic mouse for *in vivo* studies of erythropoiesis was first demonstrated by Jacobson *et al.*[3]. Recently we have described the orderly wave of erythropoiesis which sweeps through the reticulum of such animals in response to a single injection of erythropoietin[6]. This communication records preliminary work on the impairment of this response produced by total-body X-irradiation of plethoric mice.

Virgin female *CF* No. 1 mice, 7–8 weeks of age, were made polycythæmic by single intraperitoneal injections of 1 ml. of packed red cells from retired breeder mice of the same strain given on two consecutive days. Five days after the second transfusion, hæmatocrits averaged approximately 75 per cent, and the absence of reticulocytes from the peripheral blood, and of morphologically identifiable red cell precursors from bone marrow and spleen, indicated that erythropoiesis was practically eliminated. These mice now received varying doses of total-body X-irradiation (250 kV., 30 m.amp., target distance 79 cm., filter 1/4 mm. copper plus 1 mm. aluminium). Within 30 min. after completion of irradiation, animals were given a single subcutaneous injection of 6 units[7] of erythropoietin dissolved in 0·25 ml. saline, a dose which we have previously demonstrated will evoke maximal erythropoietic response[6]. Two days after this injection (when concentration of normoblasts in the marrow and spleen is rising, and the first reticulocytes are appearing in the peripheral blood of unirradiated controls)[6], each animal received 1 mc. of iron-59 citrate through the tail vein. Four days after this radioiron injection, blood was withdrawn by cardiac puncture, and the percentage iron-59 incorporated in newly formed peripheral red cells was determined[1].

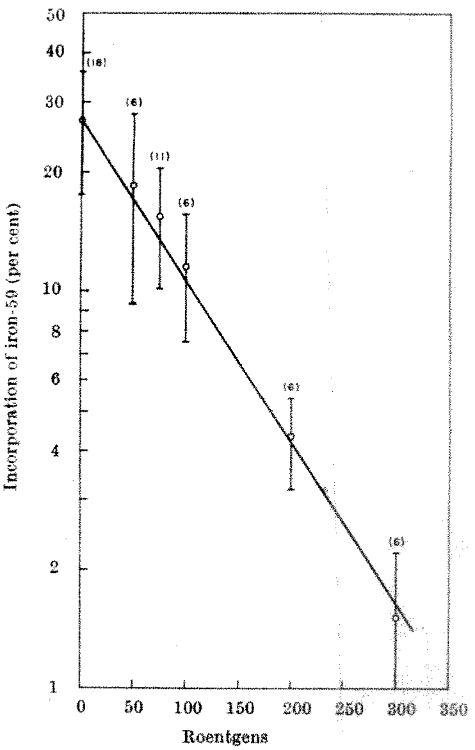

Fig. 1. Impaired response to erythropoietin in the irradiated polycythæmic mouse. Number of mice in brackets

Fig. 1 shows the percentage radioiron incorporation in the red cells of control and irradiated animals plotted on a vertical logarithmic scale. Results are expressed as mean values ± 1 standard deviation, and the number of animals in each group is indicated in parenthesis. Although variation within any group is great, particularly at the lower doses of radiation, mean values indicate that the response of a given group can be predicted, and the suppressive effect of as little as 50 r. is clearly demonstrated. (In a group of mice receiving 400 r., incorporation of radioiron was only 0·6 per cent, indicating almost complete suppression of erythropoiesis.)

While the suppressive effect of radiation on erythropoiesis has been clearly described by previous authors[8], these preliminary results seem worth reporting because they describe a simple quantitative method of evaluating it. In addition, they suggest a way of investigating the sensitivity to irradiation of the stem cells *in vivo*. Since erythropoiesis is virtually suspended in the hypertransfused mouse at the time of irradiation, it seems reasonable to attribute its suppression, as measured by red cell iron-59 incorporation, to the direct action of radiation on the undifferentiated red cell precursors, although an indirect mechanism may also be contributory. Decreased iron-59 incorporation by newly formed red cells is probably not primarily a reflexion of changes in the plasma iron-level following irradiation, since we have recently demonstrated a high level of plasma iron in hypertransfused rats, which, unlike the plasma iron in normal animals, is not further elevated following radiation (Gurney, C. W., and Taylor, K. T., unpublished results). It must be stressed that only effective erythropoiesis is being measured, and future investigation must also include a study of the blood-forming organs to assess the degree to which stem cells damaged by irradiation undergo differentiation and then succumb while still erythrocyte precursors.

In addition to affording a means for the simple quantitative determination of irradiation damage and recovery of a population of cells, we believe this model offers possibilities for investigation into the nature and kinetics of the stem-cell compartment, and it is for these reasons that these preliminary observations are reported.

We are indebted to L. O. Jacobson for discussion of the problem and for constructive criticism of the manuscript.

Development of the Islets of Langerhans in Man

VERY little has been published about the differentiation of the α and β cells in the development of the pancreatic islets in man. The only work since the introduction of the modern granule stains is that of Ferner and Stoeckenius[1] (based on twelve fœtal pancreases), and Schultze Jena[2] (based on six fœtal pancreases).

The material for the present work was 36 pancreases from human fœtuses with weights ranging from 34–3,000 gm. (10 wk. gestation to full term), stained by Gomori's chrome-alum hæmatoxylin phloxin method[3] and/or by chrome-alum hæmatoxylin with Gomori's one-stage trichrome counterstain. Eleven pancreases were from fœtuses between 10–20 wk. gestation. It is the islets in these early months of gestation, in particular, which have not been adequately described before.

Four stages are observed in the development of the islets. These overlap so that any one pancreas will show islets in more than one stage :

(1) State of budding islets. In the third gestational month, clusters of islet-cells bud off from the ducts. Differentiated α and β cells are already present. The β cells form a central cluster, around which ungranulated islet-cells and occasional α cells are ranged.

(2) Bipolar stage. As the islets grow, the β cells become grouped at the tip of the islet farthest from the duct, while the α cells form a calyx at the base of the islet. The proportion of ungranulated cells diminishes. Islets in this bipolar phase are observed from the fifth to the eighth gestational month.

(3) 'Mantle-islet' stage. The α cells at the base of the islets proliferate and grow right round the β cells. The islet now has a kernel of β cells and a shell of α cells. Some ungranulated cells are still present among the α cells.

There is a good deal of overlapping between the bipolar and mantle-islet stages. Mantle-islets are seen as early as the fifth gestational month, and dominate the picture from about the sixth gestational month.

(4) Stage of mature islets. From the eighth gestational month onward, a few islets can be found where the α and β cells have the more-or-less haphazard distribution characteristic of the mature adult islet, although the majority are 'mantle-islets' right up to term and beyond.

A detailed account of this work, with photomicrographs, will be reported elsewhere.

PATHOLOGY

Serological Tests for Toxoplasmosis

INTEREST in various serological tests for toxoplasmosis has increased considerably in recent years. Siim and Lind[1], in a preliminary communication, have recently described a flocculation test using toxoplasma antigen adsorbed on to acrylic particles. They stated that preliminary results of absorption experiments showed the existence of more than one toxoplasma antigen. The following experiments carried out in this Laboratory may be of interest.

A high-titre human antitoxoplasma serum was absorbed with toxoplasma-infected mouse peritoneal exudate at room temperature (20° C.). This removed almost all the hæmagglutinating, complement-fixing and dye-test antibodies. Absorption of the same serum overnight with human red cells coated with toxoplasma antigen (as used in the hæmagglutination test of Jacobs and Lunde[2]) removed the hæmagglutinating antibody but the dye test and complement-fixation antibodies were unaffected.

Control tests were set up using a normal human serum, absorbed with toxoplasma suspension, and a normal human serum absorbed with red cells coated with toxoplasma antigen. This experiment excluded effects due to elution of soluble toxoplasma antigen. Absorption of the antitoxoplasma serum with human unsensitized cells did not alter the titres of the dye, hæmagglutinating or complement-fixing antibodies. The results are summarized in Table 1.

The results of this experiment were substantiated by using a HeLa cell tissue culture toxoplasma antigen to absorb a hyperimmune serum from another patient. The effect of using a tissue culture antigen

Table 1. ABSORPTION OF ANTITOXOPLASMA SERUM

	Dye test	Hæmagglutination test	Complement-fixation test
Antitoxoplasma serum unabsorbed	Positive at 1/1,280	Positive at 1/1,280	Positive at 1/640
Antitoxoplasma serum absorbed with toxoplasma suspension	Positive at 1/40	Negative at 1/20	Negative at 1/20
Antitoxoplasma serum absorbed with sensitized human red cells	Positive at 1/1,280	Negative at 1/20	Positive at 1/1,280
Antitoxoplasma serum absorbed with unsensitized human red cells	Positive at 1/1,280	Positive at 1/1,280	Positive at 1/1,280
Normal human serum control absorbed with toxoplasma suspension and then mixed with antitoxoplasma serum	Positive at 1/640	Positive at 1/320	Positive at 1/640
Normal human serum control absorbed with sensitized human red cells and then mixed with antitoxoplasma serum	Positive at 1/640	Positive at 1/640	Positive at 1/640

as an absorbent was essentially the same as that with the mouse exudate antigen.

These experiments demonstrate that the antibody measured in the hæmagglutination test differs from that in either the dye or complement-fixation tests. Therefore the antigen or antigens responsible for the hæmagglutination test differ from those responsible for the dye and complement-fixation tests.

Effect of a Magnetic Field on Sarcoma 37 Ascites Tumour Cells

THIS communication deals with work on the effect of magnetic field on living ascites tumour cells *in vitro*. The hanging-drop culture was prepared by diluting a 7-day-old transplanted ascites mouse tumour with suitable aliquots of Tyrode solution. The culture slide to be exposed to the field was then placed between the poles of an Alnico permanent magnet in a horizontal position at a constant temperature of 37° C. The field strength used during the experiment was about 4,000 gauss and was determined independently by the susceptibility technique. The control slides not exposed to the field were treated identically. The microscopic examination of the slides was carried out periodically.

The control tumour cells showed normal growth and active differentiation, even after 18 hr., whereas most tumour cells exposed to the field showed complete degeneration at the end of this period. These experiments were repeated several times with reproducible results. The slides made after 18 hr. were stained with acetocarmine and photomicrographs were made.

Although it is not possible to explain these results clearly at the present time, the following postulates and assumptions are considered in working out a hypothesis for this purpose. (1) The 'chemical components' in the cells have varying magnitudes of magnetic susceptibility representing the diamagnetic and the permanent and any transient paramagnetic contributions. Hence, the permanent and any transient components will experience varying forces under the influence of the magnetic field. (2) Although these forces are small from a macroscopic point of view, they may be enough to upset the delicate balance (chemical and other equilibria) inside and outside the cell. (3) Such changes are assumed, at least in part, to produce the degeneration of the cells.

We wish to thank Dr. G. S. Sperti for his encouragement and Messrs. Albert Gerth and Robert Neagele for their valuable assistance. Further work on the effect of a magnetic field on living cells will be published elsewhere.

Association of Detectable Antibodies produced by *Haemonchus* spp. Infections in Cattle, with Serum Globulin Fractions

EARLIER investigations have shown that cattle which exhibit a marked degree of natural resistance to infection with *Haemonchus* spp. also develop higher complement-fixation titres than susceptible cattle, and that rises in the complement-fixation antibody titres often occurred at the same time as rises in the gamma one fraction of the serum globulin. This resistance has been shown to be heritable[1,2]. These observations were made under field conditions where extraneous stimuli were likely to produce changes in the globulin fractions, so that the correlation between complement-fixation titres and the γ-1-globulin fraction was not always consistent and definite conclusions were not possible. To clarify this situation, cattle sera known to be positive by the complement-fixation test were fractionated and the fractions identified and tested for antibody content. The following is a brief account of the procedure and results obtained.

The β- and γ-globulins were first separated from the serum by precipitation with 16 per cent sodium sulphate at 37° C. The globulin was further fractionated on a diethylaminoethyl cellulose chromatographic column with gradient potassium acid phosphate buffer solutions ranging from pH 7·0, 0·005 M to pH 5·8, 0·1 M, after the technique in refs. 3 and 4. Three antibody positive fractions were isolated in this manner. The protein content of these fractions was estimated by the biuret colorimetric method[2,5]. The relative concentration of the individual globulins in these fractions was ascertained by adding them to a known standard serum and observing the alteration in the globulin fraction content of the serum by electrophoresis in an Antweiler microelectrophoresis apparatus. Complement-fixation test techniques were carried out as described in ref. 1, and hæmagglutination tests following the method in refs. 6 and 7.

Considerable variation occurred in the relative amount of total protein in the samples, and antibody contents have therefore been expressed as antibody potency per gm. of protein. Complement-fixation test results have been expressed as 'index ratios' (refs. 2 and 8), which is the ratio of the amount of complement fixed by the serum in the presence of antigen to the amount fixed in the absence of antigen, after corrections, if necessary, have been made for anti-complementary effects of the antigen. Details of the results are shown in Table 1.

Table 1. ANALYSIS OF ORIGINAL SERUM AND THREE COLUMN FRACTIONS

Serum specimen	Electrophoresis analysis. Per cent content of globulins				Protein content gm./100 ml.	Complement-fixation index ratio per gm. of protein	Hæmagglutination titre per gm. of protein
	Beta 1	Beta 2	Gamma 1	Gamma 2			
Original whole serum	12	28	28	32	1·36*	12·5	1/24
Column fraction 1	0	25	25	50	0·07	21	Neg.
Column fraction 2	0	70	30	0	0·09	33	1/22
Column fraction 3	52	48	0	0	0·06	Neg.	1/33

* Beta and gamma only.

The results support the original suggestion that the complement-fixation antibody is located principally in the γ-1-globulin, and also show that the hæmagglutination antibody is present in the β-globulin fraction, principally in the β-2-globulin. It has been demonstrated by other workers that the complement-fixation and hæmagglutination antibodies are independent in animals infected with *Haemonchus* spp. and the above findings confirm this.

There are at present insufficient data available to form definite conclusions as to the role of the globulin fraction in resistance to *Haemonchus* spp. infection in cattle, but there would, however, appear to be a possible association between the complement-fixation antibody, rises in the γ-1-fraction of the γ-globulins and the occurrence of a natural immunity. Present investigations into the host–parasite relationship in hæmonchosis in this laboratory suggested that rises in the γ-2-fraction of the γ-globulin may be associated with an acquired resistance to the disease.

HÆMATOLOGY

Significance of the Presence of Lewis Substances in Serum during Infancy

IT has been found that infants who develop into adults with the following phenotype: red cells Le (a − b +), ABH secretor, Les (a + b +)*, go through a phase in which the red-cell phenotype is Le (a + b +), and the secretions, as in the adult, contain ABH, Le^a and Le^b. We have been able to establish that during the phase in which Le^a substance is detectable on the red cells of these infants, it is also detectable in their serum. In the adult with Le (a − b +) red cells, although Le^b substance is present in serum, Le^a substance is not detectable although it is found in the water-soluble secretions. Our observations are summarized in Table 1.

* Les = Lewis substances in saliva.

Table 1

	Red cells		Serum		Saliva	
	Le^a	Le^b	Le^a	Le^b	Le^a	Le^b
Infant	+	+	+	+	+	+
Adult	−	+	−	+	+	+
Infant Adult	+	−	+	−	+	−
Infant Adult	−	−	−	−	−	−

The explanation of the infant Le (a + b +) red-cell phenotype appears to be that the Lewis substances he or she is capable of producing are present throughout the body. We can assume that the disappearance of detectable Le^a substance from the circulation is related to the interactions of Lewis, ABO and secretor systems. There is already evidence for this in the case of some A$_1$, Le (a − b +) individuals in whom the Le^b substance is present in low concentration on cells and in serum, and the power to detect it depends on the potency of the antisera. In our tests for Lewis substances in serum we diluted the sera 2/3 with saline, and added one volume of this to each tube of a titration of the Lewis antisera 1/1–1/16. We were fortunate in having antisera with titres respectable enough to perform the tests and for these we are indebted to Dr. I. Dunsford.

Roman type has been used for the symbols which represent phenotypes, in order to observe a convention in genetics that phenotypes are shown in Roman type and genes in italics.

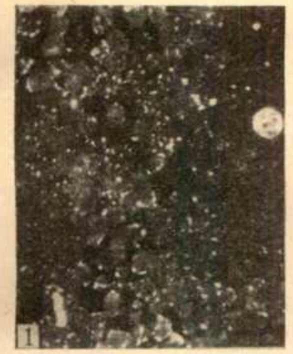
Detection of *C*-Reactive Protein by Fluorescent Antibody Techniques

THE presence of *C*-reactive protein in human serum is a highly sensitive index of inflammation or of tissue destruction[1]. It appears in the blood serum as early as 14 hr. after the injury occurs. Present knowledge points towards its being a β-globulin[2], but its origin and function are yet unknown. The methods available for the detection of *C*-reactive protein are based on precipitation[3,4], complement-fixation[5], hæmagglutination[6] and gel-diffusion[7] techniques, methods which are unsuitable for the precise localization of the substance in cells. For this purpose the fluorescent antibody technique seemed to be promising. Results of staining blood smears from people who are positive and negative for *C*-reactive protein with the fluorescent antibody techniques are described here.

Smears were made on glass slides either directly from blood taken from a finger prick or from clotted venous blood. The smears were air-dried and fixed for 10 min. in 95 per cent ethanol. The presence of *C*-reactive protein in the serum was determined in each case by the usual capillary precipitation method[4] with *C*-reactive protein anti-serum prepared in rabbits. The antiserum, purchased from Schieffelin, of New York, was also used for labelling with fluorescein *iso*thiocyanate. Labelling was carried out by the method of Marshall *et al.*[8]. The fluorescent solution was absorbed twice, once with monkey liver powder and once with guinea pig liver powder[9], and passed



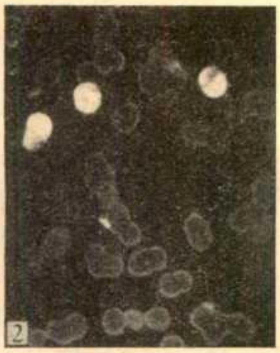


Fig. 1. Fluorescent antibody staining of *C*-reactive protein in blood smear taken from finger. Fluorescent *C*-reactive protein antibody in buffered saline. Leucocyte shows non-specific staining. (× 320)

Fig. 2. Inhibition of fluorescent antibody staining of *C*-reactive protein in blood smear taken from finger. Fluorescent *C*-reactive protein antiserum diluted in concentrated *C*-reactive protein. Staining of the latter was completely inhibited, but leucocytes continue to show non-specific staining. (× 320)

through a column of 'Dowex 2' (ref. 10). This labelled *C*-reactive protein antiserum was used diluted 1 : 8.

Both direct and indirect staining methods were used. The direct method consisted of covering the blood smears with the labelled *C*-reactive protein antiserum and allowing them to stand for 30 min. in a moist atmosphere. The smears were then rinsed for 10 min. in buffered saline, mounted under a cover-slip in glycerol saline at *p*H 7·6 and examined. The indirect method was carried out as follows. Smears were covered with unlabelled *C*-reactive protein antiserum and allowed to stand for 30 min. in a wet chamber. The smears were then washed for 10 min. in buffered saline and covered with labelled anti-rabbit globulin. For the rest the procedure was as described above. Smears were examined from persons who were negative to the *C*-reactive protein by the capillary precipitation method and from persons showing various amounts of *C*-reactive protein in their serum.

Particles with intense green fluorescence, ranging in size from the barely visible to approximately $0 \cdot 3 \mu$, were present in 20 out of 25 people giving a positive response for *C*-reactive protein (Fig. 1). There was rough correspondence between the degree of the capillary precipitation and the quantity of fluorescing particles. Such fluorescing particles were not found in smears of people giving a negative response for *C*-reactive protein. Leucocytes of people giving a positive and those giving a negative response for *C*-reactive protein, as well as those of various laboratory animals, showed slight to intense fluorescent staining. This non-specific staining could be obviated by the addition of normal rabbit, sheep or guinea pig serum to the conjugated *C*-reactive protein antiserum. Thrombocytes from *C*-reactive protein-negative and -positive people, collected separately and stained as above, were negative.

A series of tests was carried out to demonstrate the specificity of the staining. Conjugated normal rabbit serum, when used instead of rabbit *C*-reactive protein antiserum, failed to demonstrate fluorescent staining. The conjugated *C*-reactive protein antiserum was diluted 1 : 8 in saline, and normal rabbit serum, normal sheep serum, normal human serum, concentrated *C*-reactive protein solution prepared from ascitic fluid[2] and in unlabelled *C*-reactive protein antiserum. The normal rabbit and sheep serum did not interfere with the appearance of the stained particles described above, but inhibited the non-specific leucocyte staining. In the presence of unlabelled *C*-reactive protein antiserum, no staining was observed, either of the particles or of leucocytes ; in the presence of concentrated *C*-reactive protein, the staining of the particles only was inhibited (Fig. 2). Surprisingly, labelled *C*-reactive protein antiserum when diluted in some normal human sera also failed to show staining. In the indirect staining procedure, the same results were observed in the staining as well as in the inhibition tests. Here also some normal human sera inhibited staining of the fluorescent particles.

Similar findings were obtained with impression smears and frozen sections from spleen, lymph nodes and liver taken *post mortem* from a patient whose serum gave a positive response to *C*-reactive protein. Fluorescent particles were observed as in the blood smears, but did not seem to be associated with any particular cell.

One of the puzzling features of this work is the fact that some specimens of serum taken from apparently healthy laboratory workers interfered with the fluorescent staining. This interference was observed both in the direct and indirect staining procedures. Seligman *et al.*[11] found traces of *C*-reactive protein in many normal human sera. Assuming that the inhibition of staining is more sensitive than the capillary precipitation reaction, one might speculate that the apparently normal sera which inhibited staining contained traces of *C*-reactive protein. The failure to detect the latter in leucocytes by the fluorescent technique is in agreement with the findings of Seligman *et al.*[11], who were unable to detect it in extracts of normal and leukæmic cells.

HISTOCHEMISTRY

Nature of the Sinus Lining Cells of the Spleen

VARIOUS opinions have been expressed on the nature of the cells lining the venous sinusoids of the spleen[1]. They have been described as forming a type of internal epithelium, as muscle cells and as separated, longitudinal endothelial ridges. Klemperer

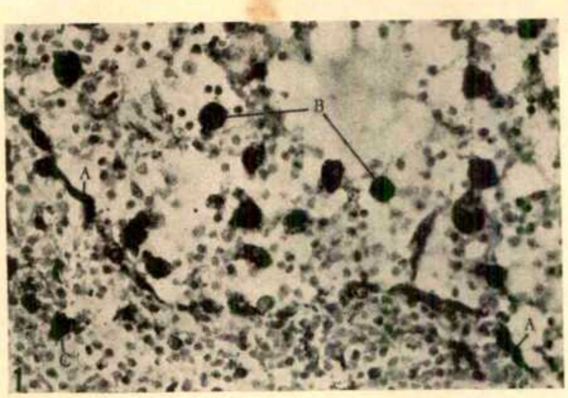

Fig. 1. Frozen section of a lymph node demonstrating non-specific esterase activity in histiocytes, (*A*) lining sinuses (littoral cells), (*B*) lying free in dilated sinus, (*C*) in medulla. α-Naphthyl acetate method. (× *c*. 240)

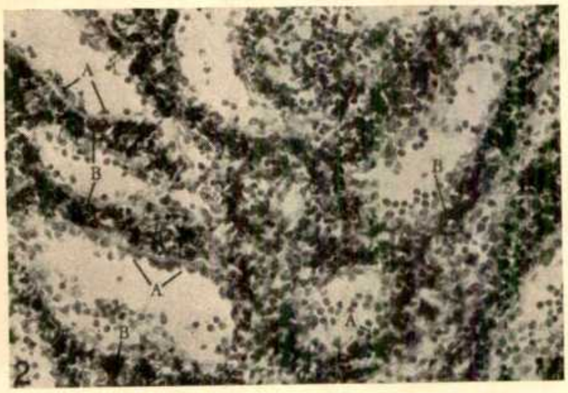

Fig. 2. Frozen section of spleen demonstrating non-specific esterase activity in histiocytes, (*B*) in cords of Billroth, but not in sinus lining cells (*A*). α-Naphthyl acetate method. (× *c*. 150)

accepted Mollier's evidence[2] that the wall of a splenic sinus is formed by a cytoplasmic reticulum with reinforcing fibres, essentially identical to the general cytoplasmic and fibrillar reticulum of the pulp. As recently as 1957 Weiss[3] stated that splenic cords are collapsed splenic sinuses, and the preponderant cell type in the cords is the same as that lining sinuses.

It is evident that interpretations of histological appearances, whether under the light or electron microscope, are influenced by artefacts. Other methods of study may therefore be more fruitful.

Braunstein *et al.*[4], from enzyme histochemical studies, regarded the splenic littoral cells as histiocytes, that is, phagocytic cells like those of lymph nodes, Kupffer cells, reticuloendothelial cells of bone-marrow and monocytes of blood. They stated further that all histiocytes manifest strong non-specific esterase and acid phosphatase activity. They also demonstrated strong alkaline phosphatase activity in capillary and lymphatic endothelium. From this study it would appear that splenic sinusoids are comparable with those of liver in that they are lined by phagocytes.

Using the histochemical techniques described by Pearse[5] for acid and alkaline phosphatase and non-specific esterase, on formalin-fixed frozen sections, I have confirmed the results of Braunstein *et al.*, in regard to the histiocytes of lymph nodes. I have not, however, been able to confirm their statements concerning the splenic sinus lining cells.

The spleens studied were obtained from monkeys, guinea pigs and human patients. The last-named group comprised two patients with lacerated spleens, two with thalassæmia, three with hereditary spherocytosis and one with thrombocytopenic purpura. In all these, non-specific esterase and acid phosphatase were demonstrable in stellate, branching histiocytes in the cords of Billroth and in Malpighian corpuscles. The sinus lining cells, however, were consistently negative for all three enzymes.

Capillary endothelium possessed the characteristic strong alkaline phosphatase activity.

It is of interest to note that Marshall's 'metalophil' technique[6] impregnates those histiocytes in lymph nodes and spleen which show non-specific esterase and acid phosphatase activity. He states, however, that the impregnation of the cells lining the splenic sinuses by metallic methods is often difficult.

These enzymatic reactions provide strong evidence that the splenic sinus lining cells are not identical with histiocytes (reticulum cells) in the pulp and in fact are not true histiocytes.

MICROBIOLOGY

A Superior Fat-synthesizing Single-spore Strain of *Lipomyces*

CONSIDERABLE attention has been devoted to the investigation of fat-producing micro-organisms as a potential industrial process. Woodbine[1] has recently reviewed this field and showed that, whereas many strains had been examined for their fat-producing abilities, no rationalized investigation for improving the fat-producing ability of an individual strain by selection had been undertaken. Such a strain could be isolated originally as either a single cell or a spore which could then be subcultured to give a genetically homogeneous strain.

Roberts[2] had isolated some single-spore cultures from strains of the fat-producing yeast genus *Lipomyces* and an investigation was carried out on ten of these strains: *B* to *H* were isolated from a parent culture of *L. lipofer*, and *I* to *L* from a culture of *L. starkeyi*.

Lactose was used as the carbon substrate by all strains (Wickerham's medium). Although *L. lipofer* was found to utilize lactose immediately, *L. starkeyi* required an adaptive period of fifteen or more days. This contradicts the evidence of Connell *et al.*[3], who claimed that none of the strains they examined would utilize lactose, and of Lodder *et al.*[4], who found that only strains of *L. lipofer* would utilize lactose and indeed used this as a diagnostic character. Van der Walt[5] and Roberts[2] found that both species would utilize lactose. One reason for the confusion would appear to be due

Table 1. RESULTS FOR THE LOW C : N RATIO IN TERMS OF TOTAL YIELD, SUGAR UTILIZED AND TOTAL FAT IN GM./L. USING *L. starkeyi*

The 'economic coefficient' is dry $\frac{\text{cell weight}}{\text{sugar utilized}} \times 100$, and the fat coefficient is $\frac{\text{fat produced}}{\text{sugar utilized}} \times 100$.

S.S.D. indicates the strains showing a significant difference ($P < 0.05$) by 'difference between means' analysis.

to the long adaptive period required by *L. starkeyi* before it can break down the lactose. This, indeed, might be used as a diagnostic character in the species differentiation of the genus *Lipomyces*.

Examination for variations in the fat-synthesizing abilities of the strains was done on two media, one with a carbon to nitrogen ratio of twenty and the other with a ratio of sixty.

With the low carbon-to-nitrogen ratio, Wickerham's[6] yeast–nitrogen base ('Difco' brand) medium was employed, containing 5 per cent lactose. Five replicates of 50 ml. of medium in 250 ml. Erlenmeyer flasks were used for each strain. The inoculum was subcultured on the glucose agar used by Starkey[8], and 0·5 ml. of a standardized cell suspension used as inoculum. The flasks were agitated at 120 r.p.m. (3 in. thrust) at 26 ± 1° C., and gathered after 33 days. Dry weight, sugar utilization and the fat percentages were assessed by the methods of Wix and Woodbine[7]. *L. lipofer* strains showed no variation, but considerable variation occurred among strains of *L. starkeyi* (Table 1). Although no variation was found with regard to the fat-synthesizing mechanism, all the single spore strains examined were found to have adapted to lactose faster than the parent strain, which had utilized only half the available sugar. Diauxie occurred, so that the 'parent' strain was adapting from the glucose to the galactose (or vice versa) fraction of the lactose when samples were harvested.

Strains *I*, *K*, and *L* had completely utilized the lactose whereas strain *J* was still utilizing the second sugar in the lactose and consequently had a significantly higher economic coefficient. This indicates that single-spore strain selection might produce strains with shorter adaptation periods toward sugars than the original strain.

In the medium with high carbon-nitrogen ratio fat production was encouraged. Six replicates for each strain were grown in 6-oz. medical flat bottles containing 35 ml. of the medium recommended by Starkey[8] but containing 3 per cent lactose. The bottles were laid on their sides to increase aeration and incubated at 26 ± 1° C. No agitation was applied. Inoculation and gathering were carried out in the same manner as in the previous experiment. No deviation occurred among the strains of *L. lipofer*. The total yield, sugar utilization, and economic coefficient trends were similar to those found in the first experiment. The differences may be summarized by division of the strains of *L. starkeyi* into three groups. Strain *P* gave the lowest yield, strains *I*, *J*, and *K* produced greater yields, whereas strain *L* produced the highest. In no case was all the lactose broken down; this is the result of the high C : N ratio of the medium and the relatively poor aeration retarding growth. Sugar utilization by the strains does not show the same pattern as is evident for the total yield, strain *L* having utilized only the same amount of sugar as strain *P*. The higher total yield of strain *L* is reflected in the higher economic coefficient which is significant at a 1 per cent level. Much of this increase has occurred due to the higher rate of fat synthesis in strain *L*. This may be shown by a comparison of the synthesis of non-fatty components for these two strains. For strain *P*, this amounts to 0·98 gm./l., whereas for strain *L* it is 1·10 gm./l., which is an increase of 11·2 per cent. If the fat-synthesizing mechanisms of both strains were similar, then strain *L* would show 11·2 per cent increase in fat produced over strain *P*, since no significant difference in sugar utilization has occurred between the strains. From Table 2, it can be calculated that the increase in fat produced by strain *L* over strain *P* is in fact 163·6 per cent. This exceptional increase in fat could be due to a more efficient synthesizing mechanism being possessed by strain *L* than by strain *P* under the high carbon/nitrogen ratio conditions used in this experiment. Strain *I* closely resembles strain *P* in all but total yield, which is significantly higher. This may be due to a greater synthesis of the non-fatty components from the same amount of sugar used. Strains *J* and *K* are very similar to each other; both have used more sugar than the other strains. Most of the increase in total yield appears to be the result of the increased synthesis of non-fatty cell components.

The general conclusion drawn from this work is that by investigation of single-spore isolates from *Lipomyces starkeyi*, strains are found with superior power to assimilate sugar and/or more efficient fat-synthesizing ability to those of the parent strain. The results indicate that improvement in such characteristics might be possible by investigating single spores isolated from a parent strain.

Table 2. RESULTS FOR THE HIGH C : N RATIO IN TERMS OF TOTAL YIELD, SUGAR UTILIZED AND TOTAL FAT IN GM./L. USING *L. starkeyi*

Strain designation		Total yield	Sugar utilized	Economic coefficient	Fat per cent	Total fat	Fat coefficient

The Cytochrome of *Pasteurella tularensis*

THE examination of cytochrome in bacterial cells has been reported earlier by W. F. Riedmüller[1], A. F. Brodie *et al.*[2], and W. S. Silver[3]. Recently, T. Yamanaka *et al.*[4] have separated and purified cytochrome from *Pseudomonas aeruginosa.* The present communication describes cytochrome components which have been detected in the highly virulent (Idaho, Nevada) strains (LD_{50} 10^{-7}) and avirulent (*P*38) strain (LD_{50} 32 mgm.) of *P. tularensis.*

Bacterial cells cultured on Hiwatashi's medium for 24 hr. at 37° C. were used. 4 gm. of cells were washed three times with distilled water in a homogenizer and centrifuged for 10 min. at 11,000 r.p.m. Cell-free extracts were obtained by treating the washed cells in a sonic oscillator (9 kc./s.) for 6 min., followed by centrifugation at 11,000 r.p.m. for 10 min. The resulting supernatant was used as the cell-free extract. Freeze-dried cells and frozen cells were prepared by the usual methods.

The optical density was measured with a Shimadzu photo-electric spectrophotometer, type *QB*–50. The absorption spectrum of the cell suspension or cell-free extract was measured using an opal glass, using Calvin and Shibata's method[5]. Cell concentrations were checked by finding the dry weight and by micro-estimation of nitrogen (indophenol method).

Using a hand spectroscope, when excess sodium dithionite was added, the native cells showed absorption bands essentially the same as the virulent and avirulent strains, though an absorption band at around 560 mμ was found to be stronger in the virulent strains (Fig. 1). Similar results were obtained with cells grown for 48 hr. on a blood-free medium.

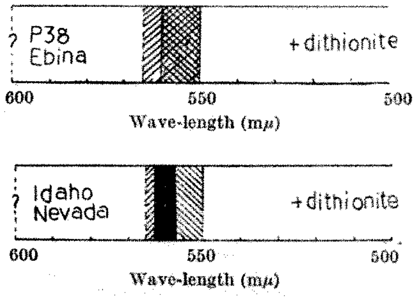

Fig. 1. Cytochrome components of *P. tularensis*. After reduction with sodium dithionate, the samples were examined for their cytochrome components by means of a Zeiss hand-spectroscope at room temperature and during immersion in liquid air

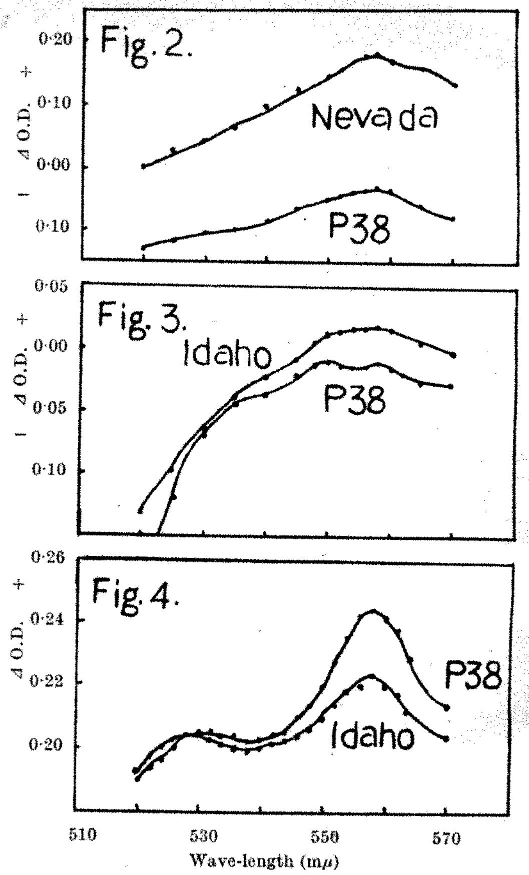

Fig. 2. Freeze-dried cells. Fig. 3. Native cells. Fig. 4. Particles. Optical density (O.D.) represents the difference between the oxidized and reduced forms

(1) Lyophilized cell preparations: 100 mgm. of dry cells were thoroughly dispersed in 10 ml. of 0·2 *M* phosphate buffer (*p*H 7·0) in a homogenizer, and the differential spectra (optical densities) were measured by the difference between cell suspensions previously reduced by excess sodium dithionite and by excess potassium ferricyanide. In Fig. 2, $\Delta E(=E_{\text{max.}} - E_{510})$ is plotted against wave-length for the two strains, and $E_{\text{max.}}$ is seen to be at 558 mμ:

Virulent strain: $\Delta E = 0\cdot17 - 0\cdot090 = 0\cdot080$
Avirulent strain: $\Delta E = -0\cdot040 - (-0\cdot100) = -0\cdot060$

As the dry weight is the same, cytochrome as measured by ($E_{558-540}$) from the virulent strain is greater by $\Delta E = 0\cdot02$ than the avirulent strain.

(2) Resting native cells: 2 gm. of wet cells per 10 ml. of 0·2 *M* phosphate buffer (*p*H 7·0) were suspended by homogenization, and the differential spectra were measured as before. The results are shown in Fig. 3 and Table 1, giving the value of ΔE corrected for the respective protein contents. The latter was remarkably large in the virulent strain, but $E_{\text{max.}}$ is still at about 558 mμ.

Table 1. CYTOCHROME ($E_{558-540}$) CONTENTS OF *P. tularensis*

Specimens	Native cells		Particles	
Strain	*P* 38	Idaho	*P* 38	Idaho
ΔE (O.D.)	0·013	0·035	0·042	0·023
N (γ/ml.)	7,680	6,440	5,040	870
ΔE/gm. protein	0·27	0·87	1·33	4·24
Differences		< 0·60		< 2·91

(3) Cell-free extracts: The cell-free particles extracted from the cells as described were examined spectroscopically. When absorption at about 560 mμ due to contamination had been removed, there was a strong alpha-absorption peak at 558 mμ like the so-called cytochrome b_1 (Fig. 4, Table 1).

These particles can be repeatedly oxidized and reduced like other cytochromes, and showed higher succinoxidase activity by the respirometry or reduction of trimethyl tetrazolium chloride than the other fractions[6]. Hence the absorption band at about 558 mμ may well be that of a cytochrome b_1 type pigment.

Thus it seems that *P. tularensis* contains cytochrome b_1, the amount of which in the whole cell and in the cell-free extract is greater for the virulent strain than for the avirulent strain.

Pseudomonadaceae as a Source of Bacterial Contamination in Tissue Culture

The pleuro-pneumonia-like organisms cause considerable difficulty in tissue culture work, as many lines of cell cultures are contaminated with these organisms[1]. I have found that members of the Pseudomonadaceae could play a part as contaminants of tissue culture. It is well known that these bacteria are frequently a source of bacterial contamination in stored blood and blood derivatives[2].

I have isolated from apparently healthy tissue-cultures of human origin (human embryonic and baby kidneys and *KB* cells) a Gram-negative bacillus identified according to *Bergey's Manual of Determinative Bacteriology* (7th edit., 1957) as *Pseudomonas fragi*.

The main characteristics of the organism isolated were as follows:

P. fragi is a Gram-negative rod with a polar flagellum (0·5–1·0 × 0·75–4·0μ). It grows well on agar slants as white, glistening and butyrous colonies. In broth cultures a thin pellicle and a sediment are formed. The saccharolytic and proteolytic activities are poor; the organism produces acid from glucose, arabinose and galactose. Litmus milk is coagulated in 2–3 weeks, and it produces a characteristic 'strawberry' odour. On potato, *P. fragi* grows in raised, white colonies, which later become brown. It does not produce pigments.

The important observations for the tissue-culture work are: (1) *P. fragi* does not grow at 37° C., but remains viable at this temperature in the human embryonic and baby kidney tissue-culture for at least 30 days, and it can persist in *KB* cells through 65 passages made at three-day intervals without causing any visible damage to the cells; it grows at temperatures of 10°–30° C., the optimum for growth being 20° C. (2) It is a minute organism and it can pass through sintered glass filters (*G*5) commonly used for the preparation of tissue-culture media.

Because of these two characteristics it can remain undetected in contaminated tissue cultures if the sterility controls are not tested at room temperature (18°–20° C.). The organism is widespread in Nature, and can be encountered in air, soil and water. In my experience tissue-cultures were contaminated from tap water, and the organisms reached the tissue-culture media primarily through contaminated glassware and sintered-glass filters. It was detected by chance.

P. fragi can easily be detected in control tests for sterility. Cultures can be set up on ordinary bacteriological media incubated after plating at room temperature. The incubation period must be sufficient to permit growth of the organism. Direct growth from tissue cultures may be slower on account of the antibiotics added to the media. *P. fragi* grows in visible colonies from a tissue-culture medium containing 100 i.u. of penicillin and 100 μgm. of streptomycin in 48 hr.

A great number of saprophytes and plant parasites belong to the Pseudomonadaceae. Many members of this family have been isolated from water and I believe that, like *P. fragi* in my experiments, they could contaminate tissue cultures and remain there as latent contaminants.

BIOLOGY

Sun Navigation in Birds ?

C. J. Pennycuick[1] has advanced a new hypothesis of Sun navigation in birds. The bird is supposed to measure the Sun's altitude and the rate of change of altitude and to compare these quantities with the respective memorized conditions at home.

The experimental evidence available does not agree with this theory in at least two major respects:

(1) The Sun's altitude: data have been presented[2] in which pigeons, following a phase-shift of their chronometers of 6 hr. clockwise, were released during the common light period of the artificially shifted and the natural day (which appears to be afternoon to the bird, but actually is forenoon). Only at one particular time of day (9.00 local time) do the altitudes of the anticipated and realized Sun with which the bird is confronted agree. All birds released before that time should, according to the hypothesis presented by Mr. Pennycuick, take their headings towards east to south-east, all birds released after that time towards north-west to north. This clearly was not the case. There was a deviation to the left, with reference to the headings of the controls, no matter what time and from which direction or distance the birds were released.

(2) In determining the rate of change of altitude either: (*a*) the bird has to be able to discriminate between a Sun going up and a Sun going down; or if not, (*b*) there would be an ambiguity during at least some portions of the day. Mr. Pennycuick does

not mention this point in his paper. An additional point of evidence against Sun navigation is implied by the data referred to under (1) if case (2*a*) should obtain for the rate of change of altitude. The birds should expect a decrease in altitude but will observe an increase in altitude. However, instead of eastward headings, as would be predicted by the hypothesis, there was a deviation to the left.

The first evidence of the orientational reaction of pigeons to a phase-shift of their chronometers[2] has, meanwhile, been confirmed by the results of experiments involving other degrees of phase-shift[3-5]. These results, however, were not yet generally available when Mr. Pennycuick's manuscript was submitted for publication.

[3] Schmidt-Koenig, K., *Science*, **131**, 826 (1960).

[4] Schmidt-Koenig, K., *Cold Spring Harbor Symposia*, **25**, 389 (1961).

[5] Schmidt-Koenig, K., *Z. f. Tierpsychol.* (in the press).

(1) In the paper referred to, I followed Matthews[1] in assuming that the pigeon, on release, compares the Sun's altitude with the remembered altitude seen at the same time of day at home. In Schmidt-Koenig's 'clock-shifting' experiments the birds were accustomed to a light–dark rhythm advanced by 6 hr. in a light-proof room. Since they could not see the Sun during the training period, they clearly could not remember its altitude for subsequent comparison with the altitude observed on release. Hence these experiments shed no light on the possible use of altitudes for navigation in the way postulated, and neither the predictions stated nor any others based on altitude measurements would follow from my hypothesis.

(2) Schmidt-Koenig's experiments might have been interpreted in at least two ways by the pigeons.

(*a*) They may (as Schmidt-Koenig seems to assume) accept the 'shifted day', forgetting that the shift had been applied and assuming that they were still at home. On release in normal daylight they should then respond as though they had been taken a quarter of the way round the world, to the west. This is a very large displacement compared with any with which pigeons normally have to contend, and the release distances from home (5·5–100 km.) were insignificant by comparison. They would thus head east if a two-dimensional navigation system were being used.

If rate of change of altitude alone were being used (altitude being ruled out) they might respond to the gross difference which would occur—the Sun going up when, according to the time of day, it should be going down (Schmidt-Koenig gives no reason for his doubts as to whether the birds could distinguish opposite directions of movement). On the simple method of interpreting this, which is postulated in my paper, the birds would then orient themselves at right angles to the Sun's direction, with the Sun on their right. That they did not do so might be evidence against Sun navigation, but more likely it indicates that Schmidt-Koenig's interpretation of his experiment is not the correct one. The fact that behavioural rhythms became synchronized to the shifted day is no proof that the shift had been forgotten: the experiments in which pigeons were trained to take food in a particular direction referred to the Sun, also purporting to show that the clock had indeed been shifted, are also inconclusive, since there is no reason why the birds should associate this task with homing orientation—indeed, it was shown that most of them would not even allow for the Sun's motion during the day unless they were specifically trained to do so.

(*b*) The birds could alternatively have supposed that they had been taken for a few days to a place where the light–dark rhythm was advanced by 6 hr., and then brought back and released in the general neighbourhood of home (as had in fact happened). It is well known that pigeons will return to their old home after confinement in a distant place for much longer than the short training periods (4–10 days) used by Schmidt-Koenig, which amounts to the same thing. The experiment then becomes a test of ability to orient homeward after being denied sight of the Sun for a few days, during which the time-sense of the birds was subjected to severe stress. No specific effects would be predicted from this, but one might expect some general disorientation, giving increased scatter of direction of departure and reduced success in homing. These were observed.

It is true that the differences observed in directions of departure between experimentals and controls would not be predicted on my hypothesis, but Schmidt-Koenig has not explained these either. Probably the design of these experiments was too ambiguous to lead to any definite predictions.

Schmidt-Koenig's results are of great interest in that they confirm that pigeons have a time-sense, and that certain manifestations of it can be interfered with by applying shifted light–dark rhythms; but he is not justified in assuming that an experiment in which the bird is not allowed to see either the real Sun, or an artificial sun moving in a calculated path, will lead to results predictable from a theory of Sun navigation. In any event the time-shifts used (6–12 hr.) were unreasonably large: shifts of the order of 5–30 min. should produce effects comparable to those of the homing distances which have been used in previous experiments on pigeons.

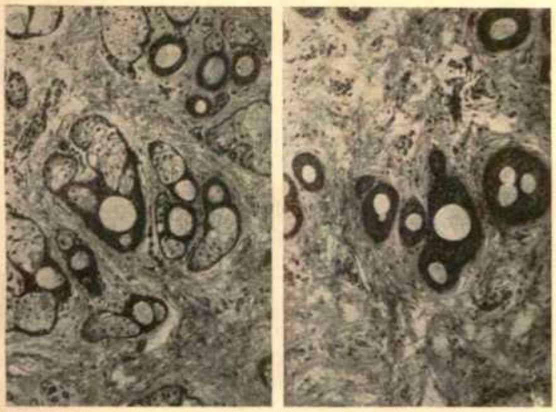
Bundles of Follicles in Adult Romney Ewes

Bundles of secondary follicles have been shown in the Karakul[1], Herdwick[2], Cheviot[2], Merino[3] and several other breeds[4] of sheep, and the formation of these bundles by the branching of follicles during their development has been demonstrated in the Karakul[1] and the Merino[3]. Branched primary (*P*) follicles have been described in the Merino and the Corriedale by Lyne[5], who also discussed his findings in relation to the fact that secondary/primary (*S*/*P*) ratios are normally determined from sections cut at the level of the sebaceous glands. At this level, branching follicles



(*a*) (*b*)

Fig. 1. A primary follicle bundle and a secondary follicle bundle ; *a*, at the level of the sebaceous glands ; *b*, above the level of the sebaceous glands, showing the coalescence of the root sheaths of the follicles. (× 100)

will not always be apparent so that some branching P follicles will be classified as secondary (S) follicles.

In recent work at Massey Agricultural College, skin samples were taken from the face (0·5 cm. trephine) and the mid-side (1 cm. trephine) of a flock of 111 2-year-old Romney ewes. Transverse skin sections were cut about the level of the sebaceous glands and stained with hæmatoxylin and eosin. During the determination of S/P ratios and follicle densities, branching P and S follicles were found in both mid-side and face samples.

It should be pointed out that the purpose of the work was not to determine whether branching follicles existed in the Romney breed ; therefore, these observations are not based on complete serial sections of the follicles. However, in the light of Hardy and Lyne's[3] and Lyne's[5] work, it is reasonable to assume that if the root-sheaths of two follicles coalesce at a level above that of the sebaceous glands, then, nearer the skin surface, the lumens of the two follicles will do so as well (Fig. 1). Furthermore, as the branching follicles were observed mainly in those sections or part of sections cut higher than the level of the sebaceous glands, it is clear that the proportion of sheep showing branched follicles will depend on whether such sheep had sections cut at this level.

Branching S follicles were found in the mid-side samples of twenty-one of the 111 sheep (Fig. 1). Even within the limitations of the sections there appeared to be variations between sheep in the number of bundles of S follicles in the area sampled as the number of bundles varied from 1 to more than $80/\pi$ cm.^{2}. Again, within the limitations of the sections, the number of fibres/bundle varied from 2–5.

The occurrence of six branched P follicles in the mid-side sample of one sheep, which also showed marked S follicle branching, and the appearance of several more in the face samples of five sheep, was noted, again in those sections cut above the level of the sebaceous glands (Fig. 1).

In view of the work by Hardy and Lyne[3] and Lyne[5], it is unlikely that the branching follicles found in this study are anomalies as suggested by Auber and Ryder[2], although until the factors leading to the formation of these follicles have been determined, this must remain a possibility.

These findings suggest, therefore, that an investigation into the method and time of development and extent of branching of follicles in the Romney breed is needed. Such work, making use of Lyne's[5] suggested definitions of follicle types, could establish the importance of branching follicles to the type of fleece in this breed. Furthermore, the occurrence of bundles of both P and S follicles in the Romney and Merino breeds suggests the necessity for investigating the follicle populations of breeds of other wool types, as branching follicles may be a more common unit of the fleece than was previously thought.

I am indebted to Mr. P. G. Schinckel for confirming the identification of branching P and S follicles, Mr. G. A. Wickham and Mr. B. Thatcher for preparing and examining the sections and Dr. F. Cockrem for the use of his material and for helpful criticism.

This work was carried out with the aid of a grant by the New Zealand Wool Board.

Independence of Temperature of the Rate of Ageing in *Drosophila subobscura*

THE fact that in poikilotherms an increase in temperature reduces the life-span has naturally been taken as showing that the rates of ageing processes, like those of chemical reactions, are dependent on temperature. If so, an animal which is kept for an appreciable part of its life-span at a high temperature and is then transferred to a low temperature would be expected to die at a chronologically younger age than a similar animal kept continuously at the lower temperature. It has already been reported[1,2] that this expectation is not realized in the case of *D. subobscura*. Flies kept when young at 30° C. for periods equal to about half their expectation of life at that temperature and then transferred to 20° C. died at the same chronological age as did flies kept continuously at 20° C.

These results were interpreted, wrongly as we now think, as evidence that the causes of ageing at the two temperatures are different. But they can be explained in another way. Ageing processes may be defined as those processes occurring in individuals which render them more likely to die as they grow older, either from internal or external causes. It is convenient to describe the result of such processes as a decline in the 'vitality' of individuals as they grow older. It is supposed that the ageing process is not only the same at 20° C. and at 30° C., but also that its rate is the same at the two temperatures. Death occurs when the vitality of the individual falls below some threshold value, the level of which depends on the temperature at which the individual is living at the time, and which corresponds to the level of vitality necessary for survival at that temperature. Differences in longevity at different temperatures are then due, not to differences in the rate of the ageing process itself, but to different threshold-levels below which the vitality must not fall if life is to be maintained.

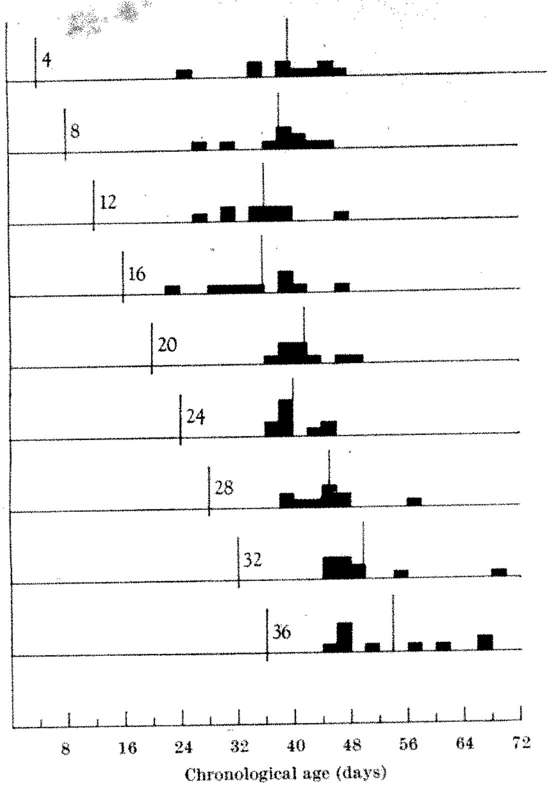

Fig. 1. Chronological ages at death of males kept for periods from 4 to 36 days at 20° C., and afterwards at 26° C.

This hypothesis would explain the earlier findings, since, provided that flies are transferred from the high to the low temperature before their vitality has fallen to the threshold-level corresponding to the higher temperature, their physiological state would be the same as that of flies of the same chronological age kept at the lower temperature. But there is another prediction from it which can easily be tested. Animals kept at a low temperature for a period equal to or greater than their expectation of life at some higher temperature should die immediately if transferred to that higher temperature. The experiment now to be described fully confirms this prediction, provided that the word "die" in the previous sentence is replaced by the phrase "start dying".

F_1 hybrid males between the *B* and *K* inbred lines were raised at the usual laboratory temperature of 20° C. A control group kept continuously at 20° C. had a mean longevity of 83·4 days. Groups of 10 males each were kept at 20° C. for periods varying from 4 to 36 days after emergence, and were then transferred to 26° C. and kept at that temperature until they died. The results are shown in Fig. 1. The first 6 groups to be transferred all died at the same chronological age of approximately 40 days, although the first group had a mean survival-time at 26° C. of 35·4 days, and the 6th group of only 16·2 days. This is exactly the result to be expected if the rate of ageing were independent of temperature. But the last four groups all had approximately the same survival time at 26° C. of about 16 days. This suggests that once the vitality has fallen below the threshold value appropriate to the temperature at which the flies are living, a second process is set in motion, a process we shall refer to as 'dying'. The threshold appropriate to 26° C. is reached at a chronological age of about 24 days, regardless of whether the flies have been living at 20° or at 26° C. If flies, aged 24 or more days, are transferred to 26° C. they start dying, a process which, at that temperature, is completed in about 16 days.

Similar results have been obtained in a number of experiments on both males and females, at temperatures ranging from 15° to 30° C. It has also been found that the 'dying' process is reversible. Males aged 12 or more days at 20° C. die after 3 or 4 days at 30° C. But males kept alternately for one day at 30° C. and for three days at 20° C. died at chronological ages varying from 53 to 85 days, after periods of from 8 to 17 days in all at 30° C. This shows that the changes occurring during the dying period at 30° C. can be repaired at 20° C.

The earlier experiments, together with those described here, lead to the following conclusions. The processes which ultimately result in the death of old flies can be divided into two stages, here called 'ageing' and 'dying'; these may correspond to the processes of induction and development suggested by Neary[3] from a study of mice. Ageing is an irreversible process the rate of which is roughly independent o temperature, at least from 15° to 30° C., and which leads to a continuous decline in the 'vitality' of the individual; by vitality is meant merely the capacity of the individual to withstand the various factors which may cause death. When the vitality falls below a certain threshold, a second process, that of dying is set in motion. The level of this threshold is dependent on temperature, being lower at lower temperatures; it is differences in the threshold-level, and no in the rate of ageing, which are mainly responsible fo differences in longevity at different temperatures. The dying process occurs at a rate which is dependent o temperature, and is terminated by death, but it ca be reversed in individuals transferred to lower temperatures.

Further Evidence of Polar Movement of Nutrients in Plants

In two earlier papers I showed that there was goo evidence for postulating polar rather than transvers movement of materials in plants[1a,b]. This conclusio was supported by later work on the movement o fluorescein in the xylem system[1c], of labelled carbon and of labelled phosphorus[3]. The two last paper describe experiments which show that carbon-14 o phosphorus-32 when introduced on one side into th leaves or the roots respectively of plants pass freel and rapidly up to the tissues on that side, but do no move transversely across the plant.

The present communication describes some exper ments which confirm the previous results, but whic have the advantage that the tissues concerned wer not mutilated by defoliation nor affected by the use c staining materials which are, to a greater or les extent, toxic to the living cells.

The technique is simple and can be carried ou without the necessity for any precautions which ma attend the use of radioactive materials. Further, th

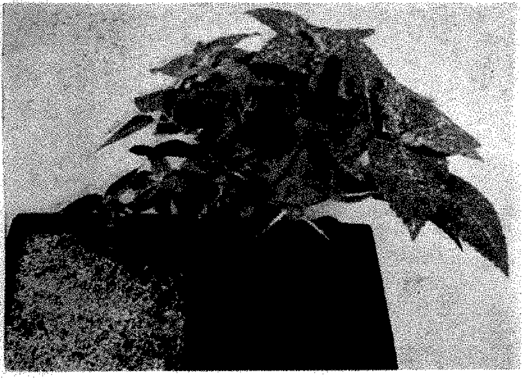

Fig. 1. Photograph of *Coleus* plant showing marked growth on the side of the plant with roots in soil

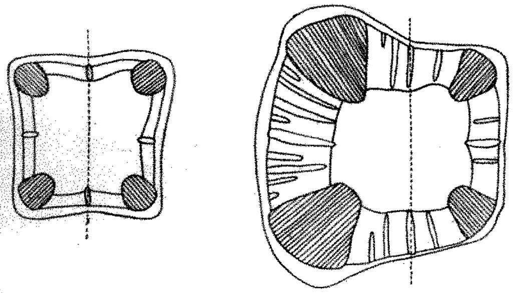

Fig. 2. Camera lucida drawing of section of *Coleus* stem (*a*) before experiment, (*b*) after three months. The dotted lines indicate the approximate position of the glass plate dividing the two media in which the cutting was grown

experiments were of comparatively long duration, showing that during a period of even three months the major portion of the metabolites move up and remain within the side on which they were originally absorbed or elaborated.

The experiments were set up as follows: young shoots of *Coleus* plants with 3–4 pairs of leaves were taken as cuttings and rooted in coarse sand without any added nutrients. After a couple of weeks or so, the end had developed a callus and adventitious rootlets had emerged. The end of the stem was then carefully slit with a razor by an incision up the middle at right angles to a pair of sides. It will be recalled that *Coleus* stems are square with pairs of opposite leaves inserted on the flat sides. In these stems there are four main vascular bundles, one at each corner of the stem. In the treated cuttings, therefore, there were two bundles on each side of the incision and the stems were symmetrical for all practical purposes.

The cuttings were then so placed on a sheet of glass dividing a wooden box into two compartments that each side of the stem and its adventitious roots was on one side of the sheet of glass. One compartment was filled with a rich loam, the other with a coarse sand without any added nutrients. Within a few days it was noted that the side of the plant above the soil was growing much more rapidly than that above the sand. The leaves on one side were much larger than the opposite members of the pairs, the axillary buds were developing into branches and the stem was much better grown on the soil side than on that over the sand. Clearly, the nutrients being absorbed from the soil were passing into and being retained by the tissues on that side of the plant.

At the end of three months a plant was photographed (Fig. 1), and all the leaves and axillary branches on the side above the soil and on that above the sand were removed. Though the alternate leaves on the other two sides also showed marked distortion —the side above the soil had grown much more than that above the sand, and similarly the axillary branches were correspondingly distorted—they were not taken into account for this measurement. Three sets of leaves and axillary branches were taken and dried at 100° C. The dry weights are given in Table 1.

Table 1

	Above soil	Above sand
Plant No. 1 (after 1 month)	1·07	0·54
Plant No. 2 (after 2 months)	1·85	0·41
Plant No. 3 (after 3 months)	7·54	1·57

Sections were made of the stem at an internode about the middle of the plant and Fig. 2 indicates the differences in the vascular tissues.

It will be noticed that the main vascular bundles on the corners of the stem above the soil had increased by about six times in area, while those above the sand had only doubled in cross-section after three months.

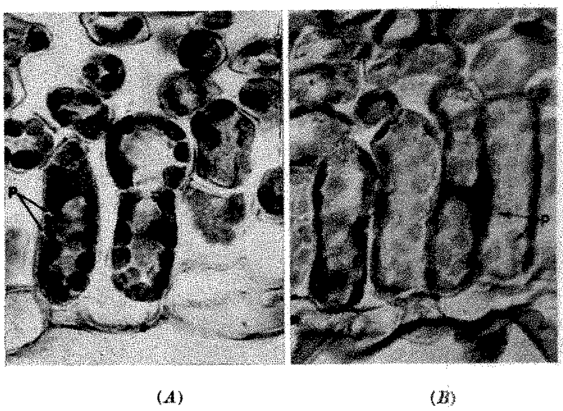
Staining Plastids in Chlorophyll-deficient Mutant Plants

Childers and McLennan[1] described collapsed, distorted palisade cells in a *viridis*-type chlorophyll mutant in alfalfa. A modification of Johansen's[2] quadruple stain was used for differentiating the plastids.

The technique is described here. Leaves were pre-fixed in Carnoy's fluid 6 : 2 : 2 for 30 sec., then fixed in Carpechenko's modification of Navashin's fluid. The tissue was dehydrated in Johansen's[2] tertiary butyl alcohol series. Sections were cut at 6μ and stained in the quadruple stain. The clearest differentiation was achieved by reducing the time in methyl violet to 7 min., while maintaining the time



(*A*) (*B*)

Fig. 1. Cross-sections of alfalfa leaves; (*A*) green leaf showing heavily stained plastids; (*B*) yellow leaf showing lightly stained but fully formed plastids. (× *c*. 575)

in fast green at 15 min. The nuclei were stained reddish-blue and the chloroplasts green. An advantage of this schedule is that de-staining is not critical and is accomplished by brief immersion in the de-staining solutions.

Nothofagus Pollen in the London Clay

THE existence of southern families and genera with disjunct distributions, such as the Restionaceae and *Nothofagus*, has been used by many authors[1,2] as evidence supporting continental drift. Some[3] have stressed the importance of Antarctica as a Tertiary link between these presently disjunct areas without explicitly invoking the notion of drift. The presence of *Nothofagus* among the pollen and spores from Seymour Island, Antarctica[4], supports such a suggestion.

Bandulska[5] assigned a leaf from the British Tertiary to *Nothofagus*, but this isolated record received no further support. Recently, Erdtman[6] has recorded pollen of the Restionaceae from the British Early Tertiary. If supported by further evidence, these reports of tropical and southern hemisphere disjunct groups in the northern hemisphere temperate region might lead some to suggest that the Eurasian land mass may have served as a 'bridge' between the southern continents. A distinct Australian element exists among the genera represented by the fossil fruits and seeds of the London Clay ; the proportion of Australian genera (40 per cent), although less than that of the genera of the Malay Islands (73 per cent), is nevertheless considerable[7].

In the course of an investigation of the pollen of the (Eocene) London Clay, I have now found, in addition to that of the Restionaceae and Proteaceae, *Nothofagus* pollen. The slides were sent to Prof. G. Erdtman of Stockholm for confirmation. He stated (personal communication) that he found it "impossible, at the present state of our knowledge, to avoid referring the grains to *Nothofagus*"; he regards the grains as more similar to certain recent *Nothofagus* pollen grains than to any other pollen grains so far known. The pollen came from the London Clay of Alum Bay, Isle of Wight, and the grains, which are 5- to 6-aperturate, compare favourably with those of *N. obliqua* of the *menziesii* group (Figs. 1–5). Harris[8] has shown that the aperture number in this group varies between 5–9. Although the exine of *Nothofagus* pollen has generally been considered to be undifferentiated, Prof. Erdtman has shown (personal communication and ref. 9) that the pollen grains in *N. obliqua* have delicate infrategillar bacula. The grains from the London Clay also have very short bacula between the nexine and the spinule-bearing tegillum.

The possibility of mis-identification has been ruled out because the pollen of *Nothofagus* is distinctive and characteristic. Its occurrence could be accounted for either by: (1) the pollen being transported long distances by sea (for example, from Australasia along the Tethys), or (2) its presence here in cooler upland areas. The first possibility is highly unlikely, although pollen has been known to cover considerable distances, while the second would be in accordance with what is implied by Bandulska's discovery.

In addition to members of disjunct groups dealt with above, I have also obtained pollen of temperate families, for example Betulaceae and Ulmaceae, from the London Clay. These families have not hitherto been recorded as megafossils at this horizon. Brett[10,11]

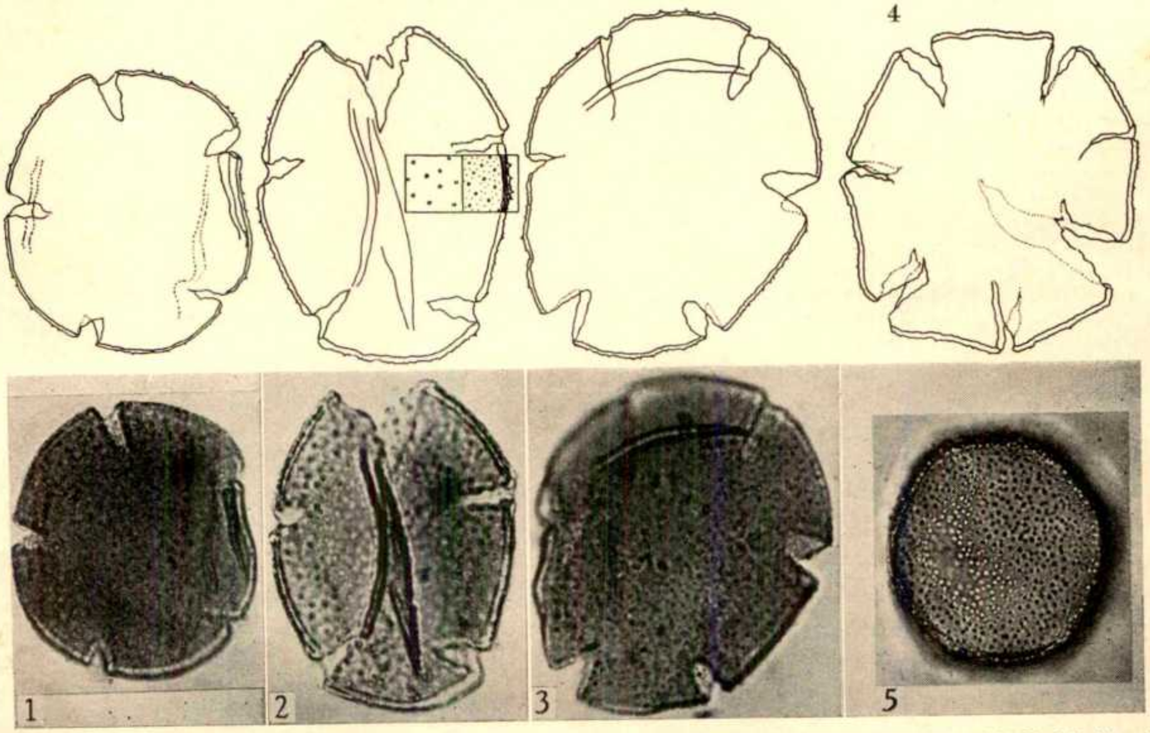

Fig. 1–3. Fossil *Nothofagus* (×1,000). Fig. 4. Recent *N. obliqua* (×1,000). Fig. 5. Recent *N. obliqua* (×750, photograph by Prof. Erdtman)

reported two temperate families (Cercidiphyllaceae, Fagaceae) preserved as petrified wood. These records of pollen and wood thus indicate the existence of a more temperate element (possibly an upland one ?) in the British Eocene flora, which is under-represented in the fruits and seeds of the well-known London Clay flora. Evidently the fossil pollen (and to a lesser extent the fossil woods) represents a broader picture of the entire flora, and it may be that the fruits represent predominantly the swamp association. Comparable results have been reported by Gray[12], who recorded the pollen of a number of temperate genera in the Eocene flora of Alabama, believed, on the evidence of megafossils, to have been tropical.

Proteolytic Activity of Crude Stem Extracts from Normal and Tumour Tissues of Plants

IN an effort to characterize more fully the tumorous tissue (crown-gall) induced in plants by *Agrobacterium tumefaciens*, the proteolytic content in the neoplastic tissues of several plants was investigated. Although a variety of enzymes have been found associated with crown-gall[1], no reports are available concerning proteolytic activities of such tissue extracts. Recent findings of increased proteolytic activity in mammalian neoplastic tissues[2,3] indicate a need for measuring the relative quantity of proteases in comparable plant tissues.

Greenhouse plants approximately 25 cm. high were inoculated by needle-puncture into stem tissue with 18-hr. agar-grown cultures of virulent or attenuated strains of *A. tumefaciens*. Tumours developing on tobacco (*Nicotiana tabacum* var. Wisconsin) were harvested approximately 5 wk. post-inoculation; on sunflower (*Helianthus annus* var. Mammoth Russian) and tomato (*Lycopersicon esculentum* var. Marglobe), 3 wk. after inoculation; and on beans (*Phaseolus vulgaris* var. Black Valentine) and *Kalanchoe daigremontiana*, approximately 6 wk. post-inoculation. Comparable areas on control stems which had been punctured under sterile conditions or inoculated with the avirulent strain *IIBNV6* were harvested at the same time, and constituted the 'normal' tissue to be compared with 'tumorous' tissue in later tests.

The excised tissue materials were ground in a Lourdes model *MM* tissue-homogenizer for 75 sec. at approximately 16,000 r.p.m., at a temperature of 1° C. A ratio of two parts buffer–potassium chloride solution to one part wet weight of plant tissue was used in the extractions for possible soluble fractions containing active proteolytic material. At *p*H 5·5, the buffer solution consisted of 0·1 *M* acetate–1·6 *M* potassium chloride[4]; at *p*H 7·5, it consisted of 0·1 *M* *tris*(hydroxymethyl)aminomethane - maleate – 1·6 *M* potassium chloride. The homogenized tissue was decanted into 50-ml. stainless steel tubes and centrifuged at –1° C. for 50 min. at approximately 20,000*g* in a Servall Superspeed refrigerated centrifuge. Supernatants were then adjusted to desired *p*H and kept at 1° C. or frozen at –17° C. until used in the digestion-reaction experiments. The Lowry[5] method was employed for all O.D. readings at 750 mμ (Spectronic 20). The Folin–Ciocalteu reagent was used in a dilution of 1-to-1, and a 1-to-5 dilution of supernatant from the TCA (trichloroacetic acid)-precipitated samples was used to eliminate interference in the development of the colorimetric reaction.

A digestion-reaction mixture consisting of 3 ml. buffer, 2 ml. demineralized water, 2 ml. substrate (urea-denatured bovine serum albumin, fraction V), and 1 ml. tissue extract was contained in a glass-stoppered reaction flask, and controlled at 35° C. for 18 hr. A 4-ml. aliquot was removed for the Lowry determination, and the remaining 4 ml. was employed as a final *p*H check on the reaction solution, which had previously been adjusted to the desired *p*H (buffer, substrate, and extract were all at this *p*H before addition to the reaction mixture). 'Zero' time systems containing exactly one-half the quantities of the respective digestion reaction mixtures served as control (blank) comparator systems for all readings at 750 mμ. A 5 per cent TCA solution was added to each 'zero' system immediately before incorporation of the tissue extract. Spontaneous hydrolysis controls for substrate and tissue extracts were tested with the other test systems. Since a low level of spontaneous hydrolysis prevailed, no corrections were made for the final O.D. readings of the digestion reaction.

The results in Table 1 indicate that, with the exceptions of sunflower and Kalanchoe stem tumour tissues, all other plants showed a much higher level of proteolytic activity in tumorous tissue than in their normal counterparts. The O.D. readings for tumorous tissues consistently reflected, in part, the proteolytic levels in normal tissues. For example, when normal tobacco tissue extracts yielded O.D. readings of 0·080 and 0·023, their respective tumour tissue extracts resulted in O.D. readings of 0·345 and 0·152. The total and protein nitrogen results appear

Bacteriological examinations of the reaction mixtures at termination of digestion period indicated no gross contamination.

to correspond to the relative proteolytic activities of normal and tumour tissue extracts from a given plant. However, it should be noted that no absolute quantitative relationship exists between O.D. readings and nitrogen contents. Until such time as one can evaluate the relative ratios between non-enzymatic nitrogen (nucleic acid, nucleo-protein, etc.) and proteolytic-enzyme-nitrogen, the relationship can only serve as an indicator of higher or lower proteolytic activity within a single set of stem extracts.

Reports of protease activity in leaf tissue of tobacco[6] and more pronounced proteolytic activity in leaf than in stem or root tissue in soybean[7] prompted a study of the relative proteolytic activity in leaf-tumour and normal tissues. Kalanchoe (Table 1) was selected because of its low level of activity in stem-tissue extracts. The results indicate a definitely higher level of activity in leaf tumour than in the stem tumour, although no apparent difference seems to exist in the respective normal tissues. Experiments are now in progress which are intended to evaluate the proteolytic relationship of leaf to stem tumour extracts of all the plants used in this work.

In conjunction with the results in Table 1, there are three additional observations: although the recorded results are based on freshly extracted material, extracts of tobacco frozen for 64 days showed no diminution in proteolytic potency. Secondly, activators such as BAL (2,3 dimercaptopropanol) and cysteine-hydrochloride actually decreased the proteolytic response of both normal and tumour tissue extracts when incorporated into the digestion-reaction mixture. Weil *et al.*[9] reported a comparable finding for proteases of certain aerobic bacteria with cysteine. Lastly, preliminary studies with stem extracts from tobacco and tomato at *p*H ranges from 2·5–8·5 indicate that the best range for proteolytic activity of the crude extracts lies at approximately 4·5. Additional work with frozen extracts, extended *p*H ranges for the best activities, and the effect of activators is now in progress.

The majority of our initial stem work was carried out at *p*H 5·5. Later experiments at alkaline *p*H ranges indicated a low level of activity. It was thought advisable to find what relationship exists between the extracting *p*H and the digestion *p*H. The results in Table 2 indicate clearly that, although a tissue may be extracted at *p*H 7·5 (low activity), it still possesses an active proteolytic principle, which can be demonstrated by adjusting this extract to *p*H 5·5 (high activity) and carrying out the digestion at this *p*H. Conversely, if an active extract at *p*H 5·5 is adjusted to *p*H 7·5 and the digestion reaction conducted at this latter *p*H, there will be a very low level of proteolytic activity.

In conclusion, it can be noted that crude extracts from tumorous stem tissue of tobacco, tomato and bean possess greater proteolytic activity than their respective normal tissues; that no apparent difference in proteolytic activity between tumour and normal stem extracts from sunflower and Kalanchoe can be demonstrated; and that with an acid *p*H (5·5) of digestion there is greater proteolytic activity than with alkaline conditions.

Table 2. EFFECT OF RECIPROCAL ADJUSTMENT OF *p*H ON PROTEOLYTIC ACTIVITY OF EXTRACTS FROM NORMAL AND TUMOROUS TOBACCO STEM TISSUE

Fungal Colonization of a Developing Salt Marsh

DURING work on fungal colonization of a developing salt marsh at Gibraltar Point, Lincolnshire, National Grid reference *TF*555576 (a preliminary account of which has been given[1]), the rhizosphere populations were used as indicators of changing fungal populations in the different areas of colonization by phanerogams. The number of fungal isolations from mud uncolonized by higher plants and from the rhizospheres of the common salt marsh plants are given in Table 1. Five Petri dishes per sampling site were inoculated with approximately 0·5 gm. fresh mud each month that samples were collected. This mud was covered with mud extract agar[2] (Warcup soil plate technique[3]) using larger inocula than recommended in the original technique to compensate for the paucity of fungi in the muds as compared with normal soils.

The percentage differences from bare mud have been calculated to illustrate the increased fungal coloniza-

Table 1. NUMBERS OF FUNGAL ISOLATIONS FROM DIFFERENT SAMPLING SITES

	Sampling site	No. of isolations	No. of samples	Average isolations per sample	Percentage difference from bare mud †
	Bare mud	148	12	12·3	—
A	Low *Salicornia**	162	12	13·5	+9·8
	Lower *Spartina*	102	11	9·3	−24·4
B	Middle *Salicornia*	111	8	13·9	+13·0
	Upper *Spartina*	97	10	9·7	−21·1
C	High *Salicornia*	104	8	13·0	+5·7
	Halimione	90	6	15·0	+22·0
	Suaeda	113	7	16·1	+30·9
	Puccinellia	100	6	16·6	+35·0

* Plants grouped under *A* were sampled at the same horizontal level on the marsh: this applies equally to *B* and *C*.

† Percentage of difference = difference between number of fungi isolated from rhizospheres and from bare mud, calculated as a percentage of the bare mud isolations.

tion up the shore. These changes may reflect the greater amount of organic matter present as a result of increasing cover by higher plants, and may also reflect the reduced periods of inundation by the sea.

The exceptions to the general increase call for comment. The high *Salicornia* zone shows a smaller difference from bare mud than the lower *Salicornia* zone, and this is the more striking when compared with the results obtained from *Halimione*, *Suaeda* and *Puccinellia* at the same level. This may be a reflexion of the stunted growth of the high *Salicornia* plants.

The two *Spartina* sites show a marked decrease in numbers of isolations compared with bare mud, and again this is emphasized by the increases obtained from the rhizospheres of nearby *Salicornia* plants. Depression in fungal numbers under *Spartina* may be a concomitant of the growth habit of these plants: many, particularly those in the lower zone, grow in water-filled depressions where conditions frequently lead to the formation of black muds by the activities of sulphate-reducing and possibly other sulphide-producing bacteria. Similar black muds are also found in the upper *Spartina* zone, where there may be interpolated sandy horizons. A preliminary comparison of non-reduced and reduced *Spartina* rhizosphere muds indicates that it is the condition of the reduced muds (possibly the low Eh, or the toxic effect of accumulated sulphides) and not any inhibitory effect of the *Spartina* which causes the depression in fungal numbers.

Physiological aspects of this work are now being studied: ecological aspects are being prepared for publication.

Thanks are due to Prof. C. G. C. Chesters for his help in the preparation of this communication, and to Mrs. M. Turner and Mr. T. R. G. Gray for many fruitful discussions.

Molybdenum and the Fixation of Nitrogen in *Myrica* Root Nodules

We have shown elsewhere[1] that nodulated plants of *Casuarina* and *Alnus*, grown under conditions which entail dependence on the fixation of elemental nitrogen, develop symptoms of severe nitrogen deficiency when deprived of molybdenum; this and other evidence obtained is wholly consistent with the view that, as in other biological nitrogen-fixing systems, molybdenum fulfils an essential role in the fixation proceeding in the root nodules of these non-legumes.

Work has now been extended to a third genus, *Myrica*. Young plants of *M. gale*, from seed sown in peat (experiment I) or purified sand (experiment II), were transplanted at the two-leaf stage into water-culture in 'Pyrex' beakers, the culture solution being prepared from reagents purified from molybdenum at the Long Ashton Research Station. All elements known to be essential were provided, except that no combined nitrogen was supplied (apart from an initial addition of 0·4 mgm. ammonium–nitrogen per plant in experiment I and 2·0 mgm. per plant in experiment II, to sustain the plants over the period of nodule formation), while molybdenum was omitted from certain cultures. Nodulation was secured by application to the root systems of an inoculum prepared by crushing nodules from field plants of *M. gale* in water. The plants were grown by daylight in the greenhouses of the Botany Department, University of Glasgow; other details of procedure were as described elsewhere[1].

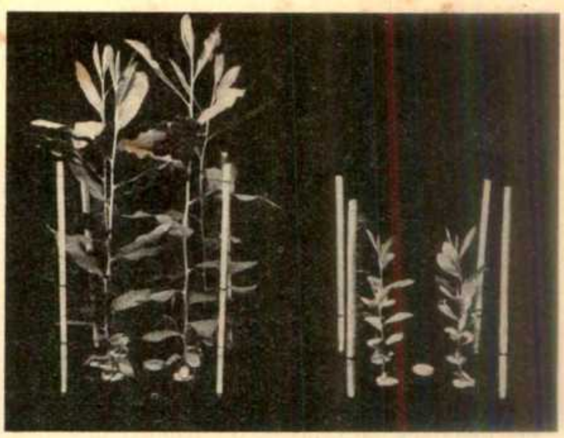

Fig. 1. Nodulated plants of *Myrica gale* after 12 weeks growth in water culture with (left) and without molybdenum supplied. (× 3/16). Photograph by Mr. R. Cowper

Nodules appeared some 2 wk. after inoculation, followed, after a further interval, by the commencement of vigorous growth in the plants supplied with molybdenum, indicative of the onset of fixation of nitrogen in the nodules. The plants not supplied with molybdenum lagged behind in their growth and developed symptoms of nitrogen deficiency; they were much reduced in stature and had small, pale-green leaves. Fig. 1 illustrates the disparity between the two types of plant at harvest after twelve weeks growth in water culture, while results based on the examination of some twenty plants in each treatment are provided in Table 1.

The results confirm the poor growth of the plants deprived of molybdenum and their deficiency in nitrogen. Fixation of nitrogen per plant, calculated by deducting from the total nitrogen per plant (Table 1) the mean nitrogen content of non-nodulated control plants, amounted to 15·0 mgm. (+Mo) and 1·5 mgm. (−Mo) in experiment I, and 13·7 mgm. (+Mo) and

Table 1

	Treatment	Mean dry weight per plant, mgm.*	Mean per cent nitrogen in plant dry matter	Mean total nitrogen per plant, mgm.	Molybdenum, p.p.m. in dry matter		
					Nodules	Shoot	Roots
Experiment I	+Mo	557	2·76	15·3	78·61	31·10	5·83
	−Mo	97	1·59	1·5	1·58	0·16	2·71
Experiment II	+Mo	510	2·92	14·9	273·70	52·34	33·94
	−Mo	150	1·95	2·9	0·93	0·18	0·97

* Statistical analysis of the dry weight data showed the differences between treatments to be significant at $P = 0·01$.

1·8 mgm. (−Mo) in experiment II. Relative to plant size, nodulation was actually better in the plants deprived of molybdenum, since nodule dry weight amounted to 14·4 per cent of whole plant dry weight in their case, but only to 7·1 per cent where molybdenum was supplied (mean values for the two experiments). Where molybdenum was provided, 383 mgm. of nitrogen was fixed per gm. of nodule dry matter formed, whereas the corresponding value for the molybdenum-deficient plants was only 83 mgm.; thus with molybdenum available, the nodule tissues were nearly five times more effective in fixation. Certain plants, deprived initially of molybdenum, were supplied with the element at an intermediate stage and showed obvious benefit within a few days.

The results in Table 1 also indicate the high accumulative capacity of the nodules for molybdenum. The higher molybdenum content, particularly in nodules and roots, shown in the plus-molybdenum plants of experiment II is possibly related to the circumstance that this experiment was conducted during the most favourable period climatically (May–August). In both experiments 0·05 p.p.m. of molybdenum was supplied in the culture solution where appropriate, some 17 per cent of the total supplied being absorbed by the plants in experiment I and 34 per cent in experiment II. Of the total molybdenum present in the plants at harvest, 24 per cent was in the nodules when molybdenum was supplied and 32 per cent when it was not.

The above results closely resemble those obtained in experiments with *Casuarina* and *Alnus*[1], and point to a special role for molybdenum in fixation in *Myrica* nodules also. A further finding of possible significance is that the two samples of field nodules of *M. gale* examined in this work proved to have molybdenum contents of 3·04 and 1·40 p.p.m. in the dry matter respectively; the latter value is of the same order as those for the nodules of plants cultured without molybdenum which fixed little nitrogen.

Technical assistance was provided by Miss K. McCormick and Mr. D. James.

Gibberellin Action on Growth of Seedlings in the Absence of Photosynthesis

A MAJOR effect of gibberellins on growing seedlings is often an increased dry weight, especially in the shoots growing in the light[1]. These and other observations have frequently led to suggestions that this particular gibberellin effect may be related to an increased photosynthetic carbon-fixation. We have found, however, that in light-grown seedlings that are prevented (by darkness) from performing photosynthesis, gibberellic acid can increase their dry weight over water-control seedlings. The effect of gibberellic acid in these experiments thus cannot be attributed to either direct or indirect actions on photosynthetic fixation.

Wheat, *Triticum vulgare*, var. Thorne, was germinated on 'Lucite' bars wrapped with moist paper towels in covered germinating dishes at 23 ± 1° C. during a 16-hr. day (∼500 ft. candles white light) and 17·5 ± 1° C. during the night. Four days after sowing the seedlings were transferred to darkness permanently with or without gibberellic acid. Plants, the heights of which differed by less than 2 mm., were paired so that within each experiment the population receiving treatment with gibberellic acid was comparable with the corresponding water controls. Seedlings were sown on two pieces of Whatman No. 1 filter paper moistened with 25 ml. of solutions, all at about *p*H 5·7, in 9-cm. Petri dishes. The dishes were kept in light-proof wooden boxes in the same growth-room. The plants remained in complete darkness except for a few moments of low-intensity green light while watering. After 4 days in darkness the shoots and roots were detached from the scutella, washed, and dried in an oven at 60° C. at least overnight. All plant material from a given experiment was dried for 3 days and ground in batches to a fine powder in a Wiley Mill using a 40-mesh screen. Within each batch the ground material thus was mixed so that portions removed for analysis were homogeneous and representative of the entire group of shoots or roots after each treatment (treated with gibberellic acid or control). Total carbon was determined by a modified Pregl method[2]. Soluble carbohydrate was extracted in boiling water and analysed by the anthrone method[3]. Total nitrogen was determined by a micro-Dumas method[2]. Protein was determined by the method of Lowry *et al.*[4]. In all these analyses duplicate samples never differed by more than a few per cent.

The dry weights of 8-day-old seedlings which had been transferred to darkness with or without gibberellic acid when 4 days old are listed in Table 1. In all experiments the plants weighed approximately two to three times more at 8 days than they did at 4 days. The treated seedlings, compared to control seedlings, showed typical gibberellin effects: greater dry weight of the shoot, less dry weight of the root system, and in most cases a greater dry weight of the whole plant. Uptake of the gibberellic acid itself could not have been sufficient to cause these differences in dry weight. Treatment with sucrose during the 4 days in darkness did not significantly alter the results.

Chemical analyses of dried shoots and roots from one experiment are given in Table 2. The increases in total carbon, soluble carbohydrate, total nitrogen, and protein in the shoots treated with gibberellic acid

Table 1. DRY WEIGHT OF WHEAT SEEDLINGS TREATED WITH GIBBERELLIC ACID IN DARKNESS. SEEDLINGS WERE 4 DAYS OLD WHEN TREATED, 8 DAYS OLD WHEN DRIED

Exp.	Sucrose concentration (per cent)	Concentration of acid (*M*)	No. of plants	Dry weight per plant (mgm.)

	percentage of dry weight	12·6	12·0	12·6	13·0	12·6	12·4

* Analyses were performed on finely ground dried material from plants in exp. 2*A* in Table 1

were approximately proportional to the dry weight increase.

Since the plants were not exposed to light during the time they were in contact with gibberellic acid, there could be no photosynthesis while the acid was increasing the dry weights. The gibberellic acid effects therefore could not be related in any way to photosynthetic fixation. The endosperm reserves plus photosynthesis that occurred before treatment with gibberellic acid were sufficient to produce the dry weight increases, since the addition of sucrose did not seem to greatly alter the results. The proportional increases in total carbon, soluble carbohydrate, total nitrogen, and protein suggest a general acceleration of growth under conditions in which neither carbon nor nitrogen is deficient. This effect of gibberellic acid treatment in darkness is on seedling growth proper, and has no relation to any action of the acid in breaking dormancy, because the plants were not treated with the acid until 4 days after sowing, when they were several cm. high.

These results are consistent with the finding that gibberellic acid does not increase directly either the rate or the pattern of photosynthetic $^{14}CO_2$ fixation in short-time experiments[5]. They also weaken suggestions that dry weight increases from treatment with gibberellic acid must necessarily be attributed to indirect effects on photosynthetic fixation. The fact that leaves treated in the light do not increase in chlorophyll content even though they increase in area[6] is further evidence against the theory that fixation is increased because of a greater photosynthetic area[1,7]. In his argument that fixation is increased by an accelerated mobilization of photosynthate, Alvim[8] apparently has equated photosynthesis with 'net assimilation rate'. Although we do not question that gibberellic acid can increase net assimilation, we do question that such increased net assimilation must necessarily be related to an increased photosynthetic fixation. Photosynthesis is but a part of the complex of many anabolic and catabolic processes which together determine net assimilation. Thus we are inclined to believe that an increase in dry-matter content in plants treated with gibberellic acid in light does not necessarily result from either direct or indirect increases in photosynthetic fixation, but can be attributed to altered utilization of photosynthate and other metabolites, regardless of their origin. Coulombe and Paquin[9] reported transient changes in transpiration as well as both respiratory and photosynthetic net gaseous exchanges of carbon dioxide after treatment of tomato leaves with gibberellic acid. To our knowledge, however, no one has demonstrated that gibberellin treatment can increase photosynthetic fixation, that is, the light-dependent reduction of carbon dioxide in green tissues. Products derived from photosynthesis undoubtedly are involved in the metabolic processes which underlie the response to gibberellic acid of light-grown plants, just as they are involved in other aspects of plant metabolism. But at the present time it seems doubtful whether gibberellic acid generally increases shoot dry weight by increasing photosynthetic fixation.

GENETICS

Non-disjunction of the Sex-chromosomes in the Male of *Drosophila melanogaster*

THE discovery that certain human abnormalities have a chromosomal basis has stimulated renewed interest in the phenomenon of non-disjunction. Theoretically, non-disjunction may occur in both the male and female germ cells at either the first or second meiotic division and may give rise to a considerable variety of non-disjunctional types in the progeny. In practice, only non-disjunction occurring at the first meiotic division in oocytes has so far been studied in *Drosophila*. The present communication reports the occurrence of spontaneous non-disjunction of the sex-chromosomes in *Drosophila* males.

The scheme used involves *brown-variegated*, bw^{VA}, an inversion originally obtained by H. J. Muller in the second chromosome which, in combination with the sex-linked gene *vermilion*, *v*, produces a characteristic yellow eye colour. This position effect of bw^{VA} is suppressed by the presence of an extra *Y*-chromosome, so that males of the genotype *XYY* and females of the genotype *XXY* exhibit the bright red eye colour normally associated with *v*. With the aid of this scheme, a search was made for the presence of *XXY* and *XYY* individuals in the progeny of normal *XY* males and *XX* females. Markers on the paternal and maternal *X*-chromosomes were used to decide whether non-disjunction had occurred in the father or the mother. The presence of an additional *Y* in the exceptional individuals was confirmed by progeny tests.

In addition to the already known types of non-disjunction, the following new ones occurred:

(1) *XXY* females with one paternal and one maternal *X*, which thus must have arisen through fertilization of a disjunctional egg by a non-disjunctional *XY* spermatozoon.

(2) *XYY* males with a maternal *X*. These probably arose through non-disjunction at the second meiotic division in the male. An alternative interpretation cannot be excluded, however. Lamy[1] found a small proportion of patroclinous *XXY* daughters with detached *X*'s among the progeny of attached-*X* females and attributed their occurrence to equational doubling of the *X*-chromosome in the sperm. She did not consider the possibility of non-disjunction at the second meiotic division. The frequency of *XXY* females in her experiments was considerably higher than that of *XYY* males in those reported here. If Lima-de-Faria's[2] observation that, in grasshopper chromosomes, euchromatin divides more rapidly than heterochromatin, should apply also to the chromosomes of *Drosophila*, equational doubling of the *Y* may take place very rarely or never.

The results obtained in this preliminary observation do not yet permit accurate quantitative estimates of the frequencies with which the various types of non-disjunction take place. The approximate frequencies, however, appear to be of the order of 0·01 per cent for type (1) and 0·004 per cent for type (2). The accurate frequencies as well as a possible influence of parental age will be determined in a more comprehensive investigation.

Determining Mating Type in *Neurospora* without Crossing Tests

Strains of *Neurospora crassa* belonging to either *A* or *a* mating type are morphologically indistinguishable. Mating type determinations are usually made by observing whether perithecia occur after crossing strains of unknown mating type to *A* and *a* tester strains. The tests are usually run either in two series of culture tubes or in pairs of Petri dishes. The use of tester strains on a large scale, however, may become laborious, ambiguous tests have to be re-run, and infertility sometimes confuses the results.

An alternative method which has been found useful for sex-testing numerous progeny from crosses employs a strain unable to grow on complete medium at elevated temperatures due to a mutant allele very closely linked to the mating-type locus. This strain, *unknown* (55701) (*un*), grows slowly on minimal medium at 25° C., but is stimulated by addition of acetate. At 35° C., however, no growth occurs on any medium yet tried[1]. *un* has shown very close linkage with mating type in tetrad analysis, no recombination between these two loci having as yet been obtained (Table 1). Since no recombination has been obtained, all the derived strains of *un* at present known are of the same mating type, *a*, as the one in which this mutation was originally induced[2].

Table 1. Crosses showing Linkage of *un*(55701) to *sex*

Cross	No. of asci	Recombination between *un* and *sex**
1*A* × *un a*	38	None (4)
vis A × *un a*	16	None (4)
pyr(68902) *A* × *un a*	22	None (4)
74*A* × *un ad*-5 *a*	94	None
ad-5 *A* × *un a*	21	None
frost A × *un a*	40	None
frost leu-3 *A* × *un ad*-5 *a*	56	None
leu-3 *A* × *un a*	18	None
leu-3 *A* × *un ad*-5 *a*	30	None
Total	335	

* Fiducial upper limit of recombination frequency between *un* and *sex* at the 5 per cent level is 0·011.

In practice, the *un* allele is incorporated into one of two parental stocks prior to crossing these two stocks with each other. Segregants isolated from the cross either by dissection or by sorbose plating[3] are placed in culture tubes of complete medium and incubated at 25° C. until initial growth verifies isolate viability. Complete media should include 333 mgm. sodium acetate per litre to stimulate growth of *un* at 25° C. As soon as initial growth occurs the tubes are transferred to 35° C. for 24–48 hr. Tubes should be placed at 35° C. only after initial growth is observed, because germinating *un* ascopores or incipient *un* mycelial transfers die if held excessively at 35° C.

The tubes which show no further growth at 35° C. contain the *un* allele and are, with high probability, of the same mating type as the *un* parent used in the cross. The tubes showing completed growth at 35° C. contain the *un*$^+$ allele and are, with high probability, of opposite mating type. All tubes are then returned to 25° C. where the *un* isolates will complete growth. No crossing tests and no subculturing are necessary.

Alternatively, scoring may be done exclusively at 25° C. by omitting acetate from the medium. In this case the *un* allele is readily distinguishable by markedly slow growth, provided no other segregating markers give sub-wild growth-rates.

The *un* segregation method is especially convenient when large numbers of segregants have to be scored for mating type. Investigations in which chromosomal aberrations such as translocations are being followed or where the mating type locus itself, for example, may require the sex-testing of numerous progeny. In such cases it seems more efficient to incorporate *un* into a parental stock and follow *un* segregation by means of temperature variation or slow growth-rate than to cross each isolate to two tester strains.

The accuracy of the method depends on the strength of the linkage between the *un* and *sex* loci. So long as this linkage holds, segregant mating types may be identified by the *un* phenotype. The method may be used with both visible and nutritional mutants provided none possesses the *un* type of temperature sensitivity.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Monday, June 12

Institute of Cancer Research: Royal Cancer Hospital (in the Conference Room of the Chester Beatty Research Institute, Fulham Road, London, S.W.3), at 3 p.m.—Prof. Antoine Lacassagne: First Sir Ernest Kennaway Memorial Lecture.

British Society for the Philosophy of Science (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. M. Munitz: "The Logic of Cosmology".

Tuesday, June 13

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

Wednesday, June 14

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. Honor B. Fell: "Tissue Culture in Experimental Pathology".*

Society of Chemical Industry, Food Group (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Mr. N. T. Gridgeman: "The Sensory Appraisal of Food".

Women's Engineering Society (at "Hope House", 45 Great Peter Street, London, S.W.1), at 7 p.m.—Annual General Meeting.

Thursday, June 15

Institution of Mining and Metallurgy (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 4 p.m.—Annual General Meeting. 5.15 p.m.—Mr. A. R. O. Williams: Presidential Address.

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. J. A. Shannon: "The National Institutes of Health—Programmes and Problems".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. V. C. A. Ferraro: "Magnetohydrodynamics".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Demonstrator in Organic Chemistry—The Registrar, University College of North Staffordshire, Keele, Staffs (June 14).

Assistant Lecturer in the Geology Department to teach Mineralogy—The Registrar, King's College (University of London), Strand, London, W.C.2 (June 16).

Assistant Lecturer or a Lecturer in Applied Mathematics—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (June 17).

Assistant Lecturer (with an honours degree or its equivalent, and a special knowledge of crop and grassland production) in the Department of Agriculture—The Registrar, University College of North Wales, Bangor, North Wales (June 17).

Lecturer (well qualified academically, with teaching, and preferably some industrial experience) in Organic Chemistry at Hendon Technical College—Clerk to the Governing Body, Town Hall, Hendon, London, N.W.4 (June 17).

Lecturer (with a good honours degree in mathematics and interested in mathematical statistics or in economics with statistics) to teach Mathematics and Mathematical Statistics to Institute of Statistics and economics degree finals standard—The Director of Education, The Polytechnic, 309 Regent Street, London, W.1 (June 17).

Research Demonstrator (graduate in geology), to engage in research; and a Research Assistant (graduate in geology or chemistry, or graduating this year), to assist the Professor of Geology in a study of the structure and composition of fossil and recent shells—The Registrar, University College of Swansea, Singleton Park, Swansea (June 17).

Research Students (with the degree of Bachelor or Master of a British University other than Manchester) in Science—The Registrar, The University, Manchester 13 (June 17).

Senior Lecturer/Lecturer (qualified in applied mathematics) in Mathematics—The Registrar, University College of North Staffordshire, Keele, Staffs (June 17).

Lecturer in the Department of Physiology—The Secretary, The University, Aberdeen (June 18).

Lecturer (Grade II) in Theoretical Physics—The Registrar, The University, Bristol 8 (June 19).

Senior Lecturer in Mathematics or Applied Mathematics at the University of Natal, Durban, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, June 20).

Graduate in Mechanical Engineering or Applied Mathematics, to conduct research on an aspect of vibration concerned with transport—The Secretary, University College, Gower Street, London, W.C.1 (June 24).

Lecturer in Crop Production—The Secretary, Wye College (University of London), near Ashford, Kent (June 24).

Lecturer in Metallurgy—The Registrar, The Manchester College of Science and Technology, Manchester 1 (June 24).

Assistant Lecturer (preferably with qualifications in sedimentology and an interest in recent sediments) in the Department of Geology—The Registrar, University College of Wales, Aberystwyth (June 25).

Assistant Lecturer (preferably applied mathematician) in the Department of Mathematics—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (June 30).

Lecturer in Philosophy at Monash University, Clayton, Victoria, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, June 30).

Lecturer (with a science degree with zoology as a major subject, followed by postgraduate experience leading to a higher degree and/or to published work) in Zoology at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, June 30).

Research Assistant (with special interests in climatology and meteorology, and ecology or physical geography) in Geography—The Secretary, The University, 38 North Bailey, Durham (June 30).

Research Fellow (honours graduate in chemistry, biochemistry or agricultural chemistry) in the Department of Soil Science, to study chemical changes in forest litter—The Secretary, The University, Aberdeen (June 30).

Biochemist (with experience in tracer techniques) in the Division of Experimental Biology and Virology—The Secretary, Imperial Cancer Research Fund, Lincoln's Inn Fields, London, W.C.2 (July 1).

Chair of Philosophy in the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, July 3).

Lecturer (with a good honours degree) in Philosophy at Fourah Bay College, The University College of Sierra Leone—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (July 5).

Chief Officer (with a recognized degree or equivalent qualification in botany, agricultural botany or agriculture, and preferably experience in laboratory organization and staff management) of the Official Seed Testing Station—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge (July 7).

Lecturer in Psychology at Rhodes University, Grahamstown, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, July 7).

Senior Lecturer in Psychology at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, July 15).

Senior Lecturer (with experience in concrete technology and structural design) in Civil Engineering at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, July 25).

Chair of Organic Chemistry; and Chair of Chemistry in the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, July 31).

Reader in Mathematics at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, July 31).

Senior Lecturer-in-Charge of the Department of Pharmacy, University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, July 31).

Lecturer (with a degree) in Agricultural Chemistry (Animal Nutrition); and a Lecturer (with a degree or diploma) in Agriculture (Economics)—The Principal, Harper Adams Agricultural College, Newport, Shropshire.

Postdoctoral Fellow in Organophosphorus Chemistry—The Secretary, Department of Chemistry, King's College (University of London), Strand, London, W.C.2.

TECHNICAL ASSISTANCE TO OVERSEAS COUNTRIES

THE Department of Technical Co-operation Bill, which received its second reading in the House of Commons on April 25, gives effect to the Government's decision, announced by the Prime Minister on March 11, to create a separate Department, under the charge of a Minister, to co-ordinate responsibilities and functions in regard to technical assistance to overseas countries which are at present divided between the Foreign Office, the Commonwealth Relations Office and the Colonial Office. The Minister will be known as the Secretary for Technical Co-operation, and his Department will be concerned with technical assistance, defined in the White Paper issued in March as "training in the United Kingdom and overseas, the provision of experts, administrators and other professional men and women, the provision of advisory technical and consultant services and expert missions, and the supply of equipment for training, demonstration, pilot schemes or surveys". It will not, as Sir Edward Boyle, Financial Secretary to the Treasury, emphasized at the outset of the debate, be responsible for the provision of capital, which will remain with the overseas Departments.

Sir Edward Boyle, who was moving the second reading of the Bill, said that at the beginning of 1960, about 47,500 overseas students were receiving training of some kind or other in Britain, of whom about 2,000 held some form of United Kingdom scholarship, and about 2,500 trainees have come to Britain under the technical assistance arrangements of the Colombo Plan, while 380 British experts have been employed under the Plan in south and south-east Asia. Altogether, some 6,000 professionally qualified officers were recruited in Britain to serve overseas Governments during the years 1955–60, although the table given in the White Paper* shows that the annual figure has declined from 1,467 in 1956 to 816 in 1960. Some of this educational assistance is at present handled by the Ministry of Education, the British Council, the Commonwealth Scholarship Commission and other bodies, and Sir Edward said that there is no intention of disturbing such arrangements where they were working well, though some marginal adjustment of responsibility may be necessary. In particular, he quoted the recruitment of specialists, such as biologists, as being handled more easily and efficiently if centralized in one department, irrespective of where the specialist was to serve. Sir Edward, in reply to a question about social services, to which the Bill refers, said that provision of medical services would certainly be included, as well as provision of experts to advise on starting a new industry or the provision of skilled administrators in every field.

An important responsibility of the new Department would be the administration of the scheme described in the White Paper last October for the continued employment of overseas officers. This scheme is expected to cost about £12 million a year. The responsibility for the transfer, promotion and discipline of the overseas service in dependent territories, however, would remain with the Colonial Secretary. The new Department will be concerned with the technical assistance which the United Kingdom provides through the United Nations, in particular the United Nations Expanded Programme of the Technical Assistance and Special Fund, and will take over the present work of the Technical Assistance Recruitment Unit of the Ministry of Labour, which recruits in Britain for service with the United Nations. It will also deal with technical assistance under the Colombo Plan and under the newly formed Special Commonwealth African Assistance Plan. It will be responsible, on behalf of the United Kingdom, for any technical assistance discussions in the Development Assistance Group and in the new Organization for Economic Co-operation and Development, and for the provision of technical assistance to a number of Middle East countries under the Central Treaty Organization arrangements and through the Middle East Division. The work of the British Council in education will retain its full importance, and the Ministry of Education will continue to be responsible for Britain's contribution to the United Nations Educational, Scientific and Cultural Organization.

Sir Edward anticipated that the staff of the new Department would number about 1,000, initially by transfer of posts and staff from existing overseas Departments and including about 550 from the directorates of the Overseas Services and the Overseas Geological Surveys, and its vote was estimated to be about £30 million, including certain expenditure now financed out of Colonial Development and Welfare Funds, but not involving any new expenditure. In replying on the debate, Sir Edward Boyle pointed out that British expenditure on technical aid had increased from £75 million in 1957–58 to about £100 million in 1958–59 and about £150 million in 1959–60, with a further £100 million of private investment in less-developed countries. He emphasized that there is no intention of changing the Government's policy in this respect, and that British commitments to the Colonies and under-developed countries are likely to increase. The Colonial Secretary is still responsible for more than thirty Colonial territories, and Sir Edward agreed that one of the dangers to be watched in operating the new Department is that of excessive consultation with the existing overseas departments, hindering prompt decisions. He also agreed as to the importance of an adequate supply of managers and engineers to enable the power stations and factories, etc., provided by technical aid, to be operated, that the relief of poverty in under-developed lands is one of the greatest moral challenges of our times, and as to the importance of bringing more people to Britain for training in skills which would be valuable in their own country when they returned ; but he pointed out also that we should not think entirely of engineering and technical skills, and that it is important to make greater use of expert knowledge and skill.

---

* Technical Assistance from the United Kingdom for Overseas Development. Pp. 43. (Cmnd. 1308.) (London: H.M.S.O. 1961.) 2s. net.

The scale of the technical assistance already provided from the United Kingdom for overseas development is more fully displayed in the White Paper, which was freely quoted in the debate. This document includes among its annexes an impressive list of advisory committees and councils under the Colonial Office, and also of technical and other institutions in the United Kingdom which provide services overseas. Much of this service, like the contribution of private enterprise, clearly could not be included in the estimate of £150 million (£125 million bilaterally and £25 million multilaterally) given in the White Paper. The work of many of these bodies, like that of various advisory committees on research or the Colonial Development Corporation, is already known to many readers of *Nature*, though the White Paper gives some figures conveniently for reference. Thus, by the end of June 1960, the United Kingdom spent or formally committed for technical assistance to the countries of south and south-east Asia some £6,800,000, and the Government has declared its willingness to spend up to £9,000,000 for technical assistance under the Colombo Plan in the period April 1956–March 1963. Of this, about £1,585,000 was spent on the provision of some 380 experts and about £1,800,000 on equipment for training and research. About £6 million was contributed in 1960 to the various United Nations Technical Assistance activities—about double the amount contributed in 1959.

On the contribution of private bodies in the United Kingdom, the White Paper gives no information; but it refers with appreciation to the formation in 1958 of Voluntary Service Overseas, which will enable young men and women from the United Kingdom to serve as teaching and social welfare auxiliaries in the Commonwealth. This organization was welcomed in the debate in the House of Commons, though Mr. R. E. Prentice suggested that the new Ministry should initiate something on the lines of the Peace Corps started more recently by the President of the United States. Much more stress, however, had been laid on this aspect in a debate in the House of Lords on February 22, which dealt moreover with the fundamental purpose of technical aid—that of enabling the under-developed countries to raise their economies to a point where they could survive on their own. It is a combination of capital and technical skill that is required, and while these under-developed countries are at present receiving something like 4,000 million dollars a year, more than half of which is found by the United States, the United Nations Special Fund has only been able to support some 70 of the 250 projects for which it has received applications.

Lord Grantchester, after a tribute to the part Britain has played in establishing universities in its dependent or emerging territories, suggested that there is room for more co-ordination between the universities in dealing with overseas students. He also urged in particular the need for more individual advice for the students and the Governments of the countries from which they come. His suggestions for the establishment of training centres in London, where a limited number of students could obtain satisfactory training prior to entrance to a university, and for an alternative to the university course for overseas students, with particular emphasis on administration, seem worthy of consideration. Moreover, they are of the type where the initiative may well lie more fittingly with the Department of Technical Co-operation than with the Ministry of Education.

The Marquess of Lansdowne, who spoke for the Government, pointed out that if the effectiveness and volume of aid are to be increased, donor countries must encourage their experts—technicians, teachers and medical men—to serve where they are so vitally needed in the less-developed countries, concentrating on the projects of real value to the recipients and providing training facilities in their own countries. It follows from this that a Department of Technical Co-operation should be closely concerned with the establishment of the conditions which make it as easy and attractive as possible for professional men and women, as well as technicians, to serve overseas. This aspect was also urged strongly by the Bishop of Chichester. Suggesting first that it might be worth while examining our methods of rendering technical assistance in the light of ten years experience, he stressed the need especially to consider technical assistance in the context of educational assistance. The economic resources of a country cannot be developed fully without a continuing supply, from within that country, of technicians, administrators, and leaders of all sorts. He emphasized the need for public opinion to recognize and support the overriding need for teachers and educational assistance generally. He hoped that authorities in schools and universities will urge this opportunity on members of staff and students, and that technicians and scientists from industry may also contribute to such teaching for a few years.

Obviously, this is the point which the Duke of Edinburgh pressed in his Graham Clark Lecture to the Institutions of Civil, Mechanical and Electrical Engineers on April 13, and in the House of Lords debate Baroness Summerskill suggested that the universities should be assisted to establish supernumerary appointments so as to enable staff to go overseas. The Earl of Perth, who replied on the debate, referred particularly to the work of the Inter-University Council for Higher Education Overseas, and said that some £17 million from Colonial Development and Welfare Funds have been used for research and higher education; but the 30,000 students from the Commonwealth in British universities and technical colleges represent a further hidden contribution of some millions of pounds, including a very considerable effort in medical training. Scientists and technologists are already playing an important part in this effort; indeed, one theme of the Duke of Edinburgh's Graham Clark Lecture was that engineers have a responsibility to help in improving the material welfare of the poorer countries. It should also be remembered that a number of leading scientists have for many years been urging this responsibility and its implications on their colleagues.

At the Committee stage of the Bill on May 10, Sir Edward Boyle said that the Overseas Research Council will not itself be responsible for expenditure from Exchequer funds, but the new Department will, in general, take over research work in the United Kingdom which is now financed by the three overseas Departments, and in particular it will take over certain research work now financed from Colonial Development and Welfare Funds. Sir Edward also agreed as to the importance of the new Department having ample sources of information and that it is desirable that the new Department, which will have a small but important information branch, should give some publicity to its technical assistance work. Sir Edward's remarks did not, however, make the exact position of the Overseas Research Council very clear, and it is essential that the position should be carefully watched.

The debate on the Department of Technical Co-operation Bill scarcely touched on the aspect of capital investment, but some speakers were not entirely satisfied that capital aid is not within the Department's scope. Nevertheless, the debate showed that the interrelation of capital aid and technical aid, in the sense of personal service, is fully recognized, more so, perhaps, than in Dr. V. K. R. V. Rao's eighteenth Montague Burton Lecture on International Relations at Leeds last November*. In this lecture, on "International Aid for Economic Development: Possibilities and Limitations", which has recently been published, Dr. Rao, after reviewing the various attempts which have been made to accelerate the economic development of the backward territories with international and bilateral aid, suggests that all such aid should be internationalized and channelled through a modified International Development Association, for which he outlines a revised plan. He believes that such a scheme would deal automatically with the limitations at present placed on international aid—by resources, capacity for repayment or for absorption, or by the risk of demoralizing the recipient countries so that dependence replaces self-reliance.

The fundamental condition stressed by Dr. Rao, however, is a change in psychology, the recognition on the part of nations that they are all parts of the world, and that their citizens are all members of the human race. The establishment of a Department of Technical Co-operation certainly recognizes that need and should help to co-ordinate the British contribution both to British dependent territories and elsewhere. What is also required, however, is the clear understanding and firm support of those who will provide the expert knowledge, and for that reason alone the Department when it is established should receive careful attention by scientific and professional workers of all kinds, both individually and through their professional associations. There is nothing in the White Paper to suggest that weaknesses already apparent in regard to overseas research are recognized, and while the magnitude of the overseas research effort of Britain is not apparent either, that effort is sufficiently large in terms both of man-power and of expenditure for it to be important that resources should be wisely and efficiently used. Apart from that, however, the formation of the new Department should be a further stimulus to the constructive thinking as well as the personal service that are essential to enable technical assistance to match the opportunities becoming available, either in magnitude or in quality.

INSECT BIOCHEMISTRY

The Biochemistry of Insects

By Darcy Gilmour. Pp. xii+343. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1961) 64*s*.

In recent years an increasing number of biochemists have come to use insects as the source of their material for study; and entomologists studying the toxicology of insecticides have found the need for more knowledge of insect biochemistry. The time was therefore ripe for the appearance of this first text dealing with the subject. A difficult problem in such a book is how much introductory matter to include. The author assumes a general knowledge of chemistry and biochemistry; but whenever metabolic cycles or sequences are discussed the reader is tactfully reminded of the main outline of what is known of these processes in general biochemistry. Emphasis throughout is on what has come to be called 'dynamic biochemistry': the description of firmly established stepwise transformations and of the enzymes by which they are catalysed. The author recognizes the need for a sound basis of descriptive chemistry; but where well-controlled biochemical studies are lacking—as in the hardening of the insect cuticle—he makes the gap apparent to his reader.

There are large areas of the subject where the insect biochemist is mainly confirming the existence of processes already established elsewhere. But there are interesting variants, such as the predominance of glycerophosphate over lactate as the end-product of the glycolytic sequence in the flight muscles of some insects. Not all insect biochemistry, however, is of this derivative sort. In some quarters the insects lead the field. The cytochromes, which were soon recognized as the universal chain for electron transfer to oxygen, were discovered and characterized in the insect. Even the recent addition to the series, the microsomal cytochrome b_5, was discovered in an insect. The pteridines, which were first identified as inert pigments in the wings of butterflies—what

---

* International Aid for Economic Development: Possibilities and Limitations. By Dr. V. K. R. V. Rao. (Eighteenth Montague Burton Lecture on International Relations.) Pp. 29. (Leeds: The University, 1960.) 6*s*.

Gowland Hopkins called 'waste products that function in ornament'—seem ever to be increasing in metabolic importance as growth factors, photolabile receptors, co-factors for the transfer of 'active formate' and so on; and some of the most suggestive work is still being done on insects. Although best known in insects, the ommochromes and their relation to tryptophan metabolism are of general interest for the light they have thrown on gene action. The sclerotin of insect cuticle, formed by the quinone tanning of protein, constitutes a new type of natural polymer which still awaits biochemical analysis: and insects provide the ideal material for studying the biochemistry of morphogenesis.

The author recognizes physiology as a reputable discipline, but he does not allow himself to be diverted into physiological discussions, beyond the minimum necessary to link up his biochemical arguments. He always draws a clear distinction between what is surmised and what has been demonstrated. All this makes a book that is distinctive and stimulating in the sense that the reader feels a strong urge to go and fill the gaps in our knowledge. Almost every point made is documented by references to original work. V. B. WIGGLESWORTH

EVOLUTION AND PHILOSOPHY

The Ascent of Life

A Philosophical Study of the Theory of Evolution. By Prof. T. A. Goudge. Pp. 236. (London: George Allen and Unwin, Ltd., 1961.) 30*s.* net.

THIS book may be warmly recommended precisely because it gives a sustained philosophical discussion of modern evolutionary theory. It is eminently readable and its moderate tone should ensure for it a place on the bookshelf of every professional evolutionist. This is not to say, however, that the arguments in the book are wholly convincing or without blemish. The philosophical approach is chiefly that of the neo-positivist or empiricist, and this approach has clearly limited the scope and value of the book. Prof. Goudge seems to consider that a philosophical explanation, while going beyond the empirical facts and assumptions, is somehow immanent in them but cannot be transcendent to them unless capable of empirical application. This point of view would again seem to narrow the value of the interpretations given. I am sure many people consider that the value of a philosophical explanation of a biological theory is precisely because it may go far beyond the theory into a wider realm of meaning which the theory may have for us in both our sentient and intellectual lives.

After an introduction and a second chapter, which is described as historical but does not give much actual history, Prof. Goudge begins the main chapters of the book. The evolutionary theory mainly considered is that of modern selection, and even here this explanation is practically limited to evolution in the light of population genetics. A certain courage is here manifested by the author because population genetics is new, highly abstracted, speculative, and its models are greatly simplified versions of the real picture. It may be fashionable to consider that evolution occurs through 'populations', but it is a serious mistake to give a philosophical account of evolution which implies that evolution occurs only by this method. There just is no evolutionary or genetical reason why a single individual (or a single pair) of organisms should not start, or have started, a new evolutionary line. This is a point which is important in considering the evolution of man, and it is missed completely by Prof. Goudge.

Other legitimate biological theories which are often misunderstood and have never been philosophically refuted, such as vitalism, finality or neo-Lamarckism are, indeed, mentioned but are unfortunately given scant treatment. On the question of finality alone the fundamental point, that without the assumption of finality many scientific statements could scarcely even be made, is ignored. It is a pity also that the basic assumptions of the theory of evolution are not given any philosophical treatment. Nevertheless, there is a wealth of ideas and suggestions in this book which should enlarge the vista of the evolutionary biologist. P. G. FOTHERGILL

HUMAN GENETICS

Recent Advances in Human Genetics

Edited by Prof. L. S. Penrose, with the assistance of Helen Lang Brown. Pp. vii+194. (London: J. and A. Churchill, Ltd., 1961.) 27*s.* 6*d.* net.

HUMAN genetics is now a branch of biology with its own methods. This is due largely to Penrose on the genetical side, and Tjio and Levan on the cytological. This small book is not a text, but consists of eight chapters by Penrose and six colleagues. In the first chapter Penrose summarizes recent work on human mutation-rates and their dependence on age. He is sceptical of the high rates (median 28 mutations per chromosome per generation) estimated for autosomal recessive defects, as compared with a median value of 6 for dominants. He believes that they often are or have been advantageous to heterozygotes. The data on ages of parents of mutants are equally interesting, and make it clear that mutation at different loci must be due to wholly different processes. Harnden and Miller deal with chromosomal abnormalities, and some sexual abnormalities in chromosomally normal people. The most striking item in Penrose's chapter on fœtal genetics is perhaps the map on p. 71 showing the distribution of anencephaly in Europe, with one peak in Ireland and western Britain, and another around Naples.

Gerald's article on the abnormal hæmoglobins is a useful snapshot of a very rapidly developing subject, and contains some 'stop-press news' which very much interested me. The subject will probably remain a little confused until a new technique is devised which will be as quick as electrophoresis, and which can distinguish between some chemically different variants that are not electrically separable. Holt deals with the ridge patterns of fingers and palms, which are among the most accessible of human characters, and, in view of the correlations exceeding 0·95 between monozygotic twins, must be mainly determined genetically. The last two chapters are largely statistical. Renwick describes the search for human linkage, and its estimation, while Smith deals mainly with other statistical problems, including his own remarkably efficient iterative method.

To a reader who had been cut off from reading for as short a time as two years, the chapters on chromosomal abnormalities and sex determination would be the most striking. Two years hence we should know a great deal more on these matters. But the whole book is very good. It is not free from errors, for example, the statement on p. 87 that "individuals heterozygous for the gene determining *Hb S* invariably possess both *Hb A* and *Hb C*". This is corrected later in the same paragraph. However, I have detected no serious mistake. It can be read with great benefit by students of other branches of genetics, and of medicine. Some knowledge of both genetics and pathology is assumed. The alternative would have been to double the volume and price of the book. Helen Lang Brown, who helped in editing, and was almost surely responsible for the very full bibliography with 526 references, deserves special thanks.

J. B. S. HALDANE

TECHNICAL APPLICATIONS OF FRESHWATER BIOLOGY

Handbuch der Frischwasser- und Abwasser-Biologie.

Von Prof. Hans Liebmann. Band 2. Lieferung 1: Pp. xi+1–160. Lieferung 2: Pp. 161–320. Lieferung 3: Pp. 321–480. Lieferung 4: Pp. 481–640. Lieferung 5: Pp. 641–800. Lieferung 6: Pp. 801–960. Lieferung 7: Pp. 961–1149. (München: R. Oldenbourg, 1960.) 20 D.M. each number.

THIS volume is the second of a pair. The first, published in 1951, dealt with freshwater biological methods and the most important chemical techniques which are needed to supplement them. It contained also an exhaustive treatment of the indicator organisms which can be used in the study of pollution, and a new exposition of the Kolkwitz and Marsson *Saprobiensystem*, which is widely used in Europe for assessing organic pollution.

The two volumes are intended to be used together, and the second contains many references to the first. In both, the emphasis is on the 'application' of biological knowledge to water technology, and although much basic freshwater biology is included it is clear that the author intends this only as a background. This approach to a subject which is often regarded as primarily academic should commend itself to readers in many disciplines concerned with the uses of water in their widest sense.

The second volume begins with a discussion of the various processes which result in natural self-purification of organically polluted waters, and this leads to a brief survey of the biology of waters in general, including artificial lakes and reservoirs. It then considers drinking water, with special reference to its origin, since the organisms which occur, or develop, in it vary according to whether it comes from underground or surface sources. Here also are described the various filtration and other methods which are normally employed, and the biological problems which may arise in their use, as well as the difficulties caused by water blooms and their control. A similar, shorter, chapter deals with swimming pools and spas.

A further section covers freshwater fisheries of all kinds, from natural rivers and streams to fish farms, and here again the emphasis is on practical management.

The author then discusses the methods of sewage purification, with particular reference to the biological processes involved. This section is a mine of information on the various processes in use on the Continent, including some, such as fish ponds, sewage ponds and irrigation, which are not used in Britain, but which might well be considered for introduction. Many readers of biology could learn much about civil engineering from these chapters, as could engineers about how their steel and concrete structures enable micro-organisms to purify effluents. Of particular interest are the accounts of the use of sewage in Munich for rearing carp, and of the biology of trickling filters and activated sludge.

The final section, written in collaboration with Dr. H. A. Stammer, gathers together the scattered literature on the toxicity of inorganic and organic chemicals to freshwater organisms, and the effects of suspended solids and high temperature on fish. It will be most useful for reference.

The book is well illustrated with photographs, and contains diagrams from many original papers. It ends with a hundred closely printed pages of references and a good index. It is, in short, an excellent book to have on one's shelf, or in the nearest library, and Dr. Liebmann is to be congratulated on having performed such a Herculean task.

I have, however, some criticisms. First, 140 D.M. is a very high price for any book, and for this one it seems unnecessarily high. Many points are discussed several times, and liberal application of a blue pencil could have made the book much shorter with no loss of content. Moreover, many figures are reproduced two or three times. There is also a very large number of misprints, only some of which are corrected in three pages of errata. Many of these involve the names of invertebrates, and Dr. Liebmann would have been well advised to submit the proofs to a zoologist. This would also have saved him from calling *Suberites* a freshwater sponge, mislabelling at least three of his photographs and making several other unnecessary mistakes. More careful editing could have removed these blemishes and lowered the price.

H. B. N. HYNES

PROTON RESONANCE

Applications of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry

By L. M. Jackman. (International Series of Monographs on Organic Chemistry, Vol. 5.) Pp. xii + 134. (London and New York: Pergamon Press, 1959.) 35*s*. net.

FROM birth to maturity, the application of nuclear magnetic resonance to problems in organic chemistry spans a period of only five years. Dr. Jackman's book is therefore timely, for which both author and publisher are to be congratulated.

The questions that nuclear magnetic resonance is asked to solve in organic chemistry are: (1) What types and number of protons can be distinguished by their chemical shift? (2) What information about the environment can be obtained when the spin-coupling components are resolved? Both topics are treated in the book although, appropriately (1) is dealt with more thoroughly. While many important spectra are described and analysed, the theoretical content is strongly qualitative, and it is possible to doubt if this severely practical outlook really conveys the elements of the subject to the uninitiated. This is perhaps not the purpose of the book, but it fails to meet the condition that the full deployment of nuclear magnetic resonance in problems of structure involves a better appreciation of its principles than, for example, ultra-violet or infra-red spectroscopy.

An account of the general theoretical and experimental background is followed by two central chapters dealing with the relationship between proton shifts and chemical structure. The information summarized here will be of immense value to structural chemists, and it is likely that the carefully assembled tables will form part of the intellectual furniture of organic laboratories for a considerable time: in fact, the exposition and illustration of factors governing the chemical shift form the strongest part of the book. Spin-spin interactions are described in a subsequent chapter wherein the position is a less happy one. The discussion ranges from examples of AB coupling which are readily apprehended even in large molecules to complex cases, for example A_2B_3, where complete resolution can only be accomplished with great difficulty. The tendency to quote, without derivation, formulæ for the frequencies and intensities of lines in a spin multiplet is unfortunate if spin-coupling constants are to be fully exploited as instruments for structure determination. It would seem that an account of electron-coupled interactions in terms that will commend themselves to organic chemists has yet to be achieved.

The book is well produced and illustrated, though misprints are fairly common. There is no doubt it will occupy a place in the bookshelves of most, if not all, organic chemistry laboratories.

J. C. D. Brand

WAVE MOTION OF OCEANS AND ATMOSPHERES

Hydrodynamics of Oceans and Atmospheres

By Carl Eckart. Pp. xi+290. (London and New York: Pergamon Press, 1960.) 63*s*. net.

This book has a misleading title in the sense that it is neither a balanced introduction nor a treatise on the hydrodynamics of oceans and atmospheres. The dust cover and preface hint at a narrower topic; the list of contents makes it clear. Most of modern dynamic oceanography and meteorlogy—general circulation, weather prediction, current and wind structure, interaction of wind and sea, turbulence, diffusion, internal friction—are scantily treated, if at all. In fact this book is a monograph, suitable for research workers in geophysical fluid dynamics, on wave motion in an inviscid fluid. Its approach is akin to that taken by the Norwegian school of meteorologists in their book *Physikalische Hydrodynamik* of 1933. Prof. Eckart considers the effects of compressibility, vertical variation of density, gravity, and Coriolis force, but not instability due to shear in the unperturbed state of equilibrium. To this limited topic he applies new methods, drawn from his great experience of mathematical physics.

The perturbation equations for various basic states are set up in the opening Chapters 1–5. At the same time, the time-mean motion of the Earth's atmosphere and sea is discussed perfunctorily, and some simple stationary models for the basic state are described in Cartesian and Mercator co-ordinates. The remaining chapters, 6–17, contain an original and powerful treatment of the perturbation equations. Ray theory of geometric optics, the Wentzel–Kramers–Brillouin approximation, and Sturm–Liouville theory are used for a variety of cases depending on the basic variation of density, and on the neglect or retention of the Earth's rotation and of the curvature of the geopotential surfaces. This treatment embraces and unifies much classical work on sound, internal gravity waves, Lamb waves, tides and Rossby waves.

Throughout the text are remarks claiming the importance of linear wave-motion. The arguments are broadly of three kinds: those that maintain the physical relevance of wave motion, those that deny the adequacy of other theories, and those that promote wave theory as a first step toward understanding more complicated phenomena such as turbulence. Lack of space has prevented the author from properly discussing rival theories or observations of the sea and atmosphere, so I have yet to be convinced that wave-motion is more than one of many topics important in geophysical fluid dynamics. However, to this one topic the author has made an extensive and original contribution.

P. G. Drazin

MAN AND HIS ANCESTRY

Man and His Ancestry

By Alan Houghton Brodrick. Pp. 256+16 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1960.) 35*s*. net.

The recent spate of semi-popular books on man and his ancestry has given the reader a wide choice. This one is useful for reference purposes since it covers a wide field and quotes many of the sources. It includes a good many new discoveries which are not widely known outside specialist journals (for example, the post-war hominid remains from China and the Neanderthal footprints cave at Toirano) and the author has some stimulating ideas about familiar facts. There are chapters on "What is Man?", "The Genealogy of the Apes", "The Discovery of Man's Antiquity" and others on the Australopithecines, the Pithecanthropoids, the Neanderthaloids and *Homo sapiens* fossils. Each chapter is divided by numerous sub-headings which help to lessen the confusion caused by rapid leaps from one subject to another.

Inevitably, Mr. Brodrick's book will be compared with *Mankind in the Making* by Prof. W. W. Howells; both have appeared within the past few months and cover essentially the same ground, both are easy to read and sprinkled with anecdotes. But while Prof. Howells is a trained anthropologist who can be relied on for accuracy, the general reader (for whom *Man and his Ancestry* is presumably intended) will be badly misled if he accepts all Mr. Brodrick's statements.

The Australopithecines are said to have lived more than a million years ago; and the beginning of the Pleistocene is set at "about two or possibly three million years ago". The Ternifine fauna is stated to be post-Villafranchian "as the presence of *Equus* indicates" (*Equus*, of course, first appeared during the Villafranchian, as the author himself points out earlier in the book). Apart from a good many minor inaccuracies of this kind, there are more serious misinterpretations. The principles of natural selection, for example, seem to have been overlooked: "Apes do not have long arms because they live in trees, they live in trees because they have long arms".

If most of this review has been taken up with criticisms, it is in the hope that the faults will be corrected in subsequent editions. If this were done, the book could be thoroughly recommended as a lively introduction to the subject of man and his ancestry. SONIA COLE

PHYSIOLOGY OF EFFECTOR ORGANS

Vergleichende Physiologie

Von Prof. W. von Buddenbrock. Band 5: Physiologie der Erfolgsorgane. (Lehrbücher und Monographien aus dem Gebiete der Exakten Wissenschaften. Reihe der Experimentellen Biologie, Band 10.) Pp. 390. (Basel und Stuttgart: Birkhauser Verlag, 1961.) 54 D.M.

WHEN, in 1936, W. von Buddenbrock published the second edition of the *Grundriss der vergleichenden Physiologie*, the rapid development of comparative physiology had made necessary a subdivision of the work. The first volume was devoted to the sense organs and the nervous system. The comparative physiology of the effector organs was the subject of Volume 2 of the new edition. After the War von Buddenbrock undertook the Herculean task of revising the whole work and incorporating it in the enormous advances in the subject that had been made, especially in the English-speaking world, immediately before and during the War. The result was the publication of a work in which Volumes 1 and 2 were devoted to sensory physiology and nervous physiology respectively. Nutrition, water and mineral economy were dealt with in Volume 3 and the comparative physiology of hormonal control in Volume 4. The present volume, the fifth in the series, is devoted to the comparative physiology of effector organs. These include muscles, cilia, flagella, chromatophores, luminous and electric organs, but there is no account of glandular effectors. A sixth volume dealing with blood, heart and respiration is in preparation.

Volume 5 is a consistent and equal partner to the preceding volumes of the work. It shares with them both their merits and their faults. On the merit side it can be said that the treatment of the subject benefits from the author's wide-ranging insight into the fundamental biological problems as well as his astonishingly up-to-date information on modern trends in research and their theoretical implications. Especially the chapters on muscle, colour-change, luminous and electric organs well bear out his claim of having incorporated the literature up to and, in some cases, including 1959. This has enabled him at least to sketch out an account of the results of modern experimental work against a background of older observational data. The faults may be considered inherent in an attempt to present comparative physiology in its entirety in a work of 6 volumes written by one author, at a time when a comparative monograph on muscles alone has appeared filling 3 volumes written by a galaxy of experts. As a reference work, then, and a progress report, the book is bound to fall short of the research worker's needs. Its usefulness as a text-book, quite apart from its bulk and price, is also doubtful. The author, having introduced a wealth of frequently conflicting research data, is justifiably reluctant to arrive at the sort of generalizations on which a student depends on to find his way into, and about, a new subject. More often than not, the student is left with a shrug of eminent shoulders where he has been looking for guidance, if only in guessing.

Thus it may well be that the book's justification and importance lie in its use by the academic teacher, especially in German-speaking countries. To him it can be an invaluable guide to the literature not least by means of the excellently arranged lists of references divided into various categories, namely review articles, older original papers and recent publications.

The volume, like the others, is well illustrated and contains many tables of qualitative and quantitative research data. The style is as lucid as ever, and the presentation bears witness to the unflinching enthusiasm, scientific honesty and wisdom of a man who has, perhaps, contributed more than any other towards the creation, moulding and consolidation of comparative physiology as an important branch of biological science. O. LOWENSTEIN

REPRODUCTION IN ANIMALS

Marshall's Physiology of Reproduction

Vol. 1, Part 2. Edited by Prof. A. S. Parkes. Third edition. Pp. xx+877. (London: Longmans Green and Co., Ltd., 1960.) 240*s*. net.

THIS is the third volume of the third edition of Marshall's *Physiology of Reproduction* to appear since 1952. The fourth and final volume is due to be published within the next twelve months.

The major part of the present volume is devoted to reproduction in the male (spermatogenesis, structure and metabolism of spermatozoa, natural and artificial insemination) and fertilization. These topics have been studied so extensively since the 1922 edition of Marshall's book that some 400 pages are necessary to summarize present-day knowledge (as against 80 pages devoted to the topics in the previous edition). It is a tribute to the editor, Prof. A. S. Parkes, and his team of distinguished authors (including the late Dr. Arthur Walton, Dr. C. R. Austin, Dr. M. W. H. Bishop, and the editor himself), that the present volume maintains the high standard of workmanship. elegant style and accuracy that we have been led to expect from the preceding two volumes.

The chapter on gonadal and gonadotrophic hormones in lower vertebrates, contributed by Prof. J. M. Dodd, provides the best comprehensive review published hitherto of this new and rapidly expanding subject. The chapter is amply and beautifully illustrated, and will be invaluable to zoologists and physiologists alike. The penultimate chapter, by Prof. A. S. Parkes and Prof. A. J. Marshall, deals with reproductive hormones in birds. The last chapter, on external factors in sexual periodicity, was drafted by F. H. A. Marshall before his death, and has been revised and brought up to date by Prof. E. C. Amoroso. It deals with many controversial topics, which are stated with both clarity and impartiality, and will prove of immense value to the many workers currently engaged in research in this field.

It is unfortunate that the volume lacks a table of contents of the preceding two volumes, and it is to be hoped that the final volume will carry a cumulative list of contents for the whole series.

Although the price of this volume is high, there can be few serious students of reproductive physiology who can afford to be without it. ANITA M. MANDL

Resonance Absorption in Nuclear Reactors

By Lawrence Dresner. (International Series of Monographs on Nuclear Energy. Division 10: Reactor Design Physics, Vol. 4.) Pp. x+131. (London and New York: Pergamon Press, 1960.) 40*s*. net.

AN important problem in the physics of nuclear reactor design is to predict the proportion of neutrons lost to the chain reaction by absorption in the nuclear resonances of uranium-238 and other elements. During recent years the accumulation of basic experimental data on resonances has enabled reactor physicists to attempt to calculate the absorption directly from neutron transport theory, as an alternative to the customary use of empirical methods.

The present monograph gives a timely account of modern theoretical work in the field, as well as a critical comparison of theory with experiment. It is primarily intended for those well versed in reactor physics, and contains little on the more descriptive type of theoretical treatment developed by the early workers.

There are two introductory chapters giving a brief historical survey and an account of the general transport theory of neutron slowing-down in absorbing media. The greater part of the book is devoted to the development of approximate methods to deal specifically with resonance absorption in homogeneous and heterogeneous systems. Various special topics are discussed, for example, the interaction between neighbouring absorbers, and the Doppler broadening of resonances due to rise in temperature. The only significant omission noted is an explanation of the empirical formulæ used for representing the experimental results. A critical discussion of these formulæ in the light of the preceding theoretical chapters would have been desirable.

A valuable feature of the book is the orderly presentation of key results from many published papers and official reports. It can be warmly recommended.

J. CODD

Plant Physiology

A Treatise. Edited by F. C. Steward. Vol. IB: Photosynthesis and Chemosynthesis. Pp. xvii+348. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 12 dollars.

THIS volume contains two articles, a longer one extending to 242 pages of text by H. Gaffron on the mechanism of photosynthesis, and a shorter one of 37 pages by M. Gibbs and J. A. Schiff on the energy relations of chemo-autotrophic bacteria. Both articles are followed by an adequate list of references.

The work of Van Niel in 1931 on photosynthetic bacteria, the discovery of the chloroplast or Hill reaction some eight years later, and subsequent work with radioactive isotopes, aimed at discovering the fate of the carbon in the carbon dioxide absorbed in photosynthesis, led to views on the mechanism of photosynthesis which are now generally, though not universally, supposed to involve the photolysis of water and the incorporation of the absorbed carbon into a phosphorylated pentose, giving a substance from each molecule of which two molecules of a phosphorylated triose, phosphoglyceric acid, are produced. In the present volume Gaffron gives a detailed account of all the processes and reactions involved in photosynthesis as suggested by recent researches and of the findings on which present-day views are based. The mechanism of photosynthesis is obviously a very complex one, and the botanist who comes to read this account without some acquaintance with the present position of the subject may find some of it, particularly the part dealing with photochemical considerations, rather difficult reading. The arguments for the views adopted are put forward very fairly.

The small article on the energy relations of chemo-autotrophic organisms brings together what is known concerning chemosynthesis in nitrifying, nitrating and non-photosynthetic sulphur bacteria, and will be found useful by those requiring information on this topic.

W. STILES

Birds of the West Indies

By James Bond. Pp. 256 + 8 plates. (London: William Collins, Sons and Co., Ltd., 1960.) 35*s*. net.

THIS is a field guide to 429 species of which 266 are illustrated, 80 being in colour. There are short descriptions of the main features of each family, which will be a help to the novice in the absence of keys. The text of each species consists of the usual descriptive material, including local names, a useful addition in a region where several languages are in use. Mercifully there are no sub-species.

Colour figures are mainly good; the line drawings have rather too much detail for the size reduction and are inclined to be fuzzy, though this may be partly the fault of the paper used, for the letters of the text also are sometimes lacking in sharpness.

James Bond has been associated with ornithology in the West Indies for half a lifetime, and his knowledge of the birds of that region is unequalled. This illustrated guide will be a great boon to professional and amateur, even traveller and visitor with the most casual interest in birds.

Servomechanisms

An Introduction to the Practice and Theory of Closed-Loop Position-Control Systems, with an Account of Methods of Data Transmission and Computation. By P. L. Taylor. (Electrical Engineering Series.) Pp. xiv+418. (London: Longmans Green and Co., Ltd., 1960.) 42*s*. net.

MR. P. L. TAYLOR, who has had considerable experience in teaching the theory of control systems to students of aeronautical and other branches of engineering, has written this introductory text-book for use in technical colleges and universities. It has refreshing elements of novelty in substance and arrangement. Within its intentionally limited scope, it is well adapted to the needs of both students and lectures.

The analysis is developed in a simple manner using, in the first half of the book, no more mathematics than simple linear differential equations. An account of such physical elements as are involved in measurement, data transmission, operation and analogue computation is given in the second chapter.

The second half of the 400 pages develops the theory of linear continuous systems, proceeding via an excellent summary of the essential properties of the complex variable to the Laplace transform, leaving the response to sinusoidally varying input quantities to be developed by an application of the Laplace transform. This sequence is not the usual one, partly because the teaching of the analysis of linear systems with sinusoidal inputs can usually presume familiarity with the techniques of electrical engineering, and partly because the physical significance of the relationships between sinusoidally varying quantities is more obvious than that between Laplace transforms. It is an interesting feature, but one that will not find favour with all teachers.

The book is confined to linear systems, except for one chapter that describes the effect of certain simple types of non-linearity, but it satisfactorily covers such matters as root loci and phase-gain diagrams. There is no discussion of on-off or sampled data systems, or of any form of discontinuous operation, or of the behaviour with randomly varying inputs. The book is thus essentially an introductory one but, within its scope, it is very good. The emphasis is on physical rather than mathematical explanations. A good selection of problems and exercises is included, with answers and hints for solution. The book is likely to be widely used in connexion with courses of limited scope, where at the commencement of the course the students have only a limited knowledge of the required mathematics.

A. TUSTIN

Abstract Set Theory

By Prof. Abraham Fraenkel. Second, completely revised edition. (Studies in Logic and the Foundations of Mathematics.) Pp. viii + 295. (Amsterdam: Elsevier Publishing Company, 1961.) 60*s*.

THE second edition of this book is in many respects different from the first edition. Its size has diminished from 479 to 295 pages; the first sections have been made more concise, remarks of secondary importance and references to literature of minor significance have been omitted. New material has been added in the text, and exercises, based on publications which have appeared during the decade 1950–1959. The bibliography has been greatly reduced, only those works actually referred to in the book appearing therein.

In the text there are three chapters. Chapter 1 on foundations, the concept of cardinal numbers; Chapter 2 on equivalence and cardinals; Chapter 3 on order and similarity, order types and ordinals. In these chapters there are sections on Cantor's set concept, finite and infinite sets, denumerable sets, the continuum, transfinite cardinals; arrangement of cardinals by magnitude, addition and multiplication of cardinals, exponentiation of cardinals, transfinite numbers and infinitesimals; ordered sets, similarity and order-types, linear sets of points, general theory of well-ordered sets, ordinals and alephs, well-ordering and comparability, the origin and significance of set theory.

The book is very ably written, and will be of great value to undergraduates (and some postgraduates), and to mathematical philosophers.

R. G. COOKE

Name This Insect

By Eric Fitch Daglish. Revised edition. Pp. xxvi + 294 (64 plates). (London: J. M. Dent and Sons, Ltd. 1960.) 21*s*. net.

THERE are said to be some 20,000 species of insects to be found in the British Isles, and possibly a million in the world. The author of a book for their identification in 300 pages of small octavo, fitting easily into the pocket, has clearly performed a feat of selection and compression.

It can be said at once that Mr. Daglish has done this most competently, within the limits that he has set himself. He has chosen some 700 British insects and presented them in the form of a key, using only such characters as can be seen at a glance, and avoiding almost all technical terms. The intention is that anyone on a country walk may carry the book, and use it to identify any insect that is big enough, or brightly coloured enough to attract his attention. The small, the obscure, and the rare insects are ignored.

The keys are clearly set out, but would be easier to use if the details of habitat and distribution were more distinct from those of colour and appearance. There are rather few text-figures; perhaps it would be difficult to have had more without introducing the technical terms that the author has avoided. The 64 plates show the appearance of 360 species, and are generally good pictures poorly printed, especially those in colour. Some are arbitrarily labelled 'all enlarged', though in fact they may be natural size, or even smaller.

Many serious entomologists would condemn such a key for giving a spurious appearance of precision, when scarcely one British insect in thirty is included, but one should not rely on any key for precise identification. The best of keys is no more than a guide, eliminating some possibilities and suggesting others. The fact that this book has been revised and reprinted after eight years suggests that the public for which it is intended has found it helpful.

HAROLD OLDROYD

Mineraly

Spravochnik. [Minerals: a Reference] Book. Vol. 1. (In Seven Volumes.) Pp. 617. (Moscow: Academy of Sciences, 1960.) 3.5 new roubles.

EARLY last year the U.S.S.R. Academy of Sciences announced the forthcoming publication of the first comprehensive compendium of mineralogy to be compiled in the Soviet Union. From the first of the promised seven volumes of this work it is now apparent that the compilation will be of outstanding importance, in many respects comparable to the seventh edition of Dana's *System of Mineralogy* (the two published volumes of which were translated into Russian in 1950 and 1954), but differing from this leading Western authority in paying much more attention to Russian research work. This initial volume sets a high standard and seems to be unusually free from errors, even in references to Western literature. It covers the native elements and intermetallic compounds, carbides, nitrides and phosphides; arsenides, antimonides and bismuthides; sulphides; selenides; and tellurides. The index lists close on 1,500 names of these minerals, printed both in Cyrillic and Roman characters. The second volume will deal with halides and oxides, Volumes 3 and 4 with silicates, Volumes 5 and 6 with other oxygen compounds, and Volume 7 with phase-equilibrium diagrams. For each mineral is given the preferred name, formula, etymology and synonyms, diagnostic characteristics, crystal structure and morphology, chemistry, behaviour on heating, occurrence in Nature, alteration, practical significance, means of distinction from similar minerals, and a selected bibliography. The editors-in-chief are F. V. Chukhrov and E. M. Bonshtedt-Kupletskaya, aided by G. P. Barsanov, N. V. Belov, and the late O. M. Shubnikova. Another 19 authors have collaborated in producing the first volume. This new text will undoubtedly rank with Dana's *System* as a principal reference work in any internationally minded mineralogical laboratory.

C. F. DAVIDSON

THE ORIGIN OF OCEAN BASINS AND CONTINENTS

By DR. J. J. GILVARRY
Allis-Chalmers Manufacturing Company, Milwaukee, Wisconsin

RECENT reviews of the problem of the origin of ocean basins and continents have been given by Howell[1], and by Jacobs, Russell and Wilson[2]. The classical hypotheses in this connexion are the tidal resonance theory of Darwin[3], involving creation of the Pacific Ocean by escape of the Moon, the theory of migrating continents originated by Taylor[4] and Wegener[5], and the various theories based on thermal convection[6]. Most such theories were devised without taking into account a discovery of the last decade that the Mohorovičić discontinuity rises from its depth of about 33 km. under the continents to within about 5 km. from the floors of the oceans. This fact implies a profound difference in the structures of ocean basins and continents[7], which creates grave difficulties for most theories of the origin of these features, in particular for the theory of migration of continents[8].

In a recent article[9], I suggested that the circular lunar maria are simply large meteoritic craters with sedimentary floors, excavated by explosive impact of meteorites on the lunar surface in the presence of a hydrosphere. The purpose of the present article is to propose an exactly analogous mode of formation of ocean basins, as the results of explosive impact of large meteorites at a pristine time when the hydrosphere covered the Earth to a roughly uniform depth. The disparity in the levels of the Mohorovičić discontinuity under continents and oceans enters the theory as an integral part.

My attention has been directed by the Editors of *Nature* to a paper by Harrison[10] which appeared about the time the original manuscript of this article was submitted for publication. Harrison hypothesizes that the Pacific Ocean was created by impact of a planetesimal, a terrestrial satellite, or a satellite of the Earth–Moon system, and conjectures a similar mode of formation for every ocean. Thus, the conclusions presented here, arrived at independently, are identical in principle with the suggestions of Harrison, but the basis of the argument is entirely independent and the proposed mechanism of crater formation differs in an essential respect. The reasoning of the present article is based on a reconstruction of the mensuration of the pristine oceans, and a correlation of their dimensions with those of the lunar maria, lunar craters (of Class V), and meteoritic and explosion craters in water[9]. Thus, the presence of a terrestrial hydrosphere at the time of formation of the ocean basins is an essential element in determining the relative dimensions of the pristine craters. In contrast, Harrison's basic argument is that creation of the Pacific Ocean by the impact of a planetesimal or satellite is energetically possible.

Origin of Ocean Basins

The largest terrestrial ocean, the Pacific, can be divided geologically into two major basins, the North Pacific and the South Pacific, by prolongation to the coast of South America of an east–west line coinciding approximately with the andesite line north of Australia. On the side of the andesite line away from the Pacific, the rocks tend to be continental in type. A similar natural division of the Atlantic into the North Atlantic and the South Atlantic can be made by a line joining South America and Africa at their closest points, roughly between Cape São Roque and Cape Palmas. With these divisions, each of the five oceans, the North Pacific, the South Pacific, the North Atlantic, the South Atlantic, and the Indian, possesses a roughly circular outline.

At the seaward limit of the continental shelf, the demarcation of each oceanic basin is an escarpment as precipitous as that forming the boundary of a lunar mare of the type of Mare Imbrium. Thus, the terrestrial oceans possess at least two features, a roughly circular outline and an encircling scarp, in common with the lunar maria of Imbrian type. A third common feature exists : as is the case with the lunar maria, the floors of the oceans lie below the mean level of the land mass. In view of these similarities, it will be postulated that the terrestrial oceans and the lunar maria of Imbrian type were formed in the same manner, by explosive impact of large meteorites in the presence of a hydrosphere. At the outset, it should be emphasized that the hypothesized meteorite impacts occurred far back in the Pre-Cambrian era (a period of time lasting about four milliard years)[11].

In the case of the lunar maria, my argument on the mode of formation was based on a correlation of their dimensions with those for explosion and meteoritic craters formed in water. For the present terrestrial oceans exclusive of marginal seas, the diameter D and depth d' are shown in Table 1, as determined from data of Kossinna[12]. For simplicity, the line of division between the North Pacific and the South Pacific, and between the North Atlantic and the South Atlantic, has been taken as the Earth's equator. Because of the inherent uncertainties, no effort has been made to correct the entries for the Pacific Oceans to take account of the location of the andesite line. The diameter shown is an equivalent diameter D fixed from the ocean area A by :

$$\tfrac{1}{4}\pi D^2 = A \qquad (1)$$

The depth d' appearing corresponds to the maximum given by Kossinna for which a significant floor area of the ocean exists ; it includes 1 km. corresponding to the mean height (840 m.) of the continents[12].

Table 1. MENSURATION OF OCEAN BASINS

Ocean	D (km.)	d' (isostatic) (km.)	d (anisostatic) (km.)	l (anisostatic) (km.)
S. Pacific	11,000	10·5 ± 0·5	39 ± 4	22 ± 2
Indian	9,700	8·5 ± 0·5	34 ± 3	19 ± 2
N. Pacific	9,500	10·5 ± 0·5	34 ± 3	19 ± 2
S. Atlantic	7,600	8·5 ± 0·5	27 ± 3	15 ± 2
N. Atlantic	6,800	9·5 ± 0·5	24 ± 2	14 ± 1

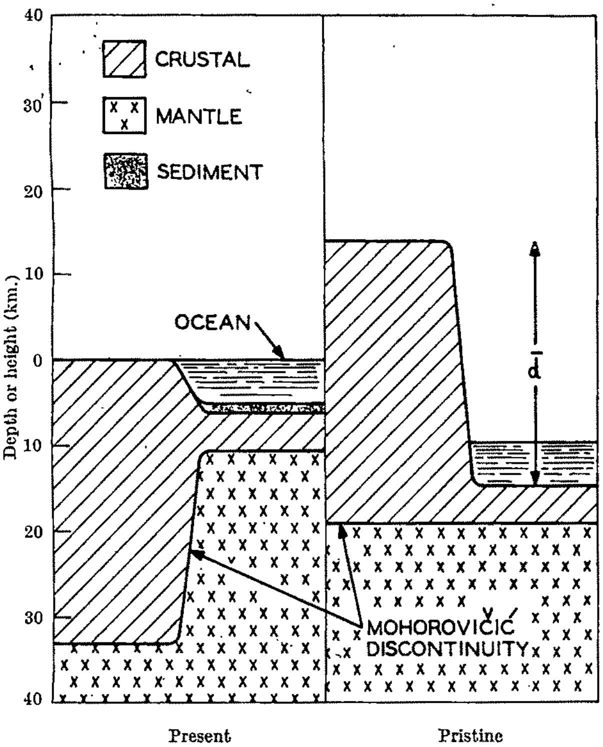

Fig. 1. Standard sections through rocks under continents and oceans at the present time (left), compared with corresponding pristine sections (right) immediately after the impacts of the meteorites forming the oceans

The values of ocean dimensions in question cannot be made the basis of a correlation with the corresponding dimensions of the lunar maria because the terrestrial ocean basins are, and have been, subject to isostatic compensation. On the other hand, the evidence is strong that the Moon is not and never was in hydrostatic equilibrium, in view of its strongly triaxial shape. This shape reflects the strength of the component materials, and is consistent with a cold origin for the Moon[13,14]. However, even if the Earth were formed cold, radioactive heating certainly would be sufficient[15] to render the mantle plastic up to the present depth of isostatic compensation (roughly between 50 and 100 km.). Thus, the ocean depths d' appearing in Table 1 must be corrected for the presence of isostasy.

For precision in terminology, the Earth's crust will be defined as the region above the Mohorovičić discontinuity, and the solid region below will be referred to as the mantle. On the left (labelled 'present') in Fig. 1 are shown standard sections through the Earth's crust and mantle, for continental and ocean columns, as deduced by Worzel and Shurbet[16] by means of relatively accurate seismic data from explosions. The standard land column consists of 33 km. of crustal rock of density 2·84 overlaying mantle rock of density 3·27. The corresponding ocean column consists of 5 km. of sea water (density 1·03), 1 km. of sediments (density 2·30), and 4½ km. of crustal rock (density 2·84) over the mantle for a total depth of 10½ km. of crust. With these densities, the land and ocean columns are in isostatic equilibrium at a depth of 33 km., corresponding to the depth of the Mohorovičić discontinuity under the continents.

At the time of impact of the meteorites forming the ocean basins, the Mohorovičić discontinuity must have been level under the areas now corresponding to continents and oceans, as shown on the right (labelled 'pristine') in Fig. 1. Its depth must have been intermediate between the present depths of this discontinuity below the oceans and continents. Using the data of Kossinna for the total area of the Earth corresponding to continents (including marginal seas) and oceans, it can be computed from the volume balance that the level in question lay 14 km. above the present depth of this discontinuity under the continents, as shown in Fig. 1. The standard land and ocean sections above the Mohorovičić discontinuity appear superposed on this base-level (with the sedimentary layer omitted). The figure represents the proper relative position of the land and ocean columns immediately after meteorite impact, when anisostatic conditions prevailed, provided two conditions have been fulfilled. The first is that isostatic adjustment of oceans and continents, from pristine to present conditions, took place by horizontal flow of mantle rock at depths below the Mohorovičić discontinuity, as occurs in the isostatic balance of the present day. The second is that each standard column (land and ocean) above the Mohorovičić discontinuity has remained approximately the same throughout the Earth's history since the oceans were first formed. This assumption is reasonable in view of the small thickness and mass of oceanic sediments compared with the corresponding quantities for a total column, and implies that isostatic readjustment was fast compared with erosive processes.

On these assumptions, a first approximation to the mean depth $\bar{d}$ of the craters corresponding to the primordial ocean basins before isostatic adjustment is fixed approximately as the difference of the thickness of crustal rock in the standard continental and oceanic columns, with the sediment thickness ignored in the latter, as indicated in Fig. 1. This estimate can be improved in two respects. The first is to include in the estimate an additive correction for the ocean sediments, since primordially these deposits must have existed in the continental column. The present thickness (1 km.) of such sediments yields 2 km. for this correction, corresponding to the fact that the total area of the deep oceans is about twice that of the remainder of the Earth. Secondly, to take account of the fact that the depths of the lunar maria were reckoned from the approximate maximum heights of the rims[9], one can include 1 km. in $\bar{d}$ corresponding to the mean height (840 m.) of the continents. The resulting value of $\bar{d}$ is entered in Table 2 with a possible error of ±10 per cent of its value. The mean height of rim $\bar{l}$ of the meteorite craters forming the primordial ocean basins can be obtained. Prior to the meteorite impact, the crustal rocks must have overlain the Mohorovičić discontinuity to an approximately uniform height L. The value of L can be computed directly from the present thicknesses of crustal rock under the continents (including marginal seas) and oceans, and the corresponding areas[12] on the surface of the Earth, as 15 km. The mean rim height $\bar{l}$ is then simply the difference of the height of the standard continental crustal column and L (the correction associated with the sediment thickness cancels approximately). The value of $\bar{l}$ appears in Table 2 with a possible error of ±10 per cent of its value. The mean diameter $\bar{D}$ of the craters corresponding to the primordial ocean basins, given in Table 2, was fixed from equation (1) with A taken as the mean area of a present ocean. These computations presume that a right circular cylinder represents a reasonable geometrical model for both the present and primordial ocean basins, and that isostatic adjustment leaves the diameter approximately the same.

Table 2. MENSURATION OF AVERAGE PRIMORDIAL OCEAN BASIN (ANISOSTATIC)

$\bar{D}$ (km.)	$\bar{d}$ (km.)	$\bar{l}$ (km.)	$\bar{r}$ (km.)
9,000	32 ± 3	18 ± 2	2,900

To find the depth and height of rim of an individual ocean basin under anisostatic conditions it will be assumed as an approximation that each basin was geometrically similar to the average basin, primordially. Thus, the anisostatic depth d corresponding to the diameter D is given by:

$$d = (\bar{d}/\bar{D})D \qquad (2)$$

and the anisostatic height of rim l is fixed by:

$$l = (\bar{l}/\bar{D})D \qquad (3)$$

These primordial dimensions are shown in Table 1 for each ocean, with a possible error of ±10 per cent of the value.

A sequence of events involving isostatic compensation, similar to that postulated here for the ocean basins, has been invoked by Daly[17] in explaining the Vredefort ring-structure of South Africa as the result of a meteorite impact. Harrison[10] recognizes the need to consider isostatic readjustment of the pristine ocean basins after meteorite impact, but he does not attempt a quantitative treatment, as carried out here. He considers the Pacific Ocean to arise from the fall of a single meteoritic body, whereas the more reasonable assumption that two impacts were responsible is made in the present work.

Correlations

Fig. 2 shows the correlations obtained between the diameter D and depth d for terrestrial explosion and meteoritic craters, on one hand, and lunar craters and circular maria, on the other[9]. The solid curves shown for craters on land represent the quadratic form:

$$D = a_1 d\,[1 + (d/a_2)] \qquad (4)$$

for hard and soft rock. The parameter a_1 was fixed from the dimensions of explosion craters[18] in basalt and sedimentary rock, while the corresponding a_2 was chosen by a least-squares fit to the dimensions of lunar craters[19] of Classes IH and IS, respectively. The craters of Class IH, lying in the highlands, and of Class IS, in the floors of the maria, correspond by inference to hard and soft rock, respectively. A close correlation exists between the data representative of terrestrial meteoritic craters in hard and soft rock, and the corresponding curves constructed from the dimensions of terrestrial explosion craters and the lunar craters in question.

The curves for craters formed in hard and soft rock under water correspond to the form:

$$D = a_1 d\,[1 + (d/a_2)^n] \qquad (5)$$

The coefficient a_1 for hard and soft rock was determined from the dimensions of craters, Glasstone (H) and Glasstone (S), respectively, formed by explosion of nuclear bombs in water[20]. This procedure presupposes that the parameter μ defined in terms of the depth of water δ by:

$$\mu = \delta/d \qquad (6)$$

have a value of the order of unity for a crater[9]. However, the resulting curves are approximately independent of the precise value of μ, so long as it is in the range $1/12 < \mu < 2$, roughly. For both hard and soft rock, the coefficient a_2 and exponent n correspond to a least-squares fit of the data for lunar craters[19] of Class V, which are the nine craters for which the representative points are displaced farthest from the curves for Class I in Fig. 2. The representative points for the lunar maria fall closely on the curve for craters formed in hard rock under water. The final link in the argument that the lunar maria are simply meteoritic craters formed in the presence of a hydrosphere is provided by the terrestrial meteoritic crater of Deep Bay[21]. It can be argued strongly that this crater must have been formed by impact of a meteorite in water, and the corresponding point lies close to the curve expected.

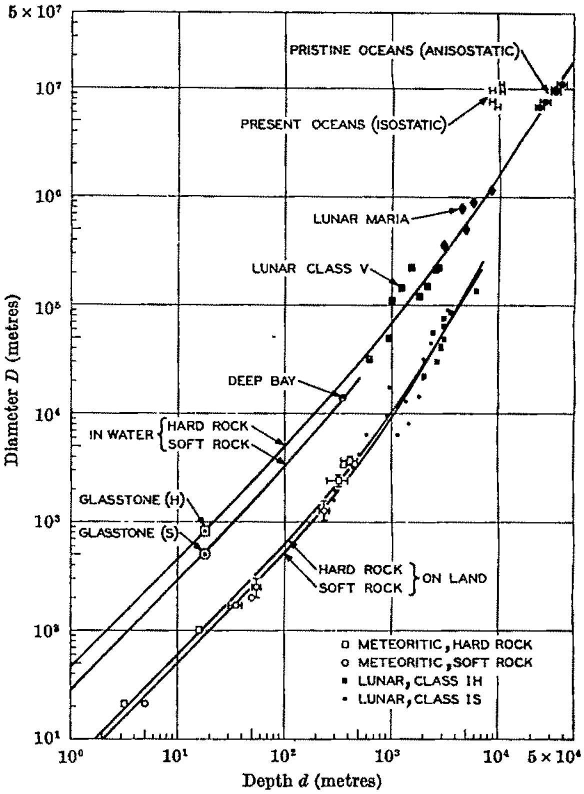

Fig. 2. Correlation of diameter versus depth for the present and pristine oceans, the lunar maria, and various classes of craters. The curves correspond to fitted functions for craters on land and in water, for hard and soft rock

Prior to the impact of the meteorites forming the ocean basins, water must have covered the Earth to a uniform depth $\bar{\delta}$ above the roughly level surface of the crustal rock. On the assumption that the total volume of sea water has not changed greatly since the ocean basins were formed, the value of $\bar{\delta}$ is approximately 3 km. Accordingly, the parameter $\bar{\mu} = \bar{\delta}/\bar{d}$ corresponding to equation (6) had a value of roughly 1/11 for the crater corresponding to the average primordial ocean, and lies within the range for which the curves of Fig. 2 for craters in hard and soft rock under water apply. The diameter D, as a function of the anisostatic depth d for each primordial ocean basin, is plotted in Fig. 2 from the data of Table 1. The correlation of the points for these data with the curve for craters formed in hard rock under water is excellent, agreeing with the fact that the substratum of an ocean basin is basaltic. Furthermore, no data on the dimensions of the lunar maria or terrestrial oceans were used in the construction of the curve in question. On the other hand, the points corresponding to the diameter D and present depth d' of an ocean show agreement with the curve only within an order of magnitude.

One might argue that the excellent correlation of diameter and depth of crater obtained is fortuitous as regards the craters corresponding to the primordial oceans. To rule out this possibility, the correlation of diameter and height of rim will be examined. It will be assumed that the relation between the diameter D and height of rim l of a crater formed in water (for $\mu \approx 1$) can be written as the linear form:

$$D = b_1 l \qquad (7)$$

with the coefficient b_1 fixed in the cases of hard and soft rock by the dimensions of Glasstone (H) and Glasstone (S), respectively. The corresponding straight lines appear in Fig. 3.

For the lunar craters of Class V, only a few uncertain heights of rim are available for comparison with the result of the corresponding line for hard rock[19]. However, the heights of rim of the lunar maria can be approximated as the maximum heights of the encircling mountains less the mean height (2 km.) of the lunar highlands above the lowlands[9]. From Schmidt's results[22], this yields the representative points for the lunar maria shown in Fig. 3. The agreement of the points with the line for craters formed in hard rock under water clearly is good. Also shown are the diameters of the primordial ocean basins as a function of the anisostatic height of rim l, from Table 1. The correlation of the points with the line for craters formed in hard rock under water is excellent. Furthermore, the fitting line was determined completely from the dimensions of Glasstone (H). As a final argument, it may be noted that the representative point[23] for the terrestrial meteoritic crater of Deep Bay (formed in soft rock) lies reasonably well on the appropriate straight line.

Analogous curves for craters in hard and soft rock on land are shown also in Fig. 3. The two curves were determined from dimensions of explosion craters in basalt and sedimentary rock[18], and of lunar craters[19] in Classes IH and IS, respectively. The correlation of the points for terrestrial meteoritic craters in hard and soft rock with the corresponding individual curves is not close, because of the sparsity and inaccuracy of the data. The general similarity of Fig. 2 and Fig. 3 is obvious.

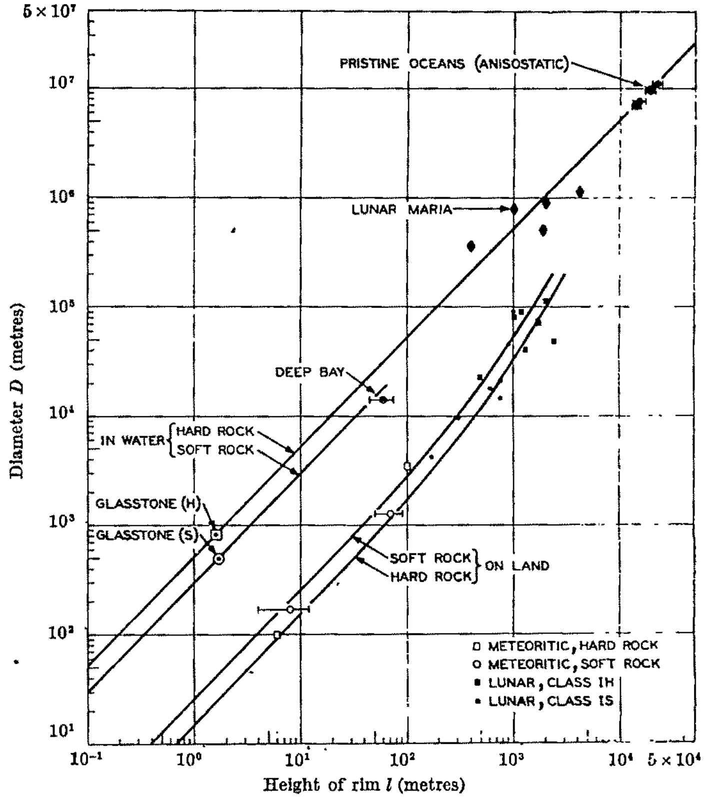

Fig. 3. Correlation of diameter versus height of rim for the pristine oceans, the lunar maria, and various classes of craters. The curves correspond to fitted functions for craters on land and in water, for hard and soft rock

In general, the correlation of the pristine dimensions of the terrestrial oceans with those of the lunar maria is excellent.

Origin of Continents

If the primordial ocean basins were large meteoritic craters, it follows that the primordial continents were simply structures corresponding to the rims of these craters. To see if the model is adequate quantitatively, one can calculate the average width of the rim of a crater corresponding to a primordial ocean. It will be assumed that the cross-section of the rim is a right triangle in the plane of the axis of symmetry of the crater, with the hypotenuse forming the outer slope and one side parallel and one perpendicular to the axis. The altitude of the triangle is the height of rim l, and the length of the base will be designated by r. The average value $\bar{r}$ of the base of the rim can be calculated from the data of Table 2 by invoking Schröter's rule[19,24] for lunar craters, that the volume of the material displaced from the crater equals the volume of the rim. This gives:

$$\bar{r} = (3/4)\bar{D}\,\{[1 + 4(\bar{d} - \bar{l})/3\,\bar{l}]^{1/2} - 1\} \qquad (8)$$

on these assumptions, and the average value of the base of the rim is entered in Table 2. It can be noted that Schröter's rule is a necessary consequence of explosive origin of a crater[25,26].

For the continents regarded as circular in plan, one can determine an average diameter from equation (1) by taking A as one-sixth of the total area of the continents (considering Eurasia as a single continent). The corresponding average diameter is approximately 5,600 km. From the result of Table 2 for $\bar{r}$ it can be seen that two abutting rims from adjacent craters corresponding to primordial oceans yield an average width of 5,800 km. for a continent. Thus, the hypothesis is closely consistent with the mean linear dimension of a continent in plan, as observed.

At the time of formation, the primordial crater rims were mountains of lunar type, and not of the folded type characteristic of present terrestrial topography. Further, these primordial mountains were of about twice the height above the Earth observed to-day for the highest peak (Mount Everest). The eroded remnants of these mountains are the continental shields of crystalline igneous and metamorphic rock of Pre-Cambrian age, forming the nuclei of the continents. The view that the continental shields are simply the eroded roots of ancient mountain systems has been expressed by Collins[27] and Wahl[28], and seems to have gained general acceptance[29].

These ideas yield a direct and natural explanation of Wegener's law[30]. This law states that the frequency curve of elevation on the Earth shows two pronounced maxima, corresponding to the ocean floor and to the continents. On the thesis of the present article, one maximum arises from the floor-level of the craters forming the primordial oceans, and the other corresponds to the rims of the craters. During the time since these rims first reached continental level, the processes of erosion, deposition, and diastrophism have maintained a balance, to yield a roughly constant mean height of the continents. The possibility of explaining the law in question was a major inducement to Wegener in formulating his theory of floating continents.

Discussion and Conclusions

It is clear that the hypothesis proposed yields a direct explanation of the origin of ocean basins and continents. The correlation of the pristine dimensions inferred for the ocean basins with those for lunar features and terrestrial craters formed in water represents a strong argument for the general validity of the ideas. The disparity in the depths of the Mohorovičić discontinuity under continents and oceans appears directly as an essential element in the argument, without the need for *ad hoc* assumptions. Furthermore, the theory is consistent with the observed average diameter of a continent, and Wegener's law follows naturally.

The considerations of this article have an important bearing on the meteoritic impact theory of the formation of lunar craters. In the view of Baldwin[19], Urey[31] and Kuiper[32], the prevalence of craters formed by meteoritic impact on the Moon is not a feature peculiar to that body, but implies a similar bombardment of the Earth by meteorites in the past. However, the lunar craters obviously extend over a wide spectrum of sizes and ages. On the other hand, only 17 craters or clusters of craters were known at the time of Baldwin's work, and all these craters were small (of diameter less than 2 km.) by lunar standards and of recent geological age.

During the past decade, the situation has changed markedly. Discoveries of meteoritic craters in this period have enlarged significantly the total number known[9,33]. The age horizon has been extended to Early Palæozoic (Brent and Holleford Craters) and the size of crater to a diameter of about 14 km. (Deep Bay). Furthermore, the discovery of cœsite in Barringer Crater[34] in Arizona and in the Rieskessel[35] in Austria has reinforced strongly the contention that crypto-explosive features[19,36] are in fact meteoritic in origin. If this view is accepted, the Vredefort structure[17] provides an example of a meteoritic crater which is roughly 130 km. in diameter and is Pre-Carboniferous in age. Finally, two large circular arcs have been noted in Canada, which may be meteoritic in origin[33], and one has a diameter of 400 km.

Since the meteorite impacts forming the ocean basins occurred far back in Pre-Cambrian times, it is implicit in my thesis that the bombardment of the Earth by meteorites has shown the same intensity throughout the ages as in the corresponding case of the Moon. At the present time, the Earth is experiencing merely the terminal phase of the process, marked by relatively sparse and small meteorites. In the past, the smaller craters on land vanished rapidly through erosion, sedimentation and diastrophism. The larger craters are relatively resistant to these processes; but another factor, isostatic readjustment, operates to make identification difficult, as in the cases of ocean basins and crypto-explosive formations. Only for craters formed by impact of large meteorites in the hydrosphere is there hope of preservation over an extended period of time, because of the protection afforded by the water from subaerial erosion. In view of the enhanced rate of sedimentation in the shallow seas close to a land mass, the chance of preservation increases with the depth of the water[37].

The primordial ocean basins were simply the largest meteoritic craters ever formed on the Earth, entirely analogous to the circular lunar maria. They owe their preservation to their size, in spite of the effects of isostatic readjustment, mountain growth, erosion, and sedimentation in masking the characteristic features of a meteoritic crater. Because of their extent, transcending that of any other hydrospheric features on the Earth, it has been possible here to correct their dimensions for isostatic readjustment in a simple manner. This particular method cannot be applied in the case of a marginal sea of the ocean; it is possible that many such seas are meteoritic in origin, but demonstration of the fact may be difficult in an individual case. A possible example is the arm of the Gulf of St. Lawrence, outlined by the coasts of Nova Scotia and New Brunswick[38]; the diameter is 300 km.

Ideas similar to mine and Harrison's[10] have been adumbrated by others. Chenoweth[39] has pointed out the close similarity between the Northern Canary Basin and Mare Crisium, and he has noted analogies in the features of the floor of the North Atlantic with structures in the basins of lunar maria. Gold[37] has speculated that the patterns of circular arcs in the zones of tectonic instability and gravity anomaly, and in regions of earthquakes and volcanoes on the Earth, may reflect the destruction of hydrostatically stratified balance by ancient meteorite impacts. A theory of Howell[1] bears a superficial resemblance to that presented here, but differs in that the meteoritic impacts considered are not explosive in nature. A full account of this work will appear elsewhere.

I thank E. W. Price and Dr. R. G. Greenler for discussions, and Helen Jackson for computational work.

GALACTIC EXPLOSIONS AS SOURCES OF RADIO EMISSION

By Prof. G. R. BURBIDGE

Yerkes Observatory and Enrico Fermi Institute for Nuclear Studies, University of Chicago

The Problem of the Energy Sources

IT is generally believed that the major source of non-thermal radio emission, both inside and outside our Galaxy, is high-energy electrons and positrons moving in weak magnetic fields. The strongest non-thermal sources in our own Galaxy, such as the Crab and the Cassiopeia *A* source, are known, or thought, to be supernova remnants, and it is possible that the majority of the non-thermal radio-frequency radiation emitted has arisen directly or indirectly from supernovæ[1]. The strongest extragalactic sources are radiating at power-levels up to 10^7 times that of our Galaxy.

The most difficult problem associated with this mechanism of emission has always been the source of the energy now contained in the high-energy particles and magnetic field. The first idea as to the source of the energy came when Baade and Minkowski[2] suggested that the source Cygnus *A* was two galaxies in collision. This was followed up by the spectroscopic work of Minkowski[3] on the source identified as *NGC* 1275. He showed that there were two large-scale regions in the system with a large relative velocity between them. However, neither this result nor the somewhat more subjective argument that some sources look like galaxies in collision is conclusive, and fundamental objections have been raised to such an explanation. On one hand, Ambartsumian[4] has shown that the frequency of collisions of galaxies in the general field is too small to explain the observed numbers of radio sources. Secondly, the major theoretical argument in favour of the collision hypothesis is that the kinetic energy dissipated in the collision is converted to magnetic and particle energy. However, as has been pointed out by me[5,6] and by Shklovsky[7], this argument requires that, depending on the system being discussed, between 1 and 100 per cent of the energy available in the collision must be transferred into these energy modes. Since the transfer process appears to be very inefficient, such a requirement seems impossible to fulfil.

Other explanations for particular sources have been proposed. In analysing the results for *M* 87, I mentioned the possibility that the annihilation of a comparatively small amount of anti-matter could give the required energy in the form of electrons and positrons without any nucleon component[8]. This argument was applied more generally by Hoyle and me[9]; but, although such an idea still has its attractions, we have been faced by a fundamental difficulty concerning the origin of anti-matter and its separation from matter. I have considered a modified version of the collision hypothesis which would apply to clusters of galaxies[10]. This theory suffers from the objection that, though some radio sources lie in clusters, many new identifications by Bolton[11] and Mills[12] show that the majority do not. Finally, Hoyle[13] has given a new treatment of the problem, again using as a basic hypothesis the idea that, in the cases of Cygnus *A* and *NGC* 1275, the only strong extragalactic sources he discusses, collisions are the source of the energy.

Since this work was done, further evidence of the different types of galaxy which are abnormally strong radio emitters has come from optical identifications using the accurate positions obtained by the observers, in particular Bolton and the California Institute of Technology group[11]. The least predictable of these results, in the light of any of the foregoing hypotheses, is the frequency with which many strong sources can be identified with single or double elliptical galaxies. The radio source which was the first system to be identified in this category, and which may be the prototype of this kind of source, is *M* 87. A number of others are listed by Bolton[11].

In what way do elliptical galaxies differ from other types in their general characteristics? First, it is believed that, on the average, they are more massive than either spiral or irregular galaxies. Secondly, they appear to contain very little gas and dust. Although the presence of the [O II] λ 3727 feature in about 30 per cent of all elliptical galaxies shows that some excited gas is present, detailed investigation in one or two cases[14] shows that there is very little gas—10^{-5}–10^{-8} of the mass—and that it is concentrated at the centre. Thirdly, studies of the luminosity distribution and the apparent sizes, together with mass estimates, suggest that elliptical galaxies are much denser than spiral galaxies.

Unquestionably, for sources such as this, the collision hypothesis can be ruled out, and it appears most probable that the sources of energy must lie in the stars in these galaxies. The only sources of energy which are adequate to explain the phenomenon in single galaxies are anti-matter, which was discussed earlier, rotational energy, and nuclear energy. Many of the elliptical galaxies probably have little rotation (*M* 87 is a spherical system) and even if they do, with very little gas spread throughout the galaxy, it would plainly be a very difficult matter to utilize such energy, so that nuclear energy is by far the most plausible origin. Shklovsky[7], in rejecting the collision hypothesis for other sources, has generalized the argument that supernovæ are the basic sources of energy for objects such as the Cygnus source and *NGC* 5128, both of which contain much gas, and also *M* 87. Without going into a critical appraisal of this latter work I would like to propose that supernovæ are also the sources of energy in all those elliptical galaxies which are strong radio emitters. In developing this hypothesis, we must bear in mind that the scanty spectroscopic data on objects of this type suggest that they do not differ noticeably from the majority of other elliptical galaxies in their stellar content.

The magnitude of the effect that we have to explain can be taken from the energy calculations that have been made for *M* 87 (ref. 8) and *NGC* 6166 (ref. 6), with these treated as typical examples. For *M* 87 it has been found that the minimum total energy for particles and magnetic field is of the order of 10^{58} ergs. In this galaxy the jet is due to visible acceleration or synchrotron radiation with electron and positron energies in the range 1–100 BeV., and magnetic fields in this region having strengths of the order of 10^{-3}–10^{-4} gauss. In all the other sources in this category, however, there is no component of optical radiation so far detected which can be due to accelerated particles. The minimum magnetic field strengths deduced are accordingly, for all these sources, not significantly larger than the fields which I believe to exist normally in the interstellar matter of our own Galaxy.

In a typical elliptical galaxy, in the central region, most of the light is contributed by *K* giants which are probably stars in the range of 1–1·5 $M_\odot$ that have evolved into the giant region of the Hertzsprung–Russell diagram. Evidence for this comes from the spectra[15,16] and the colours[17]. Much of the stellar content is, therefore, probably stars with masses $\lesssim 2\,M_\odot$.

In the normal course of evolution some stars in such a galaxy will eventually become supernovæ. Now supernovæ exploding at a rate of one every few hundred years per galaxy cannot provide the energy required for the strong sources to emit at the observed rates. This is easily shown as follows. The total energy in a radio source such as *M* 87 is $\sim 10^{58}$ ergs or the energy emitted by 10^7–10^8 supernovæ. In the normal course of events, this energy would be released by the nuclear explosions in a period of 10^9–10^{10} years. However, the time-scale for radio emission in such a source, which can be estimated from the energies of the electrons and the assumed strength of the magnetic field, is of the order of 10^7–10^8 years. Thus the reservoir of energy from the supernovæ would build up to only $\sim 10^{-2}$ of that required. For sources stronger than *M* 87, such as *NGC* 6166 or Cygnus *A*, this difficulty becomes even more severe since the normal time-scale would be $\sim 10^{11}$ years. What is needed here is a mechanism that gives rise to a large number of supernovæ explosions in a comparatively short time. The suggestion that I make, therefore, is that one supernova acts as a trigger to set off a chain reaction of stellar explosions. Is such a situation possible ?

Let us review our knowledge of stellar densities in galaxies.

Density of Stars in Galaxies

In the centre of *M* 31, a spiral galaxy, there are some $1{\cdot}3 \times 10^7$ stars within a radius of 7·4 parsecs or a mean density of 1,700 $M_\odot$/parsec^3 (ref. 18). In elliptical galaxies, the gradient of luminosity shows that the gradient in density is much steeper than it is for spirals. However, we have no way of estimating the star density at the very centre of an elliptical, that is, within about 1 parsec of the centre, since at the distance of the Virgo Cluster 1 parsec is approximately 0·01″, which is about two orders of magnitude below the seeing-limited resolving power of the largest land-based telescopes. The luminosity distribution and the velocity dispersion of the stars or gas in large elliptical galaxies such as *NGC* 3379[15] and *NGC* 4278[14] enables us to estimate the average density over a volume contained within a few seconds of the centre. If we take the results for *NGC* 4278 as an example, we find that a mass of $3 \times 10^9\,M_\odot$ is contained within a radius of 85 parsecs, or the average stellar density is 1,200/parsec^3 in this volume. The results obtained by approximating the density curve for an isothermal gas sphere correspond to approximately the same density. However, it is possible that the mean density in the central region is considerably higher than this. Moreover, recent work on *M* 32 suggests that dwarf systems may be considerably denser than large elliptical galaxies. The mean density within the radius containing half of the mass of *M* 32 is 85 times that in *NGC* 3379. If the central density of *NGC* 3379 were about 1,200 stars/parsec^3, similar to that in *NGC* 4278, then if the same model applies to all three galaxies the central density in *M* 32 is at least 100,000 stars/parsec^3.

Let us suppose that the stellar density of the very centre of a galaxy is of the order of $10^7\,M_\odot$/parsec^3. In this case, we might imagine that this density prevails over a radius of 1 parsec from the centre.

Under such conditions, application of the virial theorem shows that the velocity dispersion of the stars is about 400 km./sec. This is comparable with, or less than, the velocity dispersion of the stars in the larger bulk of the nucleus, which lies in the range 400–800 km./sec. Since such a tiny central condensation cannot be observed directly and since its contribution to the integrated light of the nucleus, of radius a few seconds, is negligible, it cannot be said that such a feature could not exist. The formation of a star cluster out of gas ejected from earlier generations of evolving stars, the gas dissipating much of its kinetic energy before stars form, makes such a system possible.

In such a dense region the probability of stellar collisions is quite high. This point has earlier been made by Shklovsky[7]. If such a stellar collision leads to a stellar explosion (and this may well be the case), this will itself provide the trigger instead of a normal supernova explosion which I shall discuss next. However, much depends on how such a dense central condensation forms and whether or not it is a physically separate entity, that is, whether the amplitudes of the orbits of the stars are less than the dimension assumed for it.

It seems fair to conclude that a reasonable extrapolation of the observations suggests that the central densities in elliptical galaxies range upward from 10^3 stars/parsec^3 to values in excess of 10^6 stars/parsec^3. Furthermore, we may speculate that densities in the range 10^6–10^7 stars/parsec^3 may be present in some cases.

It is interesting that Greenstein[19] has suggested that one of the elliptical galaxies in the pair *NGC* 4782, 4783, which is a radio source, is more centrally condensed than is the usual case. Direct plates recently taken by E. M. Burbidge at the prime focus of the 120-in. telescope of the Lick Observatory show that the nucleus of one member of the pair is much more highly condensed than the other.

Supernova Explosions

It is likely that for stars of masses not much greater than the Sun, supernova outbursts will not be of the implosion–explosion type[20], but will stem from the explosion of degenerate material in the way proposed by Hoyle and Fowler[21]. The total energy that is released in such explosions is of the order of 10^{50}–10^{51} ergs.

Energy is ejected from a supernova in γ-radiation, X-radiation, and high- and low-energy charged particles. The amount of degradation of the radiation by the supernova material itself is not known. However, it is reasonable to suppose that a considerable fraction will escape as fairly hard radiation. The comparatively small amount of visible radiation in known supernovæ, as against the total amount of nuclear energy available for release, would also suggest this. When incident on the surface of a nearby star, the major amount of the energy which is carried in γ-radiation will be scattered and absorbed. The total absorption for energies of a few MeV. will be of the order of a few grams. This corresponds to a penetration in a giant, according to the tables of Schwarzschild, of the order of 10^4–10^6 cm. in the convective zone, that is, the top of the convective zone. In a normal solar-type star it represents penetration of only a few metres or perhaps penetration to just below the bottom of the atmosphere. The low-energy charged particles will presumably be stopped from penetrating by the star's magnetic field. The high-energy particles will penetrate considerably farther than the γ-radiation.

If a flux of energy E ergs is emitted in the first supernova explosion then the energy incident on the surface of a star D cm. away will be $E/4\pi D^2$, and the energy absorbed per gram if the radiation passes through x gm. before being absorbed is $E/4\pi D^2 x$. For values of D ranging from 3×10^{17} cm. to 10^{16} cm. and E equal to 10^{50}–10^{51} ergs, with $x \simeq 5$, we find that the temperature of the surface layers of the star will be raised to values from 10^5 to 10^9 degrees.

If the material is heated to values in the upper part of this temperature-range, that is, 10^7–10^9 degrees, nuclear reactions will abruptly commence. The reactions that can occur will depend on the composition of the material present. The most probable reactions will be those involving carbon, nitrogen, oxygen and hydrogen. It appears that what we have here is the generation of a detonation wave which will, in suitable circumstances, be propagated into the interior. Without extensive numerical work it is not possible to determine how the propagation will go. Two effects have to be considered. The first is that the wave must be propagated into regions of higher density, and second, the geometry is such that there will be a focusing effect towards the centre of the star. A sudden generation of energy as the wave passes through the star will lead to explosion. The violence of this will depend on the type of star on which the radiation impinges. The problem is somewhat similar to that encountered by experimenters who are trying to generate thermonuclear reactions in a hot plasma. In their case, some of the limitation on the generation of thermonuclear power is the rate of loss of energy by bremsstrahlung processes and the confining of the plasma. However, in this case the back-scattered radiation may be lost or may simply heat the atmosphere so that it expands, but the forward-scattered radiation will be absorbed further in the star, thus causing pre-heating before the detonation front passes.

If such a chain reaction of stellar explosions occurs, the nucleus of a galaxy will slowly brighten. The rate at which it will brighten is determined by the separation of the stars and the rate at which the light from individual supernovæ fades. Suppose that the radius of the volume over which the event occurs is about 50 parsecs, then the time taken for the whole event to occur will be about 150 years. It will be a little greater than the time for radiation to travel through this volume since a finite time is needed for each star to explode after it is irradiated. The brightening of the galaxy will be very considerable, the maximum being reached just at the point at which the density of stars begins to fall off rapidly. It is this drop in density that will stop the chain reaction. The brightening may amount to something of the order of 10 mag. or greater. However, it is not clear whether such radiation will appear in the normal photographic region of the spectrum, for the following reason.

When such an event occurs, the first supernovæ will brighten the galaxy in a normal fashion, the original radiation being emitted. After a considerable amount of gas has been ejected, however, succeeding supernovæ will irradiate this gas. It will become ionized and will achieve a temperature near 10,000°. It will also have a high random velocity since the gas is ejected from the supernovæ at several thousand kilometres a second. In such a situation all the forbidden lines excited in nova shells will appear. Such a situation is reminiscent of what we see in some of the abnormal radio sources such as Cygnus *A*, *3C*-295, *NGC* 1275, and *NGC* 1068. Very strong emission features such as [O II] λ 3727, [N II] $\lambda\lambda$ 6548, 6583, $H\alpha$, [O III] $\lambda\lambda$ 4959, 5007, [Ne V] λ 3426, etc., will appear. A very large amount of energy will also be emitted in Lyman α. There are, therefore, several stages in the evolution of such a model. In the first stage, the galaxy will apparently brighten in its nuclear region. In the second stage, very strong emission lines excited by electron collisions and high random velocities will appear. In the third stage, the random velocities of the gas will die down and eventually all the gas will disappear since it has velocities considerably in excess of the escape velocity of the galaxy. Throughout all this time the radio emission is increasing in intensity and the high-energy particles are diffusing out through the galaxy. It seems probable that the supernovae give rise to the high-energy particles which move into the regions already containing some magnetic field, where they radiate. Finally, all evidence in the spectra of the explosion will have disappeared and only the radio emission will remain.

It appears that, if the nuclear regions of galaxies explode in the way indicated, they will also be strong sources of cosmic radiation. A very powerful mechanism for acceleration of particles is indicated. Consider, for example, two supernovæ which explode a few weeks or days apart. Many of the particles ejected with the first supernova shell will have a velocity much greater than that of the main body of the material in the shell and will therefore travel ahead of it. However, these particles will very soon collide with the expanding shell from the second supernova and be reflected. A large number of particles can, by this mechanism, be trapped between two supernova shells. At each reflexion they will gain energy in the way first suggested by Fermi. The energy gained through such a mechanism is enormous for particles with the right trajectories.

Conclusions

Although galaxies such as *NGC* 1068 and *NGC* 1275 can be seen to be spirals it is tempting to suppose that the same basic mechanism is operating here as is the case for the radio sources associated with elliptical galaxies. In spiral systems it is possible that there are regions where the star density is very high. Moreover, the more massive supernovæ which may be expected in such galaxies will release more energy and thus make the process more efficient. On the basis of this discussion we may tentatively classify some of the identified radio sources in an evolutionary sequence as follows:

First stage: *NGC* 1068, 1275.
Second stage: Cygnus *A*, *3C*-295.
Third stage: *M* 87, *NGC* 6166, *NGC* 4782–83 and other elliptical galaxies.

Following Bolton[23] we may suppose that *NGC* 5128 is a system in which such an explosion has occurred more than once.

I have described earlier results which suggest that high stellar densities may be present in dwarf galaxies. Let us suppose that a chain-reaction of explosions occurs in a galaxy with the characteristics of *M* 32, but at a distance corresponding to a red-shift of 100,000 km./sec. At this distance the apparent magnitude of *M* 32 would be + 25·5, below the limit of any available optical telescope. Brightening of this galaxy by explosion would bring it well above the limit of observation. However, after the supernova phase has ended the galaxy will fade again but will remain a powerful radio source. Such a phenomenon could account for many of the sources which are apparently not identified with optical galaxies.

If the model outlined here is found to be acceptable, a number of general conclusions can be made.

(1) Strong radio sources will be produced in galaxies where the star density is high. They will not necessarily always occur in the most massive galaxies, but can occur in dwarfs also. The production of a strong source is a chance event since it requires that a star become a supernova while it is in a region of high density.

(2) Elliptical galaxies which are strong sources are comparatively old when this occurs. This is because a star of solar type needs 10–20 × 10^9 years to evolve before it becomes a supernova and triggers a galactic explosion.

(3) Sources which cannot be identified with optical objects may be at great distances. Alternatively they may be centred on dwarf galaxies the nuclei of which have exploded but which now are below the detection limit of the largest optical telescopes.

(4) If strong emission lines are present in identified sources this suggests that the explosion occurred comparatively recently. Since the time-scale for brightening or fading at this period may be only hundreds or thousands of years, a programme of investigation of the optical brightnesses and spectra of such sources should be undertaken, since secular changes may be detectable. Shklovsky[7] has already suggested that such changes be looked for in *M* 87.

There is some tendency for radio sources to be identified with pairs of elliptical galaxies or with galaxies with multiple nuclei. On this picture I must conclude that there is a tendency for the components of such systems to have abnormally high stellar densities.

I am indebted to Dr. E. M. Burbidge for a number of helpful discussions. A more detailed account of these ideas will be published elsewhere.

OBITUARIES

Dr. J. Unrau

On March 2, 1961, with tragic suddenness, the death of Dr. John Unrau took one of Canada's outstanding geneticists and brought to an end a distinguished career of scientific accomplishment and leadership. Dr. Unrau's death, at the peak of his many challenging scientific activities, is mourned by his colleagues and friends in Canada and throughout the world.

John Unrau was born on January 24, 1916, at Karaguy, Orenburgski Territory, Russia. At the age of ten he moved with his family to Saskatchewan, where he obtained his early education in Mayfair and his high-school courses by correspondence. He entered the University of Saskatchewan and graduated with honours in field husbandry in 1942. In the same year he began graduate studies in genetics and plant breeding and obtained a Master degree in 1945. He then went on to Washington State University, where he undertook studies on wheat genetics under Dr. S. P. Swenson and the late Dr. Luther Smith, and received the Ph.D. degree in 1949.

In 1940, he married Mary Klassen of Mayfair. He is survived by his wife, a daughter, Mary Ann, and three sons, John, Paul and Phillip. John and Paul are students at the University of Alberta.

John Unrau's earliest research was in sunflower breeding at the Forage Crops Laboratory, Saskatoon. This study led to the development of the single-cross hybrid, 'Advance', still widely grown commercially. At Washington State University, he entered into the activities of the Department of Agronomy, and a start was made on his now well-recognized work on monosomic–nullisomic wheat. These studies of F_2 and F_3 crosses between common hexaploid wheats and Sears' chromosome-deficient series, in which he was able to associate specific genes with specific chromosomes, laid the foundation for his latter contributions to cereal genetics.

Dr. Unrau joined the staff of the University of Alberta in 1949 and became head of the Department of Plant Science in 1951. In addition to his intense research activity, he assumed a heavy teaching load and directed the research programmes of nineteen advanced graduates, many of whom have already achieved positions of responsibility and are now making significant contributions to the advancement of plant genetics in Canada. He gave much thought to, and took an active interest in, problems of university teaching and high standards of training. He participated in numerous university committees, and took an active part, as a member of the Prairie Regional Committee of the National Research Council of Canada, in the Associate Committee on Plant Breeding and the Sub-Committees of Common and Durum Wheats, Winter Wheat and Rye, and Cytogenetic Research on Cereals and Related Grasses. At the time of his death he was a member of the Honorary Advisory Council of the National Research Council of Canada and chairman of the Associate Committee on Radiation Biology.

The contributions John Unrau made to genetical research during his short professional career were numerous, leaving a lasting impact on geneticists, plant breeders and cereal cytologists alike. He was a recognized world leader in the exploitation of wheat monosomics and their use in determining gene-effects and linkage-relationships. He demonstrated that substitution lines of whole chromosomes could be used effectively to study the expression and control of quantitative characters. By the development of reciprocal substitution lines he showed that two varieties with contrasting characters could be used in precise genetic studies of character differences. While at the University of Cambridge, during 1957–58, his work led to new evidence on the origin of the *B* genome in wheat. His work on rust-resistant, soft-white, spring wheat culminated in the licensing of the important commercial variety, 'Kenhi', in 1958.

The Genetics Society of Canada owes a very profound debt to John Unrau ; to the present membership he will long be remembered. His initiative, persevering and vigorous leadership were of utmost importance in launching the Society. His wise counsel and active part in soliciting support was decisive in establishing the *Canadian Journal of Genetics and Cytology*. He was a charter member and past director of the Genetics Society of Canada. Successively as vice-president, president and past-president, the Society was indeed privileged to have his outstanding leadership until the time of his death.

John Unrau's research output of some twenty-six articles is an impressive testimony to his rather brief but intensely energetic period of scientific activity. His monument will be his published papers and the men he has trained to add to his personal contributions in genetics. The memory of his life will remain with his colleagues and fellow members of the Genetics Society of Canada as an inspiring example.

Prof. B. J. Krijgsman

Prof. B. J. Krijgsman, who was head of the Sub-department of General Physiology at the University of Cape Town, died on April 17 at the age of sixty. At the time of his death he was also acting head of the Zoology Department. He had suffered from an incurable complaint of the lungs for some years, but such was his courage and strength of will that he rose above all adversity to remain an active scientist and teacher to within a week of his death. To the very end he maintained a deep humility and sense of responsibility towards his students and colleagues, always managing to find the time and energy to give friendly advice or offer gentle criticism. Though a prolific research worker, Prof. Krijgsman was a man of exceptionally wide interests. He was a great reader, particularly favouring philosophical topics, and was very interested in art. However, his main form of relaxation was listening to music or, when his health allowed, playing the piano, on which he was an accomplished performer. It was indeed as great a privilege to know him socially as it was to work with him in the laboratory.

Prof. Krijgsman was born in Holland in 1901. After studying biology at the University of Utrecht, he became junior lecturer there in 1921, later being appointed lecturer. In 1928, after being awarded the degree of doctor of philosophy with distinction, he emigrated to Java to become head of the Veterinary Research Institute at Buitenzorg. He later combined this post with that of professor of medical zoology at Batavia. In 1935 he returned to Holland to study the physiological effects of insecticides for the Netherlands Council for Scientific and Industrial Research and to lecture at the University of Utrecht. In 1949 he accepted the post of senior lecturer in physiology, in the Zoology Department, University of Cape Town, later being appointed associate professor. At the beginning of 1959 he became the first head of the newly formed Sub-department of General Physiology.

In spite of heavy teaching duties, Prof. Krijgsman published at least one hundred and twelve original papers during his lifetime, wrote four books on zoology and contributed to six others. His wife, Mrs. Nel E. Krijgsman, was a great help to him in this respect, being not only a devoted companion but also undertaking duties as his research assistant. Prof. Krijgsman is, perhaps, best known for his studies on the physiology of the invertebrate heart and on the physiology of parasites, but, in fact, he pioneered research in many fields, and the whole subject of invertebrate physiology would have been the poorer had he turned his talents elsewhere. The world of science has lost an eminent research worker and an original thinker: the University of Cape Town has lost also a valued colleague and friend. A. C. BROWN

Dr. E. de Barry Barnett

EDWARD DE BARRY BARNETT, who died on March 23, will be greatly missed by his many former colleagues and students. He could truly be described as a character. He was held in great affection but was often unpredictable. His instructions to his executors were definitely that he did not wish any obituary notice to be published, but he left a summary of his life among his papers, realizing, no doubt, that it would not be possible to avoid such notice and desiring, as always, to be of help.

He was born on October 20, 1886, and educated at Malvern College and University College, London, graduating with first-class honours in chemistry in 1908. After holding some industrial appointments in the dyestuff and explosives industries, he went back to academic work and was appointed lecturer in organic chemistry at the Sir John Cass Technical Institute in 1919; eventually he became head of the Department and deputy principal, retiring in 1947.

He was the author of a number of well-known books, the latest of which, *Mechanism of Organic Chemical Reactions*, was published in 1956.

His own summary of his life passes very lightly over much that was significant. It does not tell of the extent or the high quality of his published papers, numbering more than a hundred, chiefly in the field of anthracene chemistry. It does not indicate his rather lonely private life as a bachelor, isolated by his deafness in so many ways. It gives no idea of the extent of his help to his students. He had an uncanny knack of selecting as junior laboratory staff those applicants who had the ability to advance. Barnett would teach them himself, at the same time often arranging and paying privately for other tuition to make good defects in their earlier education. Having got them over these hurdles, he would see that they lacked no help in gaining their degrees. There is no way of assessing the generous financial assistance that Barnett gave to so many students in days when grants from public funds were less common than they are now.

He was greatly handicapped by his deafness. His well-known "What?" with his hand cupped to his ear and his "You see what I mean to say", said in the loudest of tones, without any basis for uncertainty and not infrequently to the discomfort of those who overheard his criticism of them, remain as vivid memories. But at all these times, even when he criticized both his students and those in authority. there was a humorous twinkle in his eye and an underlying kindness in all he did.

Sir John Cass College was to him a life-time interest. He worked selflessly for its development throughout the whole of his teaching career. During the War. when much of the building was severely damaged by bombing and fire, he continued his teaching there, chiefly with classes at week-ends and by correspondence. He took more than his full share of fire-watching, spending his nights on the roof to make sure that his deafness did not cause him to miss any incidents that might have escaped his immediate attention had he been in a less-exposed position.

He is remembered by his many friends with a deep sense of loss and also with appreciation of the contribution he made not only to the advancement of chemistry but also to the development of the 'Cass'. His sincere care for the well-being and interests of his many students will not be forgotten. A. M. WARD

Mr. W. E. Lawrence

THE death on April 16 of Mr. W. E. Lawrence came as a great shock to his many friends and admirers who have, from time to time, received his help and been regaled with his varied experiences during his forty-three years of service in the Prosectorium of the Zoological Society of London.

William Edward Lawrence was born May 1, 1900. the son of a London milk-roundsman; his mother was Welsh, but "Billy", as he was affectionately known, was himself—both in physical appearance and temperament—a typical Cockney, with his ready wit, quick repartee, irrepressive sense of humour and rich fund of experiences.

Lawrence received an elementary school education at Princess Road School, Regent's Park (1904–14). Here he proved a good scholar, reaching the highest standard. Under the influence of his teacher, a Mr. Dakin, a Zoo addict, Lawrence's interests were early channelled towards animals and he made many visits with his teacher to the neighbouring Zoological Gardens. Apparently it was through Dakin's influence that "Billy" was recommended to the post in the Society's Gardens when, as was customary at that time, he left school at the age of fourteen.

He entered the 'dead house', as it was then called, as prosector's boy and was placed under the direction of the prosector's assistant, Mr. C. H. Hicks, from whom Billy learned dissection, injection and the preparation of skeletal material, albeit employed mainly on menial tasks until Hicks' promotion to superintendent's assistant in 1925, when Lawrence assumed charge of the technical aspect of the work in the Prosectorium. Apart from a brief interlude of two months in 1916 and two years war service (1917–19), he spent his working life at the Zoo, where he returned in 1920, first for a year as butcher's assistant and thereafter in the Prosectorium, where he remained until retiring on pension on October 1, 1958.

Lawrence's long service was officially recognized by his award in 1953 of the British Empire Medal in the Coronation Honours List, and in 1960 by the conferring of the Zoological Society's Bronze Medal.

One of his most outstanding memories dated from the epidemic in 1926–27 of anthrax in the Zoo's Elephant House. In January 1927, after an autopsy on an elephant, Lawrence developed two small malignant pustules which proved to contain the anthrax bacillus. He was rushed to hospital expecting to be dead in forty-eight hours, but in a few weeks he was back at work, cheerful as ever.

He leaves a widow, son and daughter, to whom the sympathy of his many friends and admirers will be extended in their recent bereavement.

W. C. OSMAN HILL

NEWS and VIEWS

The Queen's Birthday Honours List

THE following names of scientists and others associated with scientific work appear in the Queen's Birthday honours list:

K.C.M.G.: Dr. John C. R. Buchanan, medical adviser to the Secretary of State for the Colonies; Dr. Boris P. Uvarov, lately director, Anti-Locust Research Centre.

Knights: Prof. John F. Baker, professor of mechanical sciences and head of the Department of Engineering, University of Cambridge; Robert R. Blackwood, general manager, Dunlop Rubber Co. (Australia), for services to the University of Melbourne; G. Trenchard Cox, director, Victoria and Albert Museum; Arthur B. Duncan, lately chairman, Nature Conservancy; Prof. Austin Bradford Hill, professor of medical statistics, London School of Hygiene and Tropical Medicine, University of London; Dr. Thomas Malcolm Knox, principal, University of St. Andrews.

C.B.: Dr. R. C. Sutcliffe, chief scientific officer, Meteorological Office, Air Ministry.

C.M.G.: G. C. L. Clark, president of the Australian Institute of Mining and Metallurgy; A. B. Cowen, deputy chairman, Standards Association of Rhodesia and Nyasaland; A. F. MacKenzie, Federal agricultural adviser, West Indies; Dr. J. O. Poynton, director of the Institute of Medical and Veterinary Science, State of South Australia.

C.B.E.: R. E. Beales, deputy director, Central Statistical Office, Cabinet Office; Dr. D. Curran, senior psychiatrist, St. George's Hospital, London; A. K. Briant, director of agriculture, Zanzibar; Dr. W. L. Francis, director (grants and information), Headquarters, Department of Scientific and Industrial Research; Dr. J. W. Gregor, director, Scottish Society for Research in Plant Breeding; Prof. J. E. Harris, professor of zoology, University of Bristol; A. J. Nicholson, formerly chairman, Division of Entomology, Commonwealth Scientific and Industrial Research Organization, Australia; L. F. C. Northcott, principal superintendent, Materials and Explosives Division, Armament Research and Development Establishment, War Office; E. Norton, research director, Yarrow and Co., Ltd., Glasgow; J. D. Parsons, director, Royal Ordnance Factories (Explosives), War Office; Dr. W. H. Penley, deputy chief scientific officer, Royal Radar Establishment, Ministry of Aviation; H. W. Springer, registrar, University College of the West Indies; A. B. Taylor, registrar-general, Scotland; G. A. Whipple, chairman and managing director, Hilger and Watts, Ltd.; R. G. McK. Willan, chief conservator of forests, Nyasaland; Prof. F. C. Williams, professor of electrical engineering, University of Manchester.

I.S.O.: T. W. V. Jones, senior principal scientific officer, Air Ministry (Bracknell, Berks.); A. D. Fraser, director of Wild Life Conservation, Southern Rhodesia; P. Ryan, director of agriculture, State of Victoria; J. H. Griffiths, chief electrical and mechanical engineer, Tanganyika.

Taxonomic Botany at Birmingham:
Prof. J. G. Hawkes

AT a time when it is becoming widely acknowledged that there is a shortage of scientifically trained taxonomic botanists, the election of Dr. J. G. Hawkes to a chair of taxonomic botany in the Department of Botany, University of Birmingham, is a noteworthy event. Dr. Hawkes was educated at Cheltenham Grammar School and Christ's College, Cambridge. After initial research training in cytology, he joined an Imperial Agricultural Bureaux expedition to South America as taxonomic botanist, and was appointed afterwards by the Bureaux to work out the taxonomy and cytogenetics of the potato material collected on the expedition. This was the beginning of the work which has made Dr. Hawkes a world authority on *Solanum*, commanding a unique knowledge of the distribution, variation and ecology of the genus in its principal areas in the New World. In addition to leading further expeditions in Central and South America, the last in 1958, he spent two extensive periods in Colombia at the invitation of the Colombian Government organizing a national potato research programme and training groups of specialists in various aspects of breeding and pathology. Since his appointment as lecturer in flowering-plant taxonomy at the University of Birmingham in 1952, Dr. Hawkes has combined his researches on *Solanum* with a study of the Warwickshire flora. Based on new methods of recording distributional data, this may well become a model of its kind. To his chair of taxonomic botany—the first in Britain to bear the name—Dr. Hawkes thus brings the admirable combination of first-hand acquaintance with tropical and temperate floras and the experience gained from the detailed study of a major genus by modern methods.

A Pioneer of Aerology: Prof. Vilho Väisälä

MODERN weather forecasting techniques are largely based on observations derived from radio-sonde soundings. The name of Väisälä is known to all meteorologists as that of an outstanding pioneer of the radio-sonde. Väisälä's association with aerology goes back to 1916 when he was appointed head of the kite station at Ilmala, Finland. In 1919 he became head of the aerological section of the Finnish Central Meteorological Office. After making a number of improvements to the earlier aerological observing methods he began to experiment with the Väisälä radio-sonde in 1931. This reached a stage of development which could be called entirely satisfactory by 1936. In 1944 Väisälä founded a company for manufacturing radio-sondes on a commercial scale, and at present it exports them to fifteen countries. But apart from his aerological activities Väisälä has pursued an active academic career, having been a teaching assistant and lecturer in meteorology at the Finnish Institute of Physics, and culminating in a personal extraordinary professorship in meteorology at the University of Helsinki, from which he retired in 1958 at the age of sixty-nine. It is announced in the journal of the Geophysical Society of Finland, *Geophysica* (8, No. 1; 1960), that, in order to commemorate the seventieth birthday of this outstanding Finnish scientist, the Society has struck a special medal with the inscription: "The Finnish Pioneer of Aerology".

National Institute of Industrial Psychology : Dr. R. B. Buzzard

Dr. R. B. Buzzard has been appointed research director of the National Institute of Industrial Psychology. The Institute's programme of research is partly financed by grants from the Department of Scientific and Industrial Research. After graduating in physiology and qualifying in medicine, Dr. Buzzard spent ten years as a member of the Medical Research Council's scientific staff at the Experimental Psychology Laboratory in Cambridge and then, in 1953, transferred to the Council's Industrial Psychology Research Unit at University College, London. His work has been concerned with problems of research and application in industry and the armed services. They have included training interviewers, the development of personnel-selection procedures, refresher training of returned prisoners of war, and investigations into industrial injury, sickness and absence and the effects of working environments. He will bring to the Institute wide experience of investigation in fields where the gap between research and practice in industry tends to be greatest. In 1960, he was awarded the Institute's Vernon Prize, which is given in alternate years to the investigator regarded as having carried out the most valuable research in industrial psychology and physiology.

C-E-I-R, Ltd.: Prof. M. G. Kendall

Prof. M. G. Kendall is to join the Board of C-E-I-R (U.K.), Ltd., the computer research services organization. He will be responsible for the Departments of Mathematics, of Statistics and of Operational Research. He will work closely with Dr. Alexander S. Douglas, the director of technical services, whose divisional responsibilities include Departments of Computer Services, of Computer Technology and of Programming. Prof. Kendall is at present professor of statistics in the University of London (London School of Economics) and will vacate his chair on September 30. He received his mathematical training at the University of Cambridge, and entered the Administrative Class of the British Civil Service in 1930 to work in what was then the Ministry of Agriculture and Fisheries, becoming the head of the Economics Intelligence Branch. In 1940 he resigned from the Civil Service to become statistician to the Chamber of Shipping of the United Kingdom. He remained at the Chamber of Shipping until 1949, becoming joint assistant general manager in 1947. Since leaving the Chamber of Shipping in 1949, Dr. Kendall has been professor of statistics in the University of London. Among his activities in the University and at the London School of Economics have been the creation and direction of the Division of Research Techniques. Its work in statistics, econometrics, social surveys, and in operational research is known and followed in every country of the world.

Euratom : U.K. Nuclear Energy Attaché

Mr. G. H. Greenhalgh, of the United Kingdom Atomic Energy Authority, has been appointed nuclear energy attaché to the United Kingdom Delegation to the European Communities, to succeed Mr. D. H. Hill. He will be taking up his appointment in the near future. Mr. Greenhalgh, who is forty and a chemist by profession, was a member of the Extra-Mural Research Division at the Atomic Energy Research Establishment, Harwell, until 1956, when he was appointed scientific attaché to the British Embassy in Stockholm. In his new appointment, Mr. Greenhalgh will act as adviser on nuclear energy matters to the Head of the United Kingdom Delegation to the European Communities and will keep in touch with the various installations on the territory of the Community concerned with the peaceful uses of nuclear energy. The present nuclear energy attaché, Mr. Hill, will be leaving Brussels at the end of May to take up a post with the Authority's Reactor Group.

Co-ordination of Research and Development of Sources of Energy

In a written answer in the House of Commons on May 16, the Minister of Power, Mr. R. Wood, said that his Advisory Council on Research and Development existed to co-ordinate research and development in the whole field of energy. Its terms of reference were: to advise the Minister on research and development in relation to his statutory duty of securing the effective and co-ordinated development of coal, petroleum and other sources of fuel and power in Great Britain, and of promoting economy and efficiency in the supply, distribution, use and consumption of fuel and power; to advise the Minister of new scientific and technical knowledge or application of knowledge which, in the Council's opinion, should be taken into account in the performance of his statutory duties; and to keep the whole field of fuel and power under continuous review with the object of identifying problems needing research and development and advising the Minister of those problems with the view of discussion with the industries concerned.

The members of the Council are: Lord Fleck (*chairman*); Capt. (E.) W. Gregson (*deputy chairman*); Mr. M. A. L. Banks, British Petroleum Co.; Dr. C. M. Cawley, Ministry of Power; Mr. T. B. Clark, Imperial Chemical Industries, Ltd.; Sir Josiah Eccles, Electricity Council; Mr. W. K. Hutchison, Gas Council; Dr. W. A. Macfarlane, National Industrial Fuel Efficiency Service; Sir Harry Melville, Department of Scientific and Industrial Research; Mr. L. Rotherham, Central Electricity Generating

Board; Prof. M. W. Thring, University of Sheffield; Dr. F. A. Vick, Atomic Energy Research Establishment, Harwell; Mr. A. H. A. Wynn, National Coal Board.

Programme of Sounding Rockets

In reply to a question in the House of Commons on May 30, the Parliamentary Secretary for Science, Mr. D. Freeth, said that the experiments in the present sounding rocket programme are devised by United Kingdom scientists and carried out in *Skylark* rockets fired at Woomera under joint Anglo-Australian arrangements. Provision of the rockets, the main element in the cost, is estimated at about £225,000 in the current year. The possibility of enlarging this programme in co-operation with the Commonwealth and Europe is under consideration, and a co-operative sounding rocket programme is one of the first questions which is being explored by the Preparatory Commission set up to plan a possible European organization for space research. The cost could not be assessed pending the outcome of the international discussions now in progress on the co-operative development of a satellite launcher, and on the scale of activities to be carried out by the proposed European Space Research Organization.

Population Statistics in England and Wales

The second part of the *Registrar General's Statistical Review of England and Wales for the Year* 1959 has just been issued (Part 2: Tables, Population. Pp. xi+181. London: H.M.S.O., 1960. 11*s.* 6*d.* net.). There are no major changes in the presentation of the data, or the field covered, which includes population movement, births, marriages, marriage dissolution, fertility and statistics of electoral divisions and local elections. The estimated mid-year population for England and Wales was 45½ millions, of whom 22·8 per cent were children under 15, and 14·7 per cent of pensionable age (men: 65 and over; women: 60 and over). A projection prepared by the Government Actuary for the period up to 1999 predicts a slight decline in the proportion of children, and a rise in the proportion of pensioners to a maximum of 17·9 per cent in 1989. Marriages in 1959 were fractionally higher than in 1958, but the rate per 1,000 unmarried population fell slightly. The number of petitions for dissolution of marriage rose by 88 over the previous year, but at 26,300 was still lower than in any of the years 1945–57. Live births continued rising, and at 748,500 were higher than in any year since 1948. The fertility analysis shows that this is well above the level of replacement. The Registrar General has also issued an illustrated pamphlet *Why a Census* (Pp. 31. London: H.M.S.O., 1961. 1*s.* net) to make the general public familiar with the reasons for the Census taken this year, and to inform them about the questions asked and the techniques used. This is an extremely well-produced guide, which gives an indication of the scope and nature of the census programme and the uses to which the information collected can be put, in simple language.

L'Homme et L'Espace

A new monthly journal, *L'Homme et l'Espace*, made its appearance in April. It is published jointly by Dunod, 92 rue Bonaparte, Paris, VI^e, and Editions Spes, Lausanne (No. 1; Avril 1961. Pp. 56. (Lausanne: Actualité Scientifique et Technique S.A., 4 Place de la Riponne, 1961.) Abonnement annuel (12 numeros): Suisse: Fr. 45. France: N.F. 54. Autres pays: S. fr. 54. Prix du numéro: Suisse: Fr. 5. France: N.F. 6.50. Autres pays: S. fr. 8). Its object is to describe, in not too technical a manner, the present developments in space research and technology, and to discuss their wider implications for man. There is a place for a contemplative journal of this type among the many factual and technical publications on the subject, and *L'Homme et L'Espace* promises to fill that place admirably. The first issue is produced attractively, with a wealth of illustrations, and its contents are informative and varied. In the first section, on sciences, there are articles by P. Auger on European space research, M. Golay on the necessity for space research and results from it, C. de Jager on the Sun and its variability, and J. Eugster on the radiation barriers to space travel. The topics discussed in the second section, "Literature, Law, History", include ancient ideas on the universe, the predictions of Fontenelle, and space travellers in literature. The last section consists of notes on the night sky in April, comments on various space-research events, a table of satellites and a book list. English and German editions of *L'Homme et l'Espace* are planned.

General and Comparative Endocrinology

The first issue of a new international journal, entitled *General and Comparative Endocrinology*, has been published recently (1, No. 1 (April 1961). Pp. 90. (New York and London: Academic Press, Inc., 1961.) Vol. 1 (6 issues), 1961: 18 dollars). The intention of the editors is to publish original work on cellular mechanisms of hormone action, and on functional, developmental and evolutionary aspects of vertebrate and invertebrate endocrine systems. Occasional brief reviews dealing with particular aspects of endocrinology will also be included. The first number contains nine communications which describe work on insects, amphibians, reptiles and mammals. The list of members of the advisory council and board of editors contains the names of scientists of world-wide eminence, and this should help to ensure that a high standard of publication is maintained.

Bibliography of Interlingual Scientific and Technical Dictionaries

The fourth edition of the *Bibliography of Interlingual Scientific and Technical Dictionaries* includes many works published in the U.S.S.R. As in previous editions, it is arranged according to the Universal Decimal Classification and there are author and subject indexes. Nearly 900 new dictionaries have been introduced since the first edition (1951) and attention is directed to 133 new editions of works previously mentioned. It is proposed in future to bring the Bibliography up to date through the publication of supplements. Corrections, and any information or suggestions for improving the Bibliography, are invited by the Department of Natural Sciences, United Nations Educational, Scientific and Cultural Organization. Copies of the Bibliography are obtainable from H.M. Stationery Office, price 17*s.* 6*d.*

The British Museum (Natural History)

The British Museum (Natural History) has just issued a new edition of *A Short Guide to the Exhibition Galleries* (eighth edition. Pp. vi+32. London: British Museum (Natural History), 1961. 1*s.* 6*d.*).

The *Guide* follows the modern format which has now entirely replaced the rather text-book-like editions of earlier days. A useful plan of the ground floor is followed by a short historical sketch of the Museum and a description of the exhibits in the Central Hall including the bays together with an outline of the chief features in the Geological, Zoological and Mineralogical Galleries. As the Botanical Gallery is at present under reconstruction, the only botanical exhibits shown are those in the bays of the North Hall. The *Guide* is well illustrated and includes useful details concerning the library, other publications, the Children's Centre and general information about the Museum.

Science in Antarctica

An interesting assessment of the need for future research programmes in Antarctica has recently been produced by the U.S. Committee on Polar Research of the National Academy of Sciences—National Research Council (*Science in Antarctica*: A Report by the Committee on Polar Research. Part 1: *The Life Sciences in Antarctica.* Pp. xi + 162. Part 2: *The Physical Sciences in Antarctica.* Pp. xi + 131. (Publications Nos. 839 and 878.) (Washington, D.C.: National Academy of Sciences—National Research Council, 1961.) 1.50 dollars each part). The Committee has drawn on leading scientists in the United States to write individual chapters, in each of which the present state of knowledge in a particular discipline is outlined, and possibilities of future developments of research in that field are discussed.

The length of individual chapters, excluding the useful bibliographies, varies from two pages on the "General Ecology and Physiology of Antarctic Fishes" and the "Antarctic Magnetic Programme" to sixteen pages on "Antarctic Glaciology". The report has been published in two parts, and it is of interest to note that Part 1, dealing with "The Life Sciences in Antarctica", covers 162 pages compared with 131 pages on "The Physical Sciences in Antarctica". Although this is due partly to more detailed bibliographies covering the life sciences, it also serves to indicate the increased emphasis which the U.S. Committee on Polar Research would like to place on these disciplines which received little support during the International Geophysical Year. In fact, the introduction points out that the contributions of the United States to Antarctic biology are not great compared with those of other countries, and they hope that the present report will publicize the excellent opportunities in such fields for workers in the United States. The report on physical sciences includes chapters on cartography and geology, two fields of work not included in the programme for the International Geophysical Year. These are included under the section on the "Earth's Crust and Core"; other sections cover the "Heat and Water Budget of Antarctica" and "The Upper Atmosphere". The report has been produced primarily to stimulate interest among scientists within the United States in their Antarctic programme, as well as to emphasize the need for such an effort. It also forms a most useful reference source for scientific administrators connected with Antarctic programmes. The distribution of such reports outlining views of leading scientists on the most promising lines of research during the next five years is in keeping with the best traditions of science and the general atmosphere of international scientific co-operation in Antarctic matters which now prevails.

Nuclear Geochronology

Throughout the world more than a thousand research workers are engaged at present in determining the ages of rocks and minerals by methods based on radioactive decay, and as a consequence of this extensive activity it has of late become increasingly difficult for the average geologist to keep track of the many advances in absolute geochronology. Non-specialists will therefore be indebted to two new works which summarize the latest progress in this field. The New York Academy of Sciences has just published the record of last year's conference on "Geochronology of Rock Systems", edited by Prof. J. L. Kulp of Columbia University, to which more than seventy workers of many nationalities have made contributions (*Annals of the New York Academy of Sciences.* Vol. 91, Article 2. Pp. 159–594. New York; New York Academy of Sciences, 1961). Simultaneously, the Academy of Sciences of the U.S.S.R. has issued a lengthy volume in Russian on *Yadernaya Geokhronologiya* or "Nuclear Geochronology" (630 pp., 1961. Price 3.13 new roubles. Moscow, Academy of Sciences of the U.S.S.R.) which is the work of Dr. I. E. Starik of the Radium Institute in Leningrad. One of the most significant features of these publications is a growing recognition of the extent to which apparent ages are dependent on metamorphic history. A new geochronological time-scale produced by Dr. Starik from Russian evidence is in tolerably good (but far from complete) concurrence with the Holmes–Kulp chronology of the geological systems announced last year, and elaborated lately by Prof. Kulp in a comprehensive review contributed to *Science* (133, pp. 1105–1116, April 16, 1961). Both the American and Russian time-scales agree that the Silurian period, with a duration of only 20 million years, is by far the shortest in Palæozoic time—a conclusion which must surely cause Murchison to turn in his grave.

Conservation of Water

The sixth annual report of the Tweed River Purification Board covers the year ending May 15, 1960, and thus deals with events occurring during the dry summer of 1959 (Pp. 39. Newton St. Boswells: Tweed River Purification Board, 1960). In this connexion the Board is concerned with the increasing demands being made on available water supplies—in particular, the use of spray irrigation by farmers may consume very large quantities, and the Board considers that legislation on this subject should be introduced at an early date. The value of the re-use of water by industry was exemplified at some sand and gravel washing plants in the Board's area—in some cases streams would have been pumped dry and production would have been restricted if the washing water had not been re-used. It is encouraging that the report records that rivers were in a generally cleaner condition, and fish mortality in the main rivers was substantially less than during the dry conditions of 1956–57.

Cambridge Rheology Club

The first discussion meeting of the Cambridge Rheology Club, which was inaugurated on April 24, was held on May 29 at the Technological Research Station, Spillers, Ltd., Cambridge. Dr. J. R. A. Pearson (Department of Chemical Engineering, University of Cambridge), the chairman for the evening, welcomed the two visitors, Dr. M. A.

Payman (Charing Cross Hospital) and Dr. G. W. Scott-Blair (National Institute for Research in Dairying, University of Reading). The discussion on "Some Recent Research Problems encountered in the Study of Blood as a Rheological Fluid" was opened by Drs. D'A. Kok (Department of Medicine) and P. A. G. Munto (Anatomy School). A lively exchange of ideas followed with contributions mainly by the opening speakers and Drs. P. Johnson and A. T. Rowe (Department of Colloid Science), Dr. P. R. Lewis (Anatomy School) and Dr. N. A. de Bruyne (Techne, Ltd.). It was announced that the next meeting would take place at the Technological Research Station, Spillers, Ltd., on September 11, when the Cambridge Instrument Company, Ltd., Grant Instruments (Cambridge), Ltd., and Techne (Cambridge), Ltd., will exhibit and discuss rheological equipment. Further information can be obtained from Mr. H. G. Muller, Technological Research Station, Spillers, Ltd., Station Road, Cambridge.

British Conference on Insecticides and Fungicides

The Association of British Manufacturers of Agricultural Chemicals is organizing a "British Insecticide and Fungicide Conference" at the Grand Hotel, Brighton, during November 6–9. The conference is divided into eleven sessions, which include: (*a*) soil pests and diseases, including "The Eelworm Problem", by Mr. F. Jones, "Insecticide Seed Dressings" by Mr. M. J. Way and "Fungicide Seed Dressings" by Dr. Mary Noble; (*b*) systemic insecticides, including "Systemic Insecticides and Virus Control in Potatoes" by Dr. L. Broadbent and "Control of Sugar Beet Virus Yellows" by Dr. Reitberg; (*c*) forecasting of pest and disease outbreaks (Mr. G. H. Brenchley); (*d*) the control of apple mildew (Dr. R. T. Burchill); (*e*) pests of tree fruits (Dr. G. H. Dicker); (*f*) control of *Botrytis* disease (Mr. J. M. Wey); (*g*) control of fungi and nematodes (Dr. Madel); (*h*) newly developed compounds; (*i*) introduction of insecticides into agricultural practice at home and abroad (Mr. M. Cohen and Mr. G. Ordish). Further information can be obtained from the conference secretary, Mr. W. A. Williams, Association of British Manufacturers of Agricultural Chemicals, Cecil Chambers, 86 Strand, London, W.C.2.

New Universities in Britain

In a written answer given in the House of Commons on May 18, the Chancellor of the Exchequer, Mr. Selwyn Lloyd, said that the University Grants Committee had advised him that, within the scope of the building programme already announced, four new universities, in addition to those which are already being established at Brighton, Norwich and York should be established as the best means of providing places for some of the increased number of students expected. He added that the Committee had advised him that three of the four should be at Canterbury, Colchester and Coventry. The location of the fourth is being considered and the Committee hoped to report on this in the next two or three months. It is the Committee's view that the question of the establishment of any new universities beyond these four should await the report of Lord Robbins's Committee on Higher Education. No new university for Scotland was proposed because it was expected that the expansion of the existing Scottish institutions under the building programme already authorized would provide the additional places needed. Mr. Lloyd said he had accepted this advice, and had authorized the University Grants Committee to enter into discussions accordingly. The detailed proposals would take into account existing provision and plans for other forms of higher education in the areas concerned.

Announcements

Dr. T. D. Day, formerly assistant director of cancer research, Department of Experimental Pathology and Cancer Research, University of Leeds, has been appointed to direct the Tobacco Manufacturers' Standing Committee Research Unit, Harrogate.

The following were elected officers of the Salters' Company for the year 1961–62: *Master*, Sir Alexander Todd; *Upper Warden*, T. G. Hicks; *Second Warden*, Rear-Admiral W. K. Weston.

The 407th meeting of the Biochemical Society will be held in the Department of Physiology and Biochemistry, University of St. Andrews, during June 22–23, starting at 2 p.m., when there will be a colloquium on "The Quantitative Estimation of Amino Acids". Original communications will be presented on the following day.

The National Physical Laboratory, Teddington, is organizing a conference on "The Control of Noise" during June 26–28, in collaboration with the National Engineering Laboratory and the Building Research Station. The programme will include: general problems of the control of noise; hearing and the ear; measuring noise; sources of mechanical noise; propagation of sound in air; effects of noise on performance and productivity, etc. Further information can be obtained from Mr. D. W. Robinson, National Physical Laboratory, Teddington, Middlesex.

The eleventh meeting of Nobel prize winners will be held in Lindau during June 26–30. Further information can be obtained from the Sekretariat der Tagungen für Nobelpreisträger, Lindau (Bodensee), Postfach 11.

Hatfield College of Technology is organizing a summer school on the "Mathematics of Automatic Control" during June 26–30. The object of this school is to enable mathematicians and engineers working on problems of automatic control to study some of the relevant mathematical techniques developed in recent years in Britain, the United States and the U.S.S.R. Further information can be obtained from the Academic Registrar, Hatfield College of Technology, Hatfield, Herts.

The Association for the Study of Animal Behaviour is holding a three-day symposium on "Orientation and Migration" during July 11–13 in the Department of Zoology, University of Cambridge. Further information can be obtained from Dr. J. B. Free, Rothamsted Experimental Station, Harpenden, Herts.

Erratum. In the article entitled "Separation of Two Light Reactions in Noncyclic Photo-phosphorylation of Green Plants", by Dr. M. Losada, Dr. F. R. Whatley and Prof. Daniel I. Arnon, in *Nature* of May 13, p. 606, in Tables 2 and 3, entries 2 and 4, the plus sign should in each case precede the word 'Dye'.

GHANA SCIENCE ASSOCIATION

THE Ghana Science Association held for the first time a conference of all scientists in Ghana at Legon in the University College of Ghana during March 31–April 3. This coincided with the second anniversary of the Association, which was formed from the West African Science Association, after Nigeria had asked to form the Science Association of Nigeria about two years ago.

The conference was opened by the Hon. Kofi Baako, Minister of State for Presidential Matters in Parliament, who is also the Minister responsible to the President for National Research. He deputized for the President, Osagyefo Dr. Kwame Nkrumah. The Minister expressed the Osagyefo's great interest in science and its development in Ghana and appealed to the scientists to channel their efforts through peaceful uses of scientific discoveries. He also promised the help of the Government in the publication of a new scientific journal for the Association. The Minister's speech was followed by the presidential address of the Association, which was given by Mr. R. P. Baffuor, principal of the Kumasi College of Technology and the third and this year's president of the Association.

This conference appeared to have met with approval in Ghana, for although many international scientific conferences have been held in Ghana for some time past much publicity was given to this national conference by both the Press and the radio. The theme of the conference was "Science in the Development of Ghana", and no less than twenty-three papers were read in the three days in various branches of science such as physics, chemistry, botany, zoology, geology and geophysics, engineering, agriculture, medicine and soil science. The actual topics were not necessarily limited to Ghana. Most of the papers were of a general nature, and were presented for the understanding of all scientists irrespective of their speciality, but one afternoon was set aside for specialist papers, when the conference split into biological and physical sciences. Geology and soil science formed the biggest group of papers read.

The most popular paper was on traditional healing methods in Ghana, by Mr. W. S. Mensah-Dapaa, a Ghanaian science graduate who, for about two years, has been living at the shrine of a famous traditional healer at Larteh, a village about thirty-five miles from Accra. In his paper Mr. Mensah-Dapaa described in great detail the ceremony that surrounded the healing at this shrine and gave eye-witness accounts of the spectacular cures that had taken place there. He certainly aroused interest in this field, which has often been relegated to the limbo of non-scientific or quasi-spiritual practices. He appealed to the scientists to shed many of the false ideas about traditional healing, so that the best of this cult, which he claimed to be Africa's version of what prevails in varying forms all over the world, may be successfully studied and integrated into science and medicine. He also called for a department under the proposed medical school for studying the herbs and the methods of traditional healing.

Contributors were selected from all over Ghana, from the University College of Ghana, the College of Technology, research institutions like the West African Cocoa Research Institute, the Government Scientific Civil Service, and private individuals.

One significant and encouraging aspect of the conference was that for the first time an appreciable number of young Ghanaian scientists read more than one-third of the papers.

On the first full-session day, April 1, nine papers were read. The Rev. Dr. J. R. Koster, the first scientist to record sounds from the Russian satellite in 1957, read a paper on "Radio Research in Ghana". He discussed the discovery of some unusual equatorial radio propagation problems in Ghana which affect television and radio broadcasting in Ghana and elsewhere. This was followed by an illuminating talk by Mr. O. W. Snow, adviser on agricultural science to the Government of Ghana, on "Agricultural Research in Relation to Development". With particular reference to the Gezira Cotton Scheme in the Sudan Republic, Mr. Snow showed how the proper utilization of the great potential of the results of agricultural research depended largely on other factors, such as systematic layout, availability of credit and some legalized form of marketing.

After this had been followed by the paper on traditional healing methods referred to above, Mr. A. Foggie, adviser on forestry matters, read his paper on "Conservation of Natural Resources in Ghana". He covered the problems of conservation of water, vegetation, soils and wild-life in Ghana. Another paper of great interest that day was one on "Radio Isotope Unit", by Dr. A. H. Ward, of the Physics Department of the University College, in which were described the various work being carried out in Ghana with radioisotopes and the potentialities of the Radio Isotope Unit installed at the University College. Other papers for the day included the following: "Some Aspects of Genetic Expressions in Agricultural Experimentation in Ghana", by Dr. Agble, deputy chief scientific officer; "Grain Storage Problems in Ghana", by Mr. J. Forsyth, of the Faculty of Agriculture at the University College of Ghana, and finally, "The Role of Geology in the Development of Ghana", by Mr. L. A. K. Quashie, of the Geological Survey Department.

The following day was devoted to the specialist lectures. Under the chairmanship of Prof. W. J. McCallien the Physical Sciences group heard three papers. The first of these, which drew many listeners, was on "Geological and Archæological Evidence for the late Quaternary Climatic Sequence in West Africa", by Dr. O. Davies, a well-known archæologist who continues to make valuable contributions in this field in Ghana. This was followed by a paper by Dr. F. Torto, of the Department of Chemistry, on the structure of gums and mucilages in two Ghana plants, *Fagara xanthoxyloides* and *Afraegle paniculata*. The final paper of the day was on "A Seismic Investigation of the Depth of Bedrock under the Volta River at Tefle", by Mr. F. W. Hales, senior geophysicist of the Geological Survey Department. He showed that the refraction method of analysis corroborated the depth-to-bedrock data obtained by drilling at the site of the proposed bridge across the Volta River at Tefle.

The Biological Sciences group, under the chairmanship of Prof. F. W. Sansome, heard two papers on cocoa—one, "Comparable Growth Rates of Amazon and Amelonado Cocoa and Responses to Fertilizer", and the other, "Problems in the Assessment of Cocoa Varieties". The third paper was entitled "Liver Cirrhosis in Pigs in Ghana", in which the speaker, Mr. D. Zwart, introduced for discussion the problem of liver cirrhosis which attacked the local black pigs, and later also a few of the European ones, when kept under semi-intensive conditions.

The final full session day of the conference, April 3, opened with one of the popular topics, "Tuberculosis in Ghana", by the tuberculosis specialist in Ghana, Dr. A. Koch. Then followed a general paper by Prof. McCallien on "Seas and Oceans", treated with reference to geological problems in recent oceanographic studies.

Quite related to this topic was the next paper on "Outboard-Motor as a Prime Mover in the Development of Fisheries in Ghana", by Mr. E. A. Kwei, of the Government Fisheries Department. Among the other papers for the day were "The Correlation of Field, Laboratory and Analytical Studies of Engineering Structures", by Prof. Royston-Jones, of the Engineering Department, and "Classification of Black and Grey Clays of Ghana using the New U.S. System" presented by three workers led by Mr. H. B. Obeng, of the Scientific Services.

The closing address to round off the conference was given by Mr. H. O. Walker, former chief meteorologist, who made special mention of the many new Ghanaian scientists.

Arrangements are being made to publish the proceedings of the conference in the new scientific journal of the Association. J. Yanney Wilson

SATELLITES AND GEODESY

On March 24, 1961, the Royal Astronomical Society held, at its rooms in Burlington House, a geophysical discussion on "Technique of Optical Observations". The chairman for the meeting was Dr. A. H. Cook (National Physical Laboratory), who opened by remarking that the exploration of the major feature of the Earth's gravitational potential by the conventional methods of geodesy was a topic which had often been discussed at meetings of the Society. This meeting, however, would be concerned rather with the elucidation of small-scale features and the use of observations of Earth satellite positions for this purpose.

The discussion was opened by short papers from four speakers, of whom the first was Brigadier G. Bomford. Geodesists had no difficulty, he said, in deriving the size, latitude and longitude and an appropriate geoid for a piece of land, using a variety of well-known astronomical measurements. The problem was to relate the resulting co-ordinate systems for two or more land masses which were separated by a wide sea. If there were no gaps of more than, say, 500 miles to be spanned, the land masses might be connected in latitude and longitude by radar, but this would not connect the two geoids.

However, the problem might be solved by a sufficient number of simultaneous observations of the position of a satellite from each of the land masses to be connected. It was possible that non-simultaneous non-overlapping observations might be used, but this might also assume a knowledge of the geoid. Brigadier Bomford suggested that such observations would need, in order to be useful, to lead to measurements of position with an accuracy of 30 miles in a horizontal and 10 miles in a vertical direction. Connexions of this kind were required, for example, between Europe and America, across the Mediterranean and between many separated land masses in and around the Pacific.

Dr. R. d'E. Atkinson (Nautical Almanack Office) discussed the astrometric techniques which might be employed, of which there were several. One of the most convenient required the satellite to emit bright, short-duration flashes of light, which would then be photographed against the stars using a camera with an equatorial drive. If the stations were at known longitudes and latitudes, then the time of the flash was in general determined, but if longitude errors in the positions were to be taken out, a timing system with an accuracy of 1 msec. was required.

In this way, accuracies in the star positions of 0·05″ could be obtained, but this was because the long exposure reduced errors due to 'seeing' (that is, irregular variations in tropospheric refraction). At low altitudes this effect might be very important and unfortunately connexions over long distances would usually involve large zenith distances. Thus, at a zenith distance of 70° in a particular case, he had found that 'seeing' increased the angular diameter of the image from 2″ to 4·8″, suggesting that the probable error of a single observation of a satellite might be 2″, equivalent to perhaps ± 60 miles in position. But with multiple observations there would be an improvement.

Alternatively, the conventional method of observing a satellite by reflected sunlight could be used, the observations being made by means of a camera having a shutter which would make timed breaks in the trail. This would be nearly as accurate. The principal problem in this case was to obtain east–west connexions over long distances, as each of the stations could not then be in the dark.

The third paper was read by Dr. A. P. Willmore (University College, London), who pointed out that a principal instrumental difficulty in making optical observations of satellite positions arose from the fact that, viewed from a point on the Earth's surface, a satellite moves with an angular velocity which is neither constant nor accurately predictable. The problem was then to obtain a sufficient exposure to record its position. The sensitivity of a detecting system might in general be limited in any of three ways: by the necessity for recording at least a few photon events in each image element, by statistical fluctuations in the background due to the night sky or by system noise (such as chemical fog, in the case of a photographic emulsion). When these were examined for any but a rather small optical system, it was found that at the high quantum yields characteristic of a photoelectric detector, the limitation always arose from the night sky background, while at the lower quantum yield of the photographic plate, chemical fog determined the sensitivity. It could be said that the practical limits for stationary detectors were at about mag. 9 for a photographic and mag. 11 for a photoelectric detector. It appeared that by tracking the camera at the predicted angular rate of the satellite, a gain of about mag. 5 could be obtained.

In fact, the only precise tracking system of high sensitivity in operation was photographic. This was operated by the Smithsonian Astrophysical Observatory, using the specially designed Baker–Nunn cameras. These have an *f*/1 Super-Schmidt optical system of 20 in. focal length. The cameras are tracked at the predicted angular rate and satellites at a brightness of mag. 13 have been recorded.

However, systems using photoelectric detectors are being studied actively—one, for example, using image intensification by Prof. J. D. Magee at the Imperial College of Science and Technology, London, and another, using photomultipliers, at University College, London.

The advertised speaker for the last paper, Mr. W. H. Guier (Johns Hopkins University), was unfortunately unable to appear, and his place was taken, at rather short notice, by Dr. G. V. Groves (University College, London). This was an account of a radio system which offered some promise as an alternative to optical observations, namely, that employed in the *Transit* series of satellites. This requires on the satellite two or more high-frequency transmitters, with a very-high-frequency stability over the observing period of several minutes. The frequency of the transmission received at the ground is measured as a function of time. Naturally, it is not constant, but diminishes during the satellite passage, on account of the Doppler shift. The principle of the method can be very roughly described by saying that the total change of frequency during the passage is proportional to the velocity of the satellite, while the maximum rate of change depends both on the velocity and the slant range at closest approach, which can then be determined. It is necessary to make a correction for ionospheric effects, which amount to about 0·2 per cent at 100 Mc./s. They are almost inversely proportional to frequency, and can be calculated if two or more transmitters are used.

The method was first applied with encouraging success to the determination of orbital elements of the first satellites by W. H. Guier *et al.* Later, the transit system was tested in a trajectory determination of an *Atlas* rocket with an apogee height of 700 km. where comparison with a trajectory determined by radar showed differences of a few km., to which the errors of the radar would have contributed.

It has now also been used on the *Transit* 1 satellite. Observations were made at six ground stations in the northern hemisphere, and the orbital elements determined, taking tho observations for one day at a time, by reproducing to the best fit the observed frequency-time curves. It was found possible to obtain the coefficient of the third harmonic in the gravitational potential with an accuracy of about 5 per cent, and since this produces oscillations of about 5 km. amplitude, it was concluded that the accuracy of measurement was 0·5 km. It seems possible that an improvement in accuracy of an order of magnitude should be obtainable, resulting in position measurement with an accuracy of about 50 miles.

It is intended to use the *Transit* satellites for navigation, by storing up-to-date orbital elements on a tape recorder in the satellite. These would be read out on command by the ship and combined with Doppler shift observations to obtain the ship's position. During the ensuing discussion, the importance of this for gravity surveys at sea was mentioned by B. C. Browne (Cambridge), as in such observations a principal difficulty is the determination, with adequate precision, of the ship's position.

A. P. WILLMORE

GEOCHEMICAL EFFECTS OF WEATHERING

A JOINT meeting of the Clay Minerals Group of the Mineralogical Society and the British Society of Soil Science, held in the School of Agriculture, University of Cambridge, during April 6–7, was attended by approximately 100 delegates from home and overseas. At the two paper-reading sessions, the chair was occupied on the afternoon of April 6 by Prof. J. White (Sheffield) and on the morning of April 7 by Dr. H. Greene (Rothamsted Experimental Station). The topic, weathering, was discussed from many points of view (for example, mineralogical, geological, pedological and geochemical) and the conference concluded with the alternative of an excursion led by Mr. C. A. H. Hodge (Rothamsted Experimental Station) to the Brecklands area or informal visits to laboratories of the University.

Prof. C. W. Correns (University of Göttingen), in the introductory paper, outlined the experimental work done on the decomposition of mineral powders by aqueous solutions. Plastic was used in the apparatus and factors such as particle size, rate of flow, temperature, and *p*H of solution were shown to be important in determining the nature of experimental reactions with potash-felspar, albite, leucite, muscovite, tremolite, olivine and sideromelane. The results of recent experiments on the decomposition of kaolinite and montmorillonite at *p*H 7 could be of significance in the origin of bauxite. The main findings of the whole study were summarized by Dr. G. Nagelschmidt (Sheffield) to the effect that in open systems and at low temperatures, minerals tend to decompose as ions with formation of amorphous residual crusts, whereas in closed systems and at high temperatures secondary minerals are formed. He also directed attention to the formation in Nature of pseudomorphs of kaolin after felspar, and Prof. Correns commented that in an open system and over a long period this might be possible.

An experimental study of the geochemical alteration of acidic and basic igneous rocks under varying hydrodynamic and physiochemical conditions was described by Dr. G. Pedro (Versailles). Special attention was paid to the secondary formation of iron and aluminium oxides and hydroxides. The value of the ratio of $SiO_2 : (RO + R_2O)$ was found to be greater in the leachates than in the unaltered rocks. Prof. White expressed surprise at this, but Dr. Pedro thought that it might possibly be explained by the high *p*H in the system. Asked whether trace elements had been determined, Dr. Pedro replied that these results would be available very shortly. After several comments on the alteration products, a delegate described an apparatus made of tin which had been found more successful than glass.

In contrast to these experimental studies, two papers were given on natural weathering. In the first, Dr. W. W. Smith (Macaulay Institute) described the weathering of basalts and dolerites from the south-east of Scotland and the mineralogy of the resultant soils. The relative stabilities of the primary minerals in the fine sands were given, and the secondary weathering products in the rocks and soils were discussed. Contamination by glaciation had to be taken into account. With reference to the quantitative analyses of fine sands by X-ray diffraction, Dr. R. M. S. Perrin (University of Cambridge) stressed that, due to limiting factors in the method, the figures should not be taken as exact and care in interpretation is necessary. In the second paper, Mr. D. F. Ball (Bangor) described a deep profile on the Isle of Rhum in which 50 ft. of weathered gabbro is preserved under glacial drift. A thick reddened zone with high content of free iron oxide was likened to the *B* horizon of a podzol and the whole formation was considered to be a relic of interglacial weathering in a tor-like topography. Mr. L. Berry (University of Khartoum) commented that such red zones, because of their frequent discontinuity, can be difficult to interpret, but the tor-like topography is similar to that produced in humid warm climates. Reference was made by Mr. R. H. S. Robertson (Pitlochry) to red Tertiary interbasaltic weathering. Dr. R. Glentworth (Macaulay Institute) contrasted certain deeply weathered (possibly pre-glacial) granite and basic igneous exposures in Aberdeenshire with the buried parts of a granite stone circle which appear to have weathered 3 in. in approximately 3,000 years.

The usefulness of drainage-water analysis in studying the processes of weathering and soil-formation was illustrated by Dr. Perrin. Care in sampling, a knowledge of hydrology, percolation rate, and possibly composition of rain-water are all necessary and applicable in determining absolute loss of material or relative loss of elements. Instances where such analyses could provide useful information include the movement of iron in ground water gleys, problems in salt-marsh reclamation, the rate of weathering of chalk, and the genesis of soils. In addition, Dr. Perrin related the results of chemical analyses to weathering trends in soils formed on Ordovician shales and many of the interesting points which arose in interpreting these results were discussed. Other comments included one by Dr. P. H. T. Beckett (Oxford) on the relative merits of sampling drainage water or water direct from the profile. Awareness of the statistical significance of all results was stressed.

Dr. G. Rosenthal (Würzburg) considered both theoretical and practical aspects of the weathering of porous materials by freezing, and focused attention on the 'freezing-point depression' of water, which is due mainly to high pressure affected by capillary radius, pore surface area and surface tension, etc. The resistance to freezing of sandstones, roofing tiles, and bricks was noted, and it was found experimentally that the freezing temperature of brick was even lower than expected, due possibly to the inclusion of meta-kaolin with free valence-bonds which could hinder re-orientation of water into ice. Further work on surface effects was urged before tackling rocks. Asked about the effect of ion concentration, Dr. Rosenthal stated that in brick this lowered the freezing point only very slightly, but in soils and clays it would be more important. Calculations for soils would also be complicated by the wide range in pore size, and when dealing with rocks, climatic effects would have to be taken into account.

The origin of English fuller's earths was proposed by Mr. Robertson to be marine rather than volcanic and to be due to a transgression of the sea during the Upper Aptian. The heavy- mineral suite above and below the clay in the Sandgate beds was shown to be derived from the old land surface of the London Platform. Uniformity in composition of various widespread montmorillonite deposits was considered as evidence of similar conditions of formation. In reply to Dr. Nagelschmidt, Mr. Robertson suggested that the seas would have been mainly calcium ion-saturated and that any sodium ions could have been absorbed by the adjacent more porous formations. A possible tie-up in conditions with those in the Piedmont areas of the south-east of the United States was proposed by Dr. A. Muir (Rothamsted Experimental Station) and Dr. Perrin directed attention to the general absence of mica in the fuller's earth deposits.

Finally, two papers were given by Mr. J. E. G. W. Greenwood (Directorate of Overseas Geological Surveys, Tolworth) and by Mr. Berry and Mr. B. P. Ruxton (University of Khartoum) on the weathering of rocks in hot climates. The first showed how the effects of chemical weathering and thermal disintegration on rocks in arid areas can be of significance in the interpretation of aerial photographs. For a variety of igneous and metamorphic rocks, theoretical orders of response to both processes were detailed but disagreed with the observed order since, for example, thermal disintegration is apparently more effective on granite while chemical weathering is more effective on gabbro and diorite. Rock properties such as grain size, jointing, porosity, and texture were shown to have an important influence on weathering processes. In discussion, Mr. Berry advocated experimental work on the effects of thermal disintegration. In the second paper, examples of tropical weathering of granite in humid, monsoonal, semi-arid, and arid climates were chosen to illustrate different weathering features. Generally, factors such as topography, rainfall, and ground water movement were shown to influence profile development. Illustrations included photographs of 'abandoned' hills and foothill zones of laterization and intense weathering.

During the excursion to Breckland, a series of three soils developed from Gipping Till was demonstrated. The first, a very shallow rendzina, was seen at Lakenheath Warren. The other two, situated within Forestry Commission woodland, were a brown calcareous soil and a brown earth with textural *B* horizon at 95 cm. Although time was too short for a visit to a fourth profile, it was obvious that the afternoon trip had provided adequate food for thought.

The symposium, as a whole, was commendable for the wide scope given to the discussion of weathering. The importance of laboratory experiments as an aid to elucidating problems in the field was emphasized, and among recommendations during discussion were included care in choice of apparatus. methods of sampling, and assessment of significance of results. Undoubtedly, the possibilities of future research in the field of weathering are enormous.

WILMA W. SMITH

THE ARTHUR D. LITTLE RESEARCH INSTITUTE

THE annual report for 1960 of the Arthur D. Little Research Institute* records an average expansion since 1957 of about 20 per cent per annum. Sixty-five per cent of its income comes from industry and 35 per cent from Government and related agencies, about half its sponsors being British and European and the rest American. Practically all the Institute's work is classified as oriented fundamental research, and has so far been predominantly concerned with the chemistry of plant materials. The Biochemistry Section was established in 1960 to undertake the study of biochemical problems where newer techniques, such as starch-gel and high-voltage electrophoresis and paper and column chromatography with automatic densitometry, are already having their impact. Work has been initiated on the separation of the wheat gluten gel complex into its components.

The Organic Chemistry Section continued work on the polymerization of glucose and its derivatives, and already polyamides with viscosities comparable with those of nylon have been obtained using the new technique of interfacial polycondensation. In the work on the chemical modification of wood, a low-temperature catalytic acetylation process gave wood of permanent shrinkage and only slightly improved dimensional stability. Promising results have been obtained by impregnating wood with monomers and polymerizing *in situ*, and attempts have been made to reduce flammability of wood by introducing non-leachable compounds containing phosphorus. Work was initiated on the release of corrosive volatile vapours from wood at high humidity and high ambient temperatures, that is, greater than 40° C., and also to explore the properties of ethylene sulphide.

In physical chemistry, the Polymer Section continued to study the bulk properties of polyolefins, particularly the kinetics of crystallization of polyethylene, with the view of obtaining a better understanding of the effect of crystal structure on the physical properties, and has shown that the initial crystallization behaviour depends markedly on molecular weight. Work was also commenced on the kinetics of the reaction between molten aluminium and water.

The Metallurgy Section completed a three-year study of corrosion involving the screening of 470 organic compounds, to ascertain any correlation between chemical structure and inhibitory power, and although no clear-cut correlation emerged, some compounds were found to favour the inhibition of corrosion of mild steel and cast iron in acid solution while others opposed inhibition. A study of the hydrogen embrittlement of certain steels is planned. A list of publications of the Institute is appended with abstracts of those published in 1960.

THE WOOL INDUSTRIES RESEARCH ASSOCIATION

IN addressing the forty-second annual general meeting of the Wool Industries Research Association on April 19, the chairman of the Association, Mr. B. A. Smith, after referring to the opening of the new Worsted Processing Block at Torridon on March 22 (see *Nature*, 190, 313; 1961) by the Right Hon. R. G. Menzies, stressed the need for more research and technical education in the industry. The Association was just ending a quinquennial period in which the grant from the Department of Scientific and Industrial Research had been based on £170,000 of industrial income; under the new £70,000 arrangements this grant would be £59,000 on £170,000 of industrial income, but with a further £75 for every £100 supplied by industry up to a total of £25,000, and Mr. Smith asked for support for any proposal in the near future for an increase in levy.

The report of the director of research, Dr. A. B. D. Cassie, for 1960* refers to progress in constructing an apparatus for the automatic quantitative analysis of mixtures of amino-acids by separating them on a cationic exchange–resin column, converting to copper complexes, and determining the copper content polarographically. Excellent results have been obtained in the automatic assay of basic amino-acids, but citrate buffers cannot be used for chromatography because of the formation of copper-citrate complexes, and new buffer systems are being developed for amino-acid separation. Several protein components of oxidized wool have been isolated by percolating columns of the material with 5 *M* urea solution, gradually changing in *p*H from 3·0 to 5·8, and determinations by Sanger's method of the N-terminal groups of the components isolated from wool following treatment with acid gave average chain-weights of 96,500 and 20,500 for component I and component III, respectively.

Search for a method of determining the moisture content of raw wool continued, and a general survey being made of the diffusion constants of a wide range of organic molecules, from toluene and benzyl alcohol to a non-ionic detergent of mol. wt. 558, indicates that the mobility of a molecule in keratin depends more on its hydrophobic–hydrophilic balance than its size. Work completed on the breaking-time and dynamic elastic modulus of nylon confirms that changes in moisture content affect both the elastic properties and the strength of the structural elements as well as the internal viscosity.

Recent work has shown that at least one of the causes of yellowing of woollen yarn on storage is the presence in the olein of small amounts of polyunsaturated acids: linolenic acid causes permanent yellowing, but the effect of linoleic acid is less important, while pure oleic acid has little deleterious action. Laboratory and works trials have shown that the moth-proofing agent 'Dielmoth' can be applied to worsted yarn during normal bleaching processes, but the treated yarn had only poor washing fastness. Fabric construction has been shown to play an important part in the production of fabrics with durable pleats or creases.

THE BENGUELA CURRENT

IN 1953 two interesting articles appeared in *Nature*. The first was by Currie[1] and described the process of upwelling in the Benguela current. He showed that in addition to the upwelling inshore, a convection cell develops at the edge of the continental shelf which separates the cold upwelled waters from the warm oceanic waters further out to sea. This line of demarcation is used in a recent report* to define clearly what is meant by the Benguela current: "We have restricted the use of the name Benguela current to the coastal circulation in which upwelling movements occur and have referred to the oceanic circulation as the 'south-east trade wind drift'."

The second article was by Hart[2] and dealt with the preliminary results of the phytoplankton surveys. He stressed the distinction between oceanic species of the south-east trade-wind drift and the coastal forms in the rich upwelled waters. In the latter he introduced the new conception of ageing of upwelled water, by which was meant the succession of species as the characteristics of the water mass change.

In the present report the two authors have enlarged on these preliminary findings. New data on winds, surface drift, bottom topography, water temperatures, salinities, dissolved oxygen, phosphate and the species composition, density and distribution of the microplankton have been analysed and co-ordinated to form an impressive picture of the oceanography of the seas off south-west Africa.

After summarizing the results of earlier investigations, the two cruises of R.R.S. *William Scoresby* off south-west Africa are described. The first was in the southern autumn (March 3–14, 1950) and the second was in spring (September 21–October 12). They go on to show that the winds are the driving force behind the currents. Off the shelf, the south-east trades cause a drift which Defant[3] has shown to be north-north-west, parallel to the coast. Nearer the coast and on the shelf itself, there are coastal winds which are mainly south-south-west and these induce a current away from the shore and upwelling results. Many charts and sections show that this upwelled water differs from the oceanic water in temperature, salinity, dissolved oxygen and phosphate concentration. In spite of complexities due to swirls and interlocking tongues of water, the dividing line lies approximately over the edge of the continental shelf. Moreover, the vertical sections show clearly that on this line the isotherms and isohalines above the 300-m. level have an upward kink and that water from the 200–300-m. level reaches the surface inshore. The kink in the isotherms is the result of the convection cell which separates the two water masses and is well illustrated in a section which shows the distribution of the anomaly of specific volume off the mouth of the Orange River during the spring survey when active upwelling was in progress. It is suggested that conditions in the Benguela current are similar to those in upwelled waters off California where Sverdrup[4] has described a similar convection cell.

The evidence that the upwelled water comes from the 200–300-m. level denies once and for all the vague idea that the Antarctic intermediate current is concerned, for the latter lies at the 600–800-m. level. The water at the 200–300-m. level is part of the South Atlantic central water and its origin is controversial. Possibly it is the result of sinking at the sub-tropical convergence. Off south-west Africa there is a general movement to north-north-west at this level, but there are also indications, based on admittedly slender evidence, of a southerly movement along the edge of the shelf. "It is postulated that this is a compensatory movement replacing the water which has been drawn up to the surface inshore and we have therefore called it the compensation current." Vertical sections of salinity, temperature and phosphate show no discrete body of water at this level, nor is the existence of this southerly current essential to the main argument, and I doubt its existence. Indeed, the distribution of the oxygen minimum layer in the South Atlantic shown in Fig. 47 is more readily understandable as a north-westerly drift of the products of decay from the highly productive areas off south-west Africa.

The second part of the report deals with the microplankton as sampled by *N.50.V.* nets. The bulk of the catch was diatoms and peridinians. After dealing with the vexed question of terminology in which the term 'panthallassic' is revived to cover species which at different times are both neritic and oceanic, the authors give a full list of the species identified and select from this the dominants for further discussion. Their distribution is charted and their density discussed in relation to distance from the shore. In broad outline they found a dense growth of chætocerids and some other neritic species in the area of upwelling, a scant growth of *Planktoniella sol* and other oceanic forms off the shelf and a poor flora of panthallassic species in between. It is stressed that the many differences between the spring and autumn surveys may not be purely seasonal effects but the result of ageing of upwelled waters: "The more extensive coastal production in autumn (survey 1) with numerous resting spores of the dominant chætocerids is thought to represent a late stage in the succession of waters earlier enriched by upwelling . . . the succession may be repeated several times annually." This section ends with valuable notes on the ecology and distribution of the more important species and most ecologists would agree with the final warning that it is not the presence or absence of a particular species which defines a particular water mass but the differing proportions of the species within them. Statistical methods for the discrimination of floristic groups are now being developed.

Finally, the authors come to the controversial question of the mass mortality of fish in the Walvis Bay area and the cause of the anaerobic deposits which extend along the shelf for some 400 miles.

---

* Discovery Reports, Vol. XXXI. *The Benguela Current*. By T. John Hart and Ronald I. Currie. Pp. 123–298. (Cambridge: At the University Press, 1960.) 75*s.* net.

Brongersma-Sanders[5] has suggested that the mass mortality is due to poisonous blooms of dinoflagellates such as *Gymnodinium*, but this is discounted. It is argued that the decay of dense plankton on the shelf leads to a depletion of oxygen at the lower levels. Under normal meteorological conditions the currents bring in new supplies of oxygenated water, but during periods of calm, stagnation occurs and anaerobic conditions develop at the bottom which favour the growth of sulphate-reducing bacteria and the evolution of poisonous sulphuretted hydrogen. Oxygen depletion actually extends to the surface inshore and there are press reports from Swakopmund of the sea bubbling with hydrogen sulphide and mud islands rising to the surface. This, the authors infer, is the cause of the mass mortalities of fish, and certainly their meteorological evidence and vertical sections of dissolved oxygen tie in neatly with the theory.

The authors have shown that the Benguela is one of the richest currents in the oceans of the world. This impressive report provides a firm basis for its further study.

NATIONAL FORESTS OF AGRICULTURAL CROPS FOR THE WET HUMID TROPICS

By ANTONY SANTIAGO
c/o Department of Agriculture, Malaya

THE natural vegetation of the wet humid tropics consists of extensive forests of large and valuable timber trees. These large trees are of paramount importance in protecting the soil of the hillsides from erosion and its consequences, and they make the best use of the leached and acidic soils commonly found in the wet humid tropics. This forest of large trees has been, and is being, selectively destroyed to make way for 'planned forests' of agricultural crops such as rubber and oil palm, which are also able to make good use of such soils. There has been, however, a certain amount of misuse of such land in certain areas where food crops, mostly annuals, such as vegetables and short-lived perennials, such as papayas, have been cultivated. Such crops do not provide adequate cover to the soil, which is exposed to the elements and gives rise to serious soil erosion and unproductivity of the land. Such land has often been abandoned to fallow, and a system of shifting cultivation has been practised.

An ecological and economic study of the wet humid forests of certain agriculturally important large tree crops will show that there is a definite place for developing national forests of certain agricultural crops, which can grow under semi-wild conditions and which need occasional attention for satisfactory growth and crop-production. In Malaya, such agricultural crops are *Durio*, *Nephelium*, *Bertholletia*, *Garcinia*, *Lansium*, *Baccaurea* and *Metroxylon* species.

Most of the tree crops mentioned have the following characteristics :

(*a*) A number of them to this day is grown successfully under semi-wild conditions, and it is doubtful whether it is more economical to grow them under refined cultural techniques.

(*b*) The trees grow to a large size and would function effectively as binders of the soil and efficient utilizers of leached and acidic soils, as the natural forest-trees do.

(*c*) It is questionable whether such crops should be grown by smallholders who have only small pieces of land.

(*d*) The trees take 7–15 yr. to mature and are therefore not ideal for smallholders who lack capital for growing perennial crops. On the other hand, perennial crops are ideal from the point of view of the little work required to maintain crop production.

(*e*) The trees are seasonal in bearing, although there is one season of heavy bearing and another negligibly light one annually.

(*f*) There is negligible damage done to the trees in the process of harvesting the produce and is unlike rubber-tapping, which is done daily, and where inexperienced labourers can damage the trees permanently.

Therefore seasonality of fruiting, semi-wild conditions of growth to large trees and negligible damage done to such trees during the harvest provide conditions which not only find employment for labour that is occasionally unemployed at certain times of the year in the country, and prevent erosion of soil which is a national asset, but also permit the public to harvest the produce on annual lease, which can be called by tender.

Some of these trees have good durable timber, and should the trees go out of production (and this will only occur after several decades) the timber produced would give some remuneration.

At this point a question may be raised about finding planting material and the need for ensuring that planted trees bear high quality and quantity of produce. This is possible by adopting the following theoretically sound but yet unproved technique :

Seeds from trees selected for quality and quantity of produce will, in most cases, be satisfactory as planting material since this technique is practised to this very day in most of these tree crops. However, the individuals will vary in quality and quantity of the produce. In order to minimize the variability it is suggested that in planting the seedlings, twice or thrice the usual number of plants, at closer spacing, can be planted within a unit area, so that it would be possible to destroy progressively half the number of the poorer trees within a unit area, from the time the trees start bearing, to permit good growth of the remaining better trees.

By these methods, therefore, it is theoretically possible to create national forests of agricultural crops in the wet humid tropics where large acreages are still under forests. However, capital will be the problem and this may be found should the national policy-makers be convinced that the idea of national forests of agricultural crops in the wet humid tropics is sound not only theoretically but also practically.

GAS-LIQUID CHROMATOGRAPHY OF STEROL METHYL ETHERS

By R. B. CLAYTON

Conant Chemical Laboratories, Harvard University

SEVERAL reports have appeared recently of the separation of sterols and steroids by gas-liquid chromatography on a variety of liquid phases[1-4]. Up to the present time, however, no correlation has been reported between the structures of steroids and their behaviour on the gas-liquid chromatogram which might allow an accurate prediction of retention times on the basis of molecular structure[5]. Such a correlation is being attempted with the methyl ethers of neutral sterols chromatographed on polyethylene glycol succinate as the liquid phase and some preliminary findings are discussed here.

Preparation of sterol methyl ethers on a 'micro' scale (5–500γ) was carried out in 78–90 per cent yield by reaction of the sterols or their esters with methyl iodide in ether solution in the presence of potassium *t*-butoxide.

Gas-liquid chromatography was carried out using 6 ft. × 4 mm. metal columns packed with 5 per cent polyethylene glycol succinate on 'Chromosorb *W*'. The column was conditioned at 202° for 48 hr. with a slow argon flow. Operating conditions were: column 195°, vaporizer 350°, ionization detector 212°. Gas flow: 220 c.c. per min. (argon). Retention times, tabulated below, are relative to that of cholestane (retention time, 8·5 min.).

The values recorded in Table 1 show that good separations can be achieved with a number of sterols of biochemical interest and with retention times usually between 30 and 60 min. The technique has been applied to the analysis of sterols and their esters isolated from tissues by established methods.

Table 1. RELATIVE RETENTION TIMES OF STEROLS AS METHYL ETHER

	Cholestane	1·00	XVIII	$\Delta^{7,22}$-Ergostadienol	5·55
I	Cholestanol	3·60	XIX	$\Delta^{5,7}$-Ergostadienol	7·30
II	epi-Cholestanol	2·61	XX	$\Delta^{5,7,22}$-Ergostatrienol	6·52
III	Coprostanol	2·36	XXI	$\Delta^{5,24(28)}$-Ergostadienol	6·08
IV	epi-Coprostanol	3·08	XXII	Stigmastanol	6·03
V	Cholesterol	3·90	XXIII	Δ^5-Stigmastenol	6·60
VI	Δ^6-Cholestenol	4·15	XXIV	$\Delta^{5,22}$-Stigmastadienol	5·80
VII	Δ^7-Cholestenol	4·70	XXV	$\Delta^{5,24(28)}$-Stigmastadienol	7·86
VIII	Δ^8-Cholestenol	3·88	XXVI	Δ^{22}-Stigmastenol	5·40
IX	$\Delta^{8(14)}$-Cholestenol	3·73	XXVII	Lanosterol	5·32
X	$\Delta^{8,14}$-Cholestadienol	4·56	XXVIII	24,25-Dihydrolanosterol	4·00
XI	$\Delta^{5,22}$-Cholestadienol	3·83	XXIX	Agnosterol	5·60
XII	$\Delta^{5,7}$-Cholestadienol	5·50			
XIII	$\Delta^{5,24}$-Cholestadienol	5·40			
XIV	Ergostanol	4·81			
XV	Δ^5-Ergostenol	5·12			
XVI	$\Delta^{5,22}$-Ergostadienol	4·43			
XVII	Δ^7-Ergostenol	6·05			

The values shown in Table 1 are most readily interpreted in terms of the operation of three distinct factors: (1) the molecular weight; (2) the polarity; and (3) a 'conformational restriction' factor. These are considered in turn.

(1) *Molecular weight.* The stanols I, XIV. XXII form a series in which the increase in relative retention time is proportionate to the increase in molecular weight. They deviate from the log relationship of true homologous series[6].

(2) *Polarity.* The simplest polarity effects (analogous to those found in adsorption chromatography) are seen in comparing the stanols I and III with their epimers II and IV respectively. Clearly, the more hindered, axial orientation of the three methoxyl group renders the compound more mobile than its epimer in which this group is equatorial. In certain circumstances the weight and polarity factors can largely offset each other. The 4 : 4-dimethyl grouping of XXVII, XXVIII and XXIX (C_{30}) is well known to hinder the 3β oxygen function. Hence these compounds have greater mobilities than XXII (C_{29}).

Compounds having olefinic bonds in the nucleus show greater retention times than their parent stanols. The Δ^7-bond exerts the greatest effect (cf. I and VII, XIV and XVII) of any isolated double bond so far studied. The homoannular, 5,7-diene increases the retention time still further (cf. I and XII, XIV and XIX).

Table 2. RETENTION RATIOS FOR UNSATURATED STRUCTURES OF DIFFERENT MOLECULAR WEIGHT

Retention ratio*	Cholestanol	Ergostanol	Stigmastanol	Lanostanol
Δ^7/stanol	1·3	1·26	+	+
$\Delta^{5,7}$/stanol	1·52	1·52	+	+
$\Delta^{5,7}/\Delta^7$	1·17	1·2	+	+
Δ^5/stanol	1·08	1·07	1·09	+
$\Delta^{5,22}/\Delta^5$	0·98	0·87	0·88	+
$\Delta^{5,7,22}/\Delta^{5,7}$	+	0·89	+	+
Δ^{22}/stanol	+	+	0·90	+
$\Delta^{8,24}/\Delta^8$	+	+	+	1·33
$\Delta^{5,24}/\Delta^5$	1·38	+	+	+
$\Delta^{5,24(28)}/\Delta^5$	+	1·18	1·19	+

$$* \text{ Retention ratio} = \frac{\text{relative retention time of compound with } \Delta^x}{\text{relative retention time of analogue lacking } \Delta^x}$$

+ Compounds necessary for comparison not available.

Table 2 lists the ratios ('retention ratios') of the relative retention times of various compounds having certain features of unsaturation to those of their analogues which lack these features. These results show that the introduction of an isolated double bond, Δ^x, into a stanol, s, will change its relative retention time, r_s, to a new value $r_{(s+x)}$, according to the relationship:

$$r_{(s+x)} = r_s \times k_x$$

where k_x is a constant ('retention constant') for the double bond in position x, which is virtually independent of molecular weight. Further, for two non-interacting double bonds at positions x and y (for example, Δ^7 and Δ^{22} in the ergostane series) the relative retention time of the new $\Delta^{x,y}$-dienol is given by:

$$r_{(s+x+y)} = r_s \times k_x \times k_y$$

It is apparent that the 5,7-diene must be treated as a unit system in these calculations and the contribution of the Δ^{22}-bond shows an anomaly which is discussed below.

(3) '*Conformational restriction*'. Double bonds originating at C_{24} in the side-chain raise the retention time considerably, but the Δ^{22}-bond fails to increase the retention time. A scarcely measurable negative effect is seen in the cholestane series (V and XI), but in the ergostane and sitostane series the presence of a double bond at C_{22} markedly reduces the retention time. This apparent anomaly becomes intelligible from an examination of molecular models. In compounds without substitutents at C_{24}, the Δ^{22}-bond only slightly restricts the movement of the side-chain, whereas in C_{24}-substituted compounds this restriction is far more pronounced. Such a restriction could lead to some curtailment of solute-solvent interaction and prevent the dissipation of thermal energy in certain modes of intramolecular vibrations which

are available when the side-chain is saturated and hence less restricted. These effects would tend to increase the mobility of these compounds and apparently are great enough to overcome the opposing polarity effect of the Δ^{22}-bond. In Δ^{22}-cholesterol, it must be assumed that the restriction imposed on the side-chain approximately cancels out the increase in polarity which the additional double bond might otherwise confer on cholesterol.

Probably a similar conformational restriction is responsible for the difference between the retention times of cholestanol (I) and epi-coprostanol (IV).

It appears that some advance is being made in this work towards a rationalization of the behaviour of polycyclic compounds on the gas-liquid chromatogram. The concept of 'retention constants' for variously situated functional groups, such as those derived for the double bonds in this work, is an attractive one and may be of considerable practical and theoretical value. However, such constants obviously can only be used with scrupulous attention to the details of the intramolecular environment of the functional groups in question. Moreover, the influence, if any, of the nature of the liquid phase on the values of these constants remains to be determined.

I wish to thank Prof. Konrad Bloch for his interest in this work, which was supported by a grant from the American Heart Association and was conducted during tenure of an established investigatorship of the American Heart Association.

THE 'LAG-PHASE' IN SALT UPTAKE OF STORAGE TISSUE

By R. F. M. VAN STEVENINCK

Department of Botany, King's College, University of London

WHEN various dormant storage tissues are washed in aerated water, a characteristic delay in the generation of an absorption capacity occurs for which a wide variety of explanations has been offered. Rees and Skelding[1] suggested that a specific water-soluble inhibitor was present in the tissue which would prevent salt absorption until it had been leached from the tissue. In a later publication, Skelding[2] further supported this view and suggested that the inhibitory substance was formed by dark fixation of accumulated respiratory carbon dioxide. An alternative view, that salt uptake was stimulated as a result of continuous removal of electrolytes from the washed tissue, has been quite persistent[3–5], but was recently disproved by MacDonald *et al.*[6].

Unfortunately, the matter at issue is confounded by the consistent use of tap water, which may vary widely in its mineral contents, and in which the calcium ions present have the property of reducing leakage[7,8]. Dale and Sutcliffe[9], finding that certain organic acids, and also beetroot extracts containing the same organic acids, would stimulate potassium uptake of disks of beetroot tissue washed for a relatively short period (48 hr.), claimed that the lag-phase in potassium uptake was an artefact, and merely a reflexion of a time lag in the development of a chloride accumulatory system. Their results, however, showed that disks which had been washed for 2 hr. could not be stimulated. Probably the most predominant contention at present is that the lag-phase is a period during which a gradual revival of metabolic activity provides the energy required for the formation or activation of carrier molecules participating in the accumulation process[10,11], or for the protein synthesis which is thought by Steward *et al.*[12,13] to be the first requirement for salt uptake.

During the course of testing various compounds for their effect on the lag-phase of beetroot tissue, it was found that 2-amino-2(hydroxymethyl)-propane-1 : 3-diol (*tris*-(hydroxymethyl)aminomethane, or *tris*) had the remarkable property of inducing a rapid rate of uptake of potassium ions immediately after cutting the disks of tissue.

Disks of beetroot (var. Crimson Globe) prepared in the usual manner (15 mm. diameter, 1 mm. thick, average weight approximately 180 mgm.), were rapidly washed in three rinses of distilled water to remove materials released from the cut cells before commencing the experimental treatment. Batches of 25 disks (4·5 gm.) were added to each of the 150 ml. of aerated solutions to be tested, kept in 200-ml. boiling tubes and placed in a thermostat. Each treatment was done at least in triplicate. *Tris* solutions were adjusted to the required *p*H with hydrochloric acid. At required intervals, 5-ml. samples of the solutions were drawn off, and replaced by an equal volume of the original solutions, which caused a negligible change in salt concentration. Potassium and sodium contents were determined with an *EEL* flame photometer. The technique is based on the principle that changes in the absorptive capacity of the tissue are detected much more easily at very low than at high salt concentrations.

Fig. 1,*A* and *B* include typical curves for the potassium ion content of the external solution when disks of beetroot were incubated in distilled water. An initial rapid rise of potassium ions in the solution must be expected to originate from the apparent free space and Donnan free space of the tissue. However. an equilibrium should have been reached within the first hour[14], and the continued leaching of potassium ions up to 16 hr. must come from other sources, most likely the cytoplasm and/or the vacuole. The subsequent slow loss of potassium ions from the external solution occurred in the majority of cases; however, with quite a few roots, especially the older ones, leakage surpassed absorption at this stage, resulting in a net loss of potassium ions from the tissue. A marked change always set in at approximately 30–40 hr. from the start of the experiment, resulting in a period of rapid absorption, quite often causing the concentration of potassium ions of the external

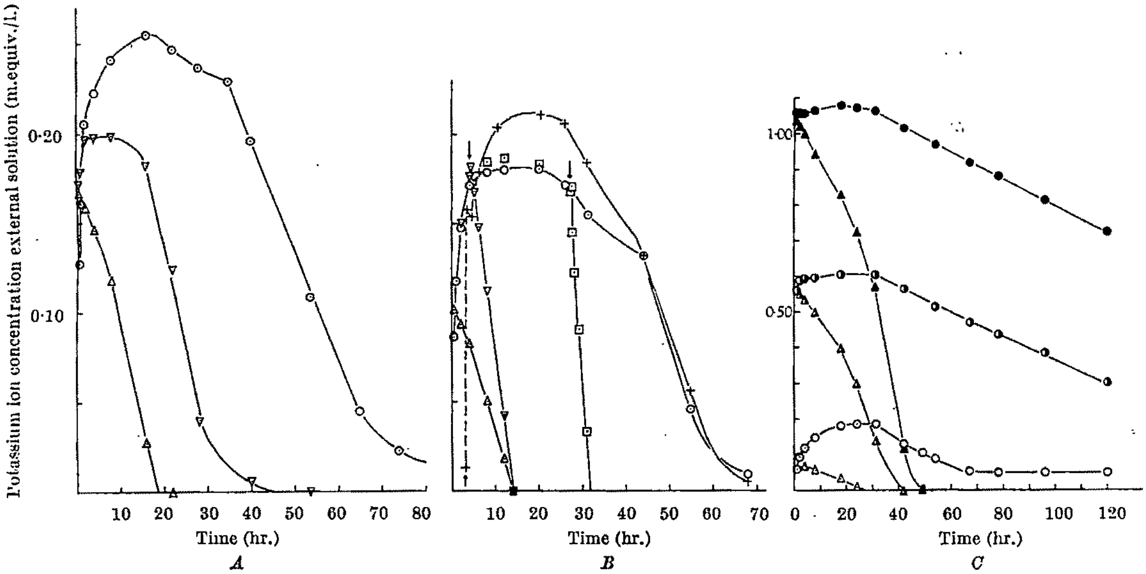

Fig. 1 *A*, *B* and *C*. Potassium ion content of the external solution (m.equiv./l.) due to leaching and subsequent re-absorption of calcium ions by red beet slices. *A*: ⊙, distilled water *p*H 6·3–6·4; △, 10^{-2} *M tris* *p*H 7·9–8·0; ▽, 10^{-2} *M tris* *p*H 6·0–6·3. Temp. 20° C. *B*: ⊙, distilled water *p*H 6·2–6·5; △, 10^{-2} *M tris* *p*H 7·9–8·0; ▽, 10^{-2} *M tris*, 4 hr. from start of experiment, added as 7·5 ml. 2×10^{-1} *M* solution, *p*H 7·85–8·0; ⊡, 10^{-2} *M tris*, 27 hr. from start of experiment, *p*H 8·0; +, 10^{-2} *M tris* for 2 hr., *p*H 8·0, followed by two rinses of ½ hr. duration each (*p*H 6·7 and 6·1, respectively), 1 ml. 0·019 *M* potassium chloride added to make up for lost potassium ions during rinsing of tissue. Temp. 21–22° C. *C*: ⊙, distilled water, *p*H 5·55–6·15; △, 10^{-2} *M tris*, *p*H 7·80–7·95; ◑, $0·5 \times 10^{-3}$ *M* potassium chloride solution, *p*H 5·50–5·95; ◭, $0·5 \times 10^{-3}$ *M* potassium chloride + 10^{-2} *M tris*, *p*H 7·80–7·90; ●, 10^{-3} *M* potassium chloride, *p*H 5·50–6·00; ▲, 10^{-3} *M* potassium chloride + 10^{-2} *M tris*, *p*H 7·50–7·80. Temp. 23° C.

solution to drop to less than 10^{-6} *M*. With an average potassium ion concentration in the tissue of close to 10^{-1} *M*/kgm., this meant that under these experimental conditions accumulation ratios of 10^5 and more were observed for potassium ions, which is much higher than any of the values recently quoted and observed by MacDonald *et al.*[6].

When 10^{-2} *M tris* (*p*H 8·0, adjusted with hydrochloric acid) was applied, more potassium ions appeared in the external solution during the first half-hour; presumably *tris* ions replaced a proportion of the potassium ions in the Donnan free space. However, this was immediately followed by a rapid uptake at a linear rate.

When the *p*H of the *tris* solution was adjusted to 6·0–6·3, leakage continued over a longer period (up to 2 hr.), and *tris* was less effective in reducing the lag-phase. A very similar curve to that at *p*H 6·0–6·3 was obtained when *tris* was applied at 10^{-3} *M* and *p*H 8·0. *Tris* has a pK_a value of 8·14 (ref. 15), and is 98·6 per cent ionic at *p*H 6·3; assuming that the base of *tris* is more effective than its ionic form, the reduced effect of *tris* at *p*H 6·0–6·3 could be ascribed to the lowering of its effective concentration.

Tris added at 4 and 27 hr. respectively from the start of the experiment had an immediate and greatly accelerating effect on uptake apart from freeing some potassium ions of the Donnan free space during the first 10 min. (Fig. 1,*B*). In another treatment, disks were immersed for 2 hr. in *tris* and were then washed with two quick rinses in water. On replacement in water containing potassium ions, equivalent to the amount lost during the rinses, it can be seen (Fig. 1,*B*, curve — + —) that the effect of *tris* on the net influx was not maintained after the *tris* had been washed away.

It yet remained possible that part of the difference between *tris* and control treatments could be due to the presence or absence of suitable anions in the respective solutions. Hence, the results of an experiment in which either $0·5 \times 10^{-3}$ *M* or 10^{-3} *M* potassium chloride was added to the external solutions are presented in Fig. 1,*C*. It can be seen that the presence of an initial amount of potassium chloride had no effect on the length of the lag-phase, or on the rate of uptake in control solutions, while it substantially increased the rate of uptake in the presence of *tris*.

Sharp contrasts were provided by the effect of *tris* on the lag-phase of other tissues (Fig. 2). Although extremely effective on carrot and parsnip tissue, it had no such effect on artichoke, swede, potato and turnip

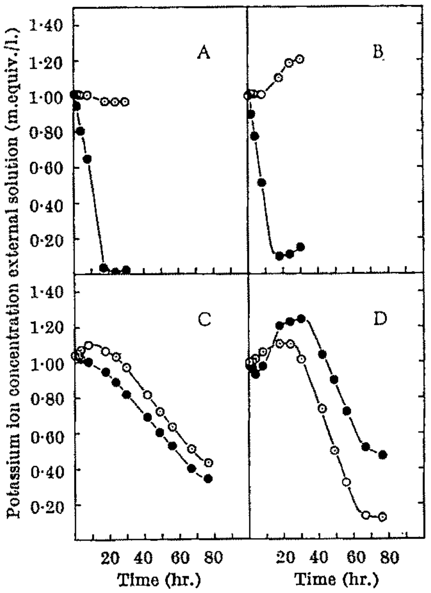

Fig. 2. Change in potassium ion content of the external solution, due to uptake or release of potassium ions at 23° C. by *A*, carrot phlœm tissue; *B*, parsnip phlœm tissue; *C*, artichoke tissue (*Helianthus*); and *D*, swede tissue. ⊙, disks in 10^{-3} *M* potassium chloride solution, *p*H 6·05–6·85, 6·00–6·70, 6·10–7·20 and 6·00–7·10 for *A*, *B* *C* and *D*, respectively; ●, disks in 10^{-3} *M* potassium chloride + 10^{-2} *M tris* solution, *p*H 7·65–7·95, 7·50–7·95, 7·85–8·00 for *A*, *B*, *C* and *D*, respectively

tissue. Hence, the effects of *tris* are quite specific, and in the case of beetroot, parsnip and carrot the characteristics of the molecule seem to fit certain requirements to make a rapid and immediate uptake of potassium ions possible.

Experiments with some readily available analogues of *tris* showed that the presence of OH-groups were essential for activity, *tris*, 2-amino-2-methyl-1 : 3-propanediol, 2-amino-2-methyl-1-propanol and 2-amino-2-methyl-propane (tertiary butylamine) form a series of declining activity (Fig. 3,*A*). In fact, tertiary butylamine had no effect on the lag-phase, and the slightly better intake of potassium ions over the distilled water treatment could have been partly due to the difference in *p*H of the solutions.

Triethanolamine and *tris* were equally effective, indicating that the nature of substituents rather than degree of substitution at the N-level was of prime importance, namely, triethanolamine was much more effective than ethanolamine while N,N-dimethyl-aminoethanol had no effect on the lag-phase (Fig. 3,*B*).

It was observed on an earlier occasion that the addition of 10^{-2} *M* calcium ions shortened the lag-phase to approximately 12 hr.[16]. This effect, rather remarkable in itself, could most probably be related to the so-called 'Viets' effect[17], that is, the stimulation of potassium ion absorption by the presence of moderately high concentrations of calcium ions, which has received considerable attention, because of its rather paradoxical nature[18,19]. Because some relationship might exist between the shortening of the lag-phase induced by the presence of calcium ions and that induced by *tris*, experiments were carried out to study the interaction of these effects. Results presented in Fig. 3,*C* show unequivocally that the effect of calcium ions prevailed when disks were immersed in a mixture of 10^{-2} *M* calcium chloride and 10^{-2} *M tris*, while, on the other hand, additions of 10^{-5}–5×10^{-5} *M* ethylenediaminetetraacetic acid (EDTA) to the medium have consistently produced small but significant enhancements of the *tris* effect (Fig. 3,*C*). Hence, it is feasible that *tris* and calcium ions compete for a common site, the bivalent calcium ions being much more efficient in this respect than the univalent *tris* ions.

The mechanism of the *tris* and calcium effects cannot be defined at present at all closely. It has been shown that calcium ions are essential for membrane formation or maintenance[20], and there is little doubt that the calcium ion status of the membrane plays an important part in the characterization of its physical and chemical properties[21,22]. It would be premature to make a pronouncement whether *tris* operates as a carrier molecule, or indirectly exerts its influence through its adsorption to the membrane structure: however, the absence of a sustained effect when *tris* is removed externally, the fact that calcium ions also can have a shortening effect on the lag-phase, and that *tris* and calcium may compete for a common site in that respect, make the second alternative more likely at present. In the presence of *tris*, accumulation ratios for potassium ions were of the order of 5×10^5, the highest ever observed. Hence, it appears that *tris* caused such change as to facilitate the approach and incorporation of potassium ions from the external solution into the membrane. For example, if a carrier operated across the plasmalemma, it could only be effective as such when the active part of the molecule is exposed at the external side of the membrane. The presence of *tris* may condition the membranes in such a way, possibly through the unfolding or swelling of proteinaceous material[23,24], as to facilitate this exposure. According to Klotz and Ayers[23] suggestions, the latter effect would increase with an increase in *p*H.

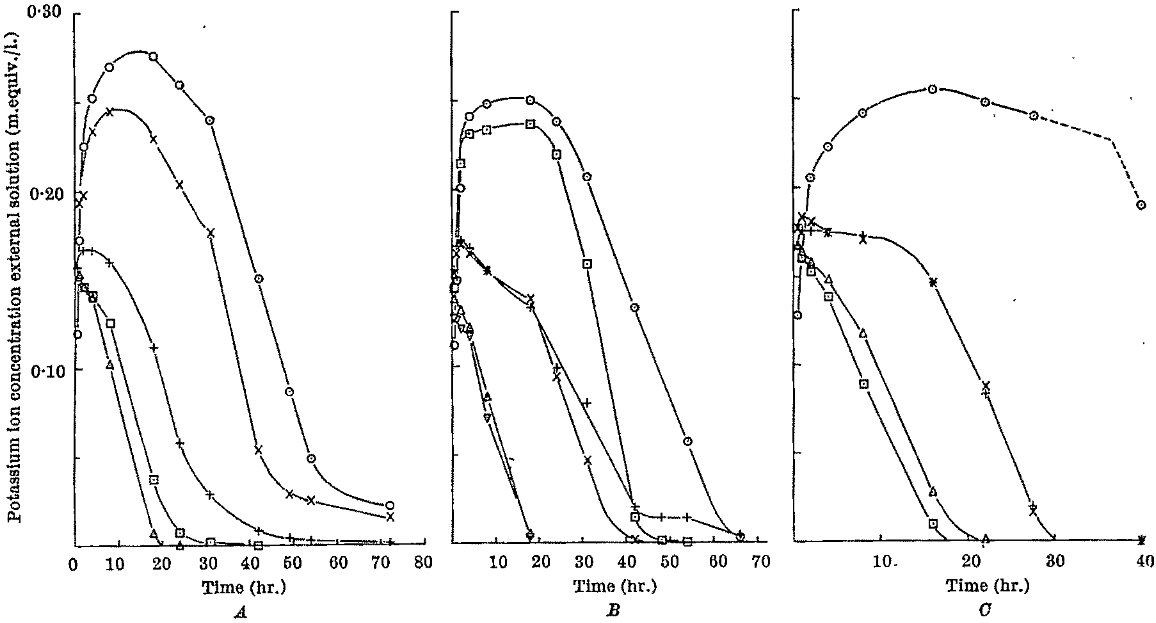

Fig. 3 *A*, *B* and *C*. Potassium ion content of the external solution (m.equiv./l.) due to leaching and subsequent re-absorption of potassium ions by red beet slices at 24° C. *A*: ⊙, distilled water, *p*H 6·35–6·70; △, 10^{-2} *M tris*, *p*H 8·20–8·35; ⊡, 10^{-2} *M* 2-amino-2-methyl 1 : 3 propanediol, *p*H 8·05–8·30; +, 10^{-2} *M* 2-amino-2-methyl 1-propanol, *p*H 8·00–8·10, *p*H adjusted with base during the course of the experiment; ×, 10^{-2} *M* 2-amino-2-methyl propane (tertiary butylamine), *p*H 7·80–7·95, *p*H adjusted with base. *B*: ⊙, distilled water, *p*H 6·25–6·55; △, 10^{-2} *M tris*, *p*H 8·1–8·2; ▽, tri-ethanolamine 10^{-2} *M*, *p*H 7·8–8·2, *p*H adjusted with base during the experiment; ⊡, N,N-di-methyl amino-ethanol 10^{-2} *M*, *p*H 7·8–8·0 (adjusted); ×, methyl amino-ethanol 10^{-2} *M*, *p*H 7·7–8·2 (adjusted); +, ethanolamine 10^{-2} *M*, *p*H 7·4–8·1 (adjusted). *C*: ⊙, distilled water, *p*H 6·3–6·4; △, 10^{-2} *M tris*, *p*H 7·9; +, 10^{-2} *M* calcium chloride, *p*H 8·0 → 7·0 → 7·5 (adjusted with saturated calcium hydroxide); ×, 10^{-2} *M* calcium chloride + 10^{-2} *M tris*, *p*H 7·8; ⊡, 10^{-2} *M tris* + 10^{-5} *M* ethylenediaminetetraacetate, *p*H 7·9

The existing data[25–28] show little effect of *p*H on uptake of potassium ions between 6 and 8 except for Hurd's[29] results, which, however, apply to uptake in aged disks and which show stimulation of uptake at *p*H 8·5. Hurd's results did show the importance of HCO_3^- with aged disks, and he regarded *tris* as an indifferent buffer, which is certainly not true for uptake during the lag-phase.

The present results do not support the views that leaching of inhibitors or of cations are pre-requisites for ion-uptake. Nor do they suggest that accumulation of carrier molecules in metabolism is essential.

I am much indebted to Prof. T. A. Bennet-Clark for his help and encouragement during the course of the investigations. This work was carried out during the tenure of New Zealand National Research Fellowship.

PHAGOCYTIC ACTIVITY IN SQUAMOUS EPITHELIA AND ITS ROLE IN CELLULAR SUSCEPTIBILITY TO FOOT-AND-MOUTH DISEASE

By Dr. H. PLATT

Research Institute (Animal Virus Diseases), Pirbright, Surrey

EXPERIMENTAL foot-and-mouth disease in the guinea pig is characterized by epithelial necrosis, and sometimes vesiculation, of squamous epithelium in certain rather sharply localized regions of the body, of which the buccal mucosa, the prepuce and the hairless parts of the feet are the most consistently involved[1]. Skin-grafting experiments have indicated that the mild environmental trauma to which these sites are constantly exposed plays an important part in rendering them susceptible to the virus, and that it probably does so principally through some direct effect on the epithelial cells[2]. Since this might be effected by an influence on the cell membranes, a study has been made in guinea pigs of the response of squamous epithelial cells in the skin and tongue to inert particles. The purpose of the present article is to report the marked phagocytic activity of injured epithelium, and its relevance to the distribution of lesions in foot-and-mouth disease.

The animals used were albino guinea pigs, weighing 500–600 gm., housed and maintained as previously described[2]. The metatarsal pads, palmar pads of the fore-feet, outer surface of the ear, skin of the flank and margin of the prepuce were inoculated intradermally with 0·02–0·05-ml. volumes of particulate suspensions, or tattooed with a sewing needle through a drop of the material on the epithelial surface. In the metatarsal pads, and in grafts of pad on the chest, injections were made via longitudinal intra-epithelial tracks. Injection of the tongue was done under nembutal anæsthesia, and inocula (0·02–0·05 ml.) were introduced into the corium underlying the dorsal epithelium via the lower surface of the tongue. The materials injected were: (1) indian ink (G. T. Gurr, Ltd.); carbon particle size < 0·5–2·0μ; this was heated for 5–10 min. at 100° before use; (2) a 5 per cent suspension of lamp-black (prepared by combustion of benzene) in reconstituted guinea pig serum; particle size < 0·5–6·0μ; (3) suspensions of ground carmine in reconstituted guinea pig serum; particle size 0·5–3·0μ; (4) saccharated iron oxide ('Colliron'; Evans Medical Supplies, Ltd.). This was injected as a clear solution. In each case, an equal volume of hyaluronidase was usually added (final concentration 75–125 turbidity-reducing units/ml.) but it was not essential. The animals were killed 6–18 hr. later, and their tissues were excised, fixed in 10 per cent neutral formalin or in carnoy, embedded in paraffin wax and sectioned at a thickness of 6μ. Sections were stained with hæmatoxylin and eosin for demonstration of carbon, with hæmatoxylin alone for carmine, or with Perl's method for saccharated iron oxide.

In all sites, a proportion of epithelial cells around the needle tracks had usually phagocytized the inert particles. The reaction was most marked in the apparently undamaged cells surrounding the zone of traumatized and necrotic tissue produced by the needle and sometimes cells up to ½ mm. from the edge of this zone contained particles. Cells from the basal layer to the upper part of the stratum spinosum showed an apparently equal capacity for phagocytosis. The amount of material engulfed varied considerably, from occasional cytoplasmic particles, often lying near the nucleus, to dense aggregates forming nuclear caps (Figs. 1 and 2). All the materials were taken up to some extent but the cells appeared to phagocytize the indian ink and saccharated iron oxide rather more readily than the other suspensions. Intra-epithelial injections in the metatarsal pads were frequently accompanied by some hæmorrhage from the dermal capillaries and, in several instances, free erythrocytes had entered the intercellular spaces of the viable epithelium around the track and been phagocytized by cells of the stratum spinosum. Some cells contained both inert particles and erythrocytes.

At the periphery of some of the inoculation sites (hairy skin, prepuce, fore-feet), where the inoculum was in contact with the basal layer remote from the needle track, cells containing particles were very much rarer. They were mostly basal cells with occasional prickle cells. In the tongue dorsum, there was marked phagocytosis by local basal and spinous cells in areas of the epithelium inadvertently damaged during inoculation, but when the suspensions were injected without epithelial damage, no phagocytosis was found.

These results demonstrate that squamous epithelial cells under the influence of local trauma are capable of considerable cell surface activity. This probably arises through activation of their amœboid mechanisms under the influence of reparative stimuli and local loss of contact inhibition[3,4]. The phagocytic activity of the epithelial cells is thus a reflexion of their cell-membrane instability.

These findings are relevant to the pathogenesis of foot-and-mouth disease, and also possibly other virus diseases in which mild traumatization plays a part in the initiation of infection[5]. In the epithelium of the mouth, feet and other sites, where continual low-grade trauma is experienced, cell-membrane instability is likely to be present in some degree. In addition, the dislocation of intercellular contacts resulting from the mechanical stresses to which these epithelia are exposed may also be expected to increase cell-membrane activity, since cells not making good all-round contact display more active pinocytosis[6]. In regions where these conditions exist therefore, the squamous epithelial cells are more likely to take up small particles such as viruses non-specifically, and the degree of stimulation needed for this may be much less than is required for the uptake of relatively gross particles such as carbon, for which an actual wound appears to be necessary. It is likely, therefore, that the distribution of lesions in foot-and-mouth disease is partly attributable to enhanced cell-membrane activity at the predilection sites, thus facilitating the entry of the virus into the local cells.

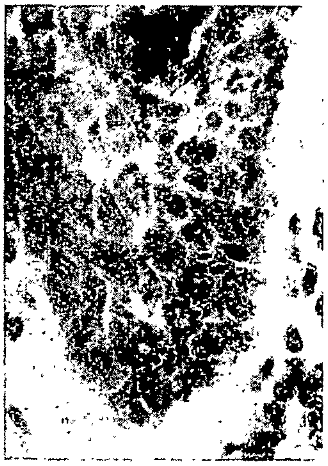

Fig. 1. Metatarsal pad; showing a rete peg with a needle track containing indian ink (above), and phagocytosis of carbon particles by local epidermal cells (hæmatoxylin and eosin, × 500)

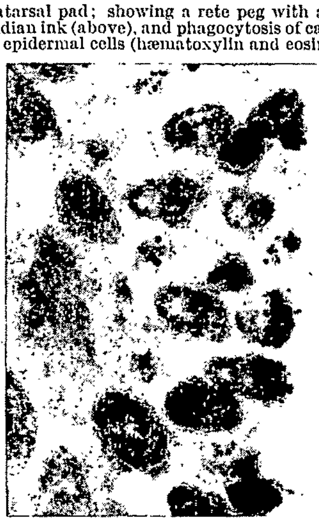

Fig. 2. As Fig. 1; showing dense aggregates of carbon in epidermal cells of a rete peg (× 1,220)

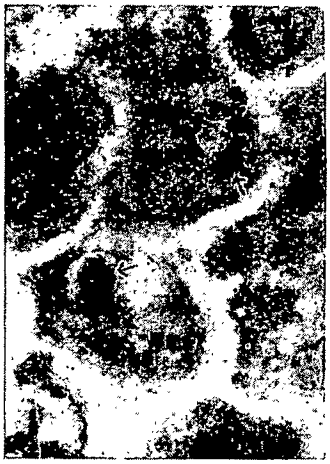

Fig. 3. Metatarsal pad; phagocytized erythrocytes (arrowed) and carbon granules in epidermal cells (hæmatoxylin and eosin, × 900)

The ability of the virus to multiply after cellular penetration presumably depends on highly specific cytochemical conditions within the host cell. In this respect, the cells at the predilection sites appear to provide a more favourable environment for multiplication of the virus than elsewhere in the skin. Thus, injection of foot-and-mouth disease virus directly into the hairy skin of the flank, or into pad grafts on the chest, produces only minimal lesions[1,2], yet the present experiments indicate that virus thus injected would be taken up by local epidermal cells around the puncture. The failure to develop typical lesions suggests that these cells are metabolically insusceptible. The cytochemical conditions necessary for multiplication of foot-and-mouth disease virus are unknown, but it is relevant that cells exhibiting active pinocytosis will take up more nutrients and fluid than their less-active neighbours[6]. Reparative influences may also play some part in determining metabolic patterns favourable to multiplication of the virus in areas of skin and mucous membrane exposed to persistent traumatization.

I wish to thank Messrs. J. R. P. Dale and R. R. H. Hill for their valuable assistance in the course of this work.

THE NUCLEOLUS

Formation of the Nucleolus in Animal Cells

In most animal cells the nucleoli disappear as visible entities during the early stages of mitosis and reappear in the daughter cells when mitosis is completed. The question arises whether the nucleolar material, which is for the most part protein, is synthesized *de novo* after mitosis, or whether it is dispersed at the beginning of mitosis without being degraded and reassembled when mitosis is at an end. In the present article an experiment is described which partially resolves this question for one cell type: the connective tissue cell of the rat.

Dispersed cultures of connective tissue cells were prepared from rat hearts and cultivated in small coverslip chambers[1]. If such cells are incubated for 30–60 min. in medium containing tritium-labelled valine and autoradiographs of the fixed preparations are made, the nucleoli in almost all the cells can be seen to be heavily labelled. (Tritium-labelled valine was prepared by an exchange reaction between tritium gas and the vapour of an ethyl ester of valine on a platinized platinum electrode at 50° C.[2]. The purified compound had a specific activity of 1·5 c./m.-mole.) It has been shown that in these cells exogenous valine is not converted to any significant extent to other compounds but is incorporated almost entirely into the valine residues of protein[3]. The autoradiographs therefore reflect the distribution of radioactive valine which has been incorporated into the proteins of the cell. Amino-acids incorporated in this way are released only very slowly over several days and thus form a relatively stable label for protein. When cells which had been incubated in the presence of radioactive valine are transferred to non-radioactive medium containing unlabelled valine, the specific activity of the valine in the free amino-acid pool of the cells falls within half an hour to negligible levels. Therefore, if cells which have been exposed to tritium-labelled valine are transferred to non-radioactive medium containing unlabelled valine and incubated in this medium until they have all undergone mitosis, autoradiographs of the daughter cells should show unlabelled nucleoli if the nucleolar protein is synthesized *de novo* from free amino-acids immediately after mitosis, and labelled nucleoli if the reappearance of these structures after mitosis involves the aggregation of material which was synthesized earlier.

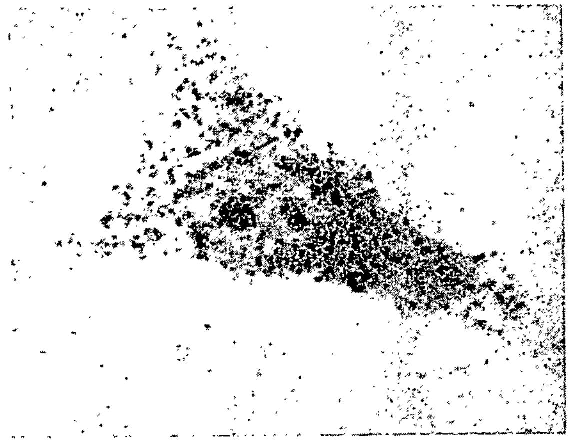

Fig. 1. Autoradiograph of a connective tissue cell incubated for 1 hr. in medium containing tritium-labelled valine. Note the heavy labelling over the nucleoli

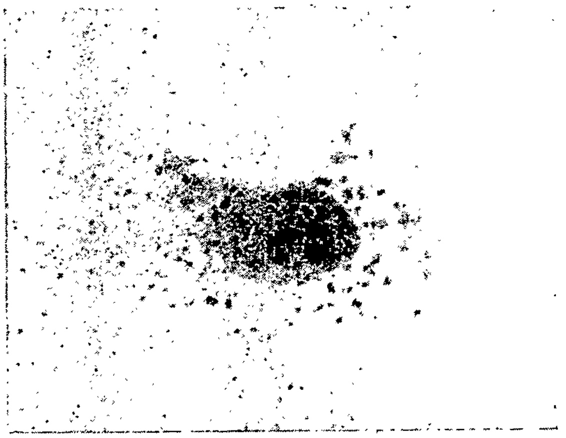

Fig. 2. Autoradiograph of a connective tissue cell from a culture incubated for 1 hr. in medium containing tritium-labelled valine and then for 40 hr. in non-radioactive medium. The nucleolus is still heavily labelled relative to the rest of the cell

The following experiment was undertaken. Replicate cultures of connective tissue cells were incubated for 1 hr. in medium containing tritium-labelled valine at a concentration of 5 μc./ml. At the end of this period some of the preparations were fixed in methanol and then extracted with 0·3 N trichloroacetic acid at 90° C. for 30 min. Autoradiographs of the fixed extracted cells were made by the usual stripping-film technique and developed after 3 days. Fig. 1 shows an autoradiograph of a cell from one of these preparations; it will be noted that the nucleoli are heavily labelled.

Other preparations were washed repeatedly with physiological saline after the period of incubation in radioactive medium and then incubated for 40 hr. in non-radioactive medium containing L-valine at a concentration of 5 mM. The mean generation time of the cells under these conditions was about 24 hr., so that by the end of 40 hr. almost all the cells would have passed through at least one mitosis. The preparations were then fixed and extracted with trichloroacetic acid. Autoradiographs were made and were again developed after 3 days. Examination of these autoradiographs showed that in the great majority of the cells the nucleoli were still heavily labelled relative to the rest of the cell, and unlabelled nucleoli were very rare. Fig. 2 shows an autoradiograph of a cell from a culture incubated for 1 hr. in radioactive medium and then for 40 hr. in non-radioactive medium.

This finding eliminates the possibility that all the nucleolar protein is formed *de novo* from free amino-acids immediately after mitosis. The ratio of the mean number of grains over the nucleoli to the mean number over the rest of the nucleus shows no great change during the 40-hr. cultivation in non-radioactive medium, thus indicating that the nucleolar proteins are not broken down and resynthesized at a rate very different from the rest of the proteins in the nucleus. The reappearance of nucleoli at the end of mitosis must therefore involve the aggregation into a visible structure of proteins which were synthesized before mitosis. The present experiment does not, of course, demonstrate that these proteins are necessarily derived from the pre-mitotic nucleoli, but this does seem to be a likely possibility.

Evidence for the Continuity of Nucleolar Material in Mitosis

IN a previous article[1] evidence is presented that in pollen grains of maize and agave, basic protein of the pre-mitotic nucleolus was divided without loss, but unequally, between the nucleoli of the resulting vegetative and generative cells. These experiments were repeated in another species and extended to include measurements on the ribonucleic acid (RNA) and the dry mass of the nucleolus. The species studied was *Strelitzia reginae* Banks, which has large pollen grains easily divested of their walls. Each nucleus has only one nucleolus and this is large (about 7μ in diameter at prophase) and not obscured by the relatively small amount of chromatin.

Measurement of Dry Mass. Anthers in which there were both pre- and post-mitotic pollen grains were fixed in acetic-alcohol (1 : 3) for 6 hr. and stored in 70 per cent alcohol at 4° until required. 2-mm. segments of anther were treated by the method of Warmke[2] and squash preparations of the pollen grains were made in 45 per cent acetic acid. With this treatment the walls of the pollen grains were separated from the contents, which could then be flattened. Photometric measurement of azure *B*-binding[3] in sectioned material indicated that the treatment in Warmke's solution did not remove a significant amount of RNA from the nucleoli. The coverslips with the squash preparations were then floated off in distilled water, rinsed twice, mounted in distilled water on other slides and ringed with rubber solution. Each preparation was examined and the positions of all cells suitable for measurement—those which were intact, flat, not folded and not obscured by debris—were noted. In all such cells the path differences of the nucleolus or nucleoli were measured at 5460 Å. with the Baker interference microscope.

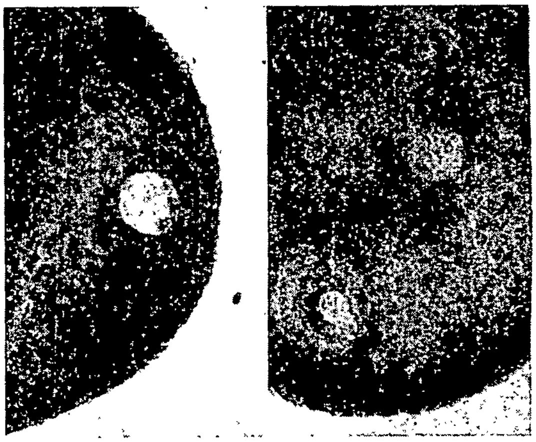

Fig. 3. Pollen grains of *Strelitzia reginae* divested of their walls, flattened and photographed through the Baker interference microscope to show nucleoli. Left, pre-mitotic; right, post-mitotic with vegetative nucleolus top, generative nucleolus bottom (× 550)

The blank reading was made on an area immediately adjacent to the nucleolus. Typical cells are shown in Fig. 3. Cells on which measurements were made were photographed, and the areas of the nucleoli were computed with a planimeter on a drawing of the projected image of the negative.

The coverslips were then floated off the slides and, because cells adhered to the slides and the coverslips, both were treated with ribonuclease at 35° for 3 hr. (0·2 per cent (w/v) in distilled water at *p*H 6). The ribonuclease (L. Light and Co.) was free from protease activity as judged by its failure to release free amino-acids from serum albumen. The slides and coverslips were washed and mounted separately in distilled water. In order to make it easier to find the cells again, the coverslips were placed on fresh slides in the same relative positions as they had occupied on the slides from which they had been removed. Path differences and areas were again measured. The preparations were then stained with azure *B*. Complete absence of stain in the nucleoli confirmed the effectiveness of the ribonuclease.

Results were obtained from two experiments and, because they did not differ significantly, they have been combined in Table 1. There is good agreement between the measurements on the two post-mitotic nucleoli for the total dry mass and the reduction in dry mass resulting from treatment with ribonuclease. It appears that in all three types of nucleoli, RNA

Table 1. MEANS AND STANDARD DEVIATIONS OF MASSES (GM. × 10^{-12}) OF NUCLEOLI IN 45 PRE-MITOTIC AND 23 POST-MITOTIC POLLEN GRAINS

Nucleolus	No.	Total dry mass	Removed by RNA-ase	Remaining after RNA-ase	Mean percentage removed by RNA-ase
Vegetative	23	115 ± 33	26 ± 13	89 ± 31	22·9
Generative		29 ± 10	6 ± 4	23 ± 9	22·3
Sum of veg. + gen.		144 ± 39	32 ± 15	112 ± 35	
Pre-mitotic	45	145 ± 29	33 ± 19	112 ± 25	22·4

Table 2. MEANS AND STANDARD DEVIATIONS OF AMOUNTS OF STAIN IN ARBITRARY UNITS (WHICH ARE DIFFERENT FOR EACH STAIN) IN NUCLEOLI BEFORE AND AFTER POLLEN GRAIN MITOSIS

Nucleoli	Azure *B*		Fast green	
	No. of cells	Amount	No. of cells	Amount
Vegetative	30	84·4 ± 11·8	16	35·3 ± 6·0
Generative		20·0 ± 4·9		9·1 ± 2·5
Veg. ± gen.		104·4 ± 13·0 } $0·6 > P > 0·5$		44·4 ± 6·0 } $0·2 > P > 0·1$
Pre-mitotic	30	102·0 ± 15·9	13	41·2 ± 6·5

accounts for about 22 per cent of the dry mass after fixation (95 per cent fiducial limits of the mean are 20·2 and 24·8 per cent).

Measurement of Basic Protein and Ribonucleic Acid. An anther from the same bud as that used in the previous experiments was fixed in 10 per cent neutral formalin, washed overnight, embedded and sectioned at a thickness of 15μ. The sections were heated in water at 90° for 10 min.[4] and then incubated for 2 hr. at 35° in 0·1 per cent (w/v) deoxyribonuclease. They were then stained in azure *B* bromide by the method of Flax and Himes[3], which is thought to be specific for RNA. The sections were differentiated until nucleoli were the only densely stained cell constituent and then mounted in thick cedarwood oil. Positions of all cells suitable for measurement—those in which the nucleoli were not cut or obscured—were noted. Measurements were made on the cells seriatim across the slide until 30 pre-mitotic and 30 post-mitotic nucleoli had been measured. The amount of stain in each nucleolus was measured at 5050 Å. with an integrating microdensitometer[5]. The blank reading was made on an area immediately adjacent to the nucleolus. The coverslip was then removed, and the slides were hydrated (and destained in the process). They were then stained with fast green *FCF* by the method of Alfert and Geschwind[6], which is thought to be specific for basic protein. During this procedure about half the cells were lost. In those remaining, the amount of stain in the nucleoli was measured at 5800 Å. (The photomultiplier was not sensitive at 6280 Å., the absorption maximum.) The results are shown in Table 2.

Again, the sum of the values for the two post-mitotic nucleoli does not differ significantly from the value in the pre-mitotic nucleolus.

Measurements were made on the amounts of azure *B* and fast green *FCF* in thirteen pre-mitotic nucleoli, and a correlation was found between the amounts of the two dyes bound ($r = 0{\cdot}663$, $0{\cdot}01 < P < 0{\cdot}02$). A similar correlation was found in measurements on sixteen vegetative nucleoli ($r = 0{\cdot}694$, $0{\cdot}01 > P > 0{\cdot}001$), but in sixteen generative nucleoli, which were considerably smaller and more difficult to measure accurately, a significant correlation was not detected because of the magnitude of the errors of measurement. A possible interpretation of this correlation is that the two stains reflect different components of what, in the intact cells, is a single structural entity, for example, ribonucleoprotein.

The demonstration by interferometry that the sum of the dry masses, after fixation, of the post-mitotic nucleoli was equal to the dry mass of the pre-mitotic nucleolus makes it possible to test the validity of an independent method of estimating a nucleolar component. For example, the fact that the amount of azure *B* bound by the two post-mitotic nucleoli together was statistically equal to the amount bound by the pre-mitotic nucleolus tends to confirm the specificity of the staining procedure and also the validity of the method of estimation. Further evidence that the different methods yield similar results is obtained from a comparison of the ratio of the mean values for the vegetative nucleoli to the mean values for the generative nucleoli. In the interferometry experiments the ratio was 3·98 for total dry mass, 4·02 for the mass removed by ribonuclease and 3·97 for the remainder; in the photometry experiments it was 4·22 for azure *B* and 3·88 for fast green *FCF*.

The results presented here give support to the view that the nucleolar material is not degraded during mitosis, but simply dispersed and re-assembled. If the nucleolar material were degraded and then re-synthesized, rather complex regulatory mechanisms would have to be postulated to explain the fact that the total amount of material in the two post-mitotic nucleoli, although these differ in size, is equal to the amount in the pre-mitotic nucleolus. In the light of the autoradiographic results reported in the preceding article, the simplest and most plausible explanation is that a substantial part of the nucleolar material maintains a structural continuity throughout mitosis. It is, of course, possible that only one component of the nucleolus, for example, protein, remains intact and that the amounts of other components, for example, ribonucleic acid, are regulated by the amount of protein present.

This work was carried out during the tenure of a Nuffield Dominion travelling fellowship at the John Innes Institute. I wish to thank Mr. L. S. Clarke for assistance with photography. I am particularly indebted to Mr. L. F. LaCour and Dr. J. McLeish for their expert advice.

HUMAN HÆMOGLOBIN A_2: CHEMISTRY, GENETICS AND EVOLUTION

By Prof. V. M. INGRAM and Dr. A. O. W. STRETTON

Division of Biochemistry, Department of Biology, Massachusetts Institute of Technology, Cambridge, Mass.

THE normal individual has at least three types of hæmoglobin. In fœtal life and in early infancy he has a specific fœtal hæmoglobin (*F*). Within a few months of birth this hæmoglobin has been replaced by adult hæmoglobin (*A*), together with a small proportion of another hæmoglobin (A_2)[1]. This hæmoglobin A_2 normally amounts to about 2·5 per cent of all hæmoglobins; however, in many instances of thalassæmia minor the proportion is doubled. We wish to report briefly the results to date of chemical studies of hæmoglobin A_2 which shed light on the possible role in thalassæmia of this form of hæmoglobin and on its evolution.

Hæmoglobin A_2 is readily distinguished from the major adult component (A) by its characteristic electrophoretic mobility ; it moves with the abnormal hæmoglobin E at pH 8·6 and pH 6·5 (ref. 1). Like hæmoglobin E, hæmoglobin A_2 shows the same unusual shift in relative electrophoretic mobility at the two pH values. At pH 8·6, hæmoglobin A_2 is close to hæmoglobin C, while at pH 6·5 it is relatively slower and moves close to hæmoglobin S.

Kunkel *et al.*[2] showed that A_2 is truly a separate hæmoglobin and not a chemical derivative of hæmoglobin A. In the ultracentrifuge, hæmoglobins A and A_2 could not be distinguished[2], which implied that their molecular weights are similar ; their spectra in the visible and ultra-violet were also indistinguishable[2]. As a result, the only difference which could be found between the hæmoglobins A and A_2 was their electrophoretic mobility, in contrast to hæmoglobin F, which differs from hæmoglobin A in its ultra-violet spectrum[3] as well as in electrophoresis[4].

Characteristically, hæmoglobin F differs also from A in having four *iso*leucine residues per molecule[5], an amino-acid notably absent from A. Our quantitative amino-acid analysis on the Spinco model Moore and Stein automatic analyser of carefully purified hæmoglobin A_2 showed the absence of *iso*leucine ($< 0·2$ residues per molecule). This finding is in contrast to the report by Rossi-Fannelli *et al.*[6], who recently published analyses of hæmoglobin A_2 containing > 6 residues of *iso*leucine per molecule. However, their preparation of hæmoglobin A_2 involved fewer purification steps than ours and might be contaminated with the non-hæm-containing protein known to have an electrophoretic mobility similar to hæmoglobin A_2.

Fingerprinting of Hæmoglobin A_2

Hæmoglobin A_2 was prepared from normal blood and from the blood of people with thalassæmia minor. The hæmoglobin solution from washed cells was carefully freed from stromal material by centrifugation at 30,000g at 2° C. Hæmoglobin A_2 was obtained by starch-block electrophoresis in 0·06 M veronal buffer pH 8·6 followed by adsorption on a short column of carboxymethyl–cellulose in 0·01 M phosphate buffer at pH 7·0. The non-hæm protein is not adsorbed under these conditions, and could therefore be separated from the hæmoglobin. The hæmoglobin was eluted with 0·2 M phosphate buffer at pH 7·0 or with 0·06 M veronal buffer at pH 8·6. After dialysis, the hæmoglobin A_2 was submitted for a second time to starch-block electrophoresis, eluted, and reconcentrated on carboxymethyl–cellulose. The protein was dialysed against 0·001 M phosphate buffer, pH 7·0, before use.

Comparison of hæmoglobin A_2 with A was made in the first instance by fingerprinting[7,8] tryptic digests of the two proteins (Fig. 1). In what follows a peptide will be named as follows: tryptic peptide number 26 (ref. 7) from hæmoglobin A is 'peptide AT-26'; similarly, peptide A_2T-26 is peptide number 26 from tryptic digests of hæmoglobin A_2, and so forth.

Several differences have been found in the fingerprints: the same peptide AT-26 in which hæmoglobin E differs from A (ref. 9) has an amino-acid substitution in hæmoglobin A_2 also ; a glutamic acid residue has been replaced by alanine in peptide A_2T-26 (Fig. 2). However, determination of the amino-acid sequence of peptide A_2T-26 showed that

it was the first of the two glutamic acid residues of peptide *AT*-26 which had changed to alanine. In hæmoglobin *E* it is the second glutamic acid which is replaced by lysine[9].

Another difference between the fingerprints of hæmoglobins *A* and A_2 is found in the peptides *AT*-12 and A_2T-12, which have the same electrophoretic mobility but differ in behaviour during chromatography. Peptide A_2T-12 is definitely slower. This difference was confirmed by the technique of dissected fingerprints[10]. The quantitative amino-acid composition of the two peptides, determined as above, was as follows: *AT*-12: $\mathrm{Ser_1,Thr_1,Gly_1,Ala_2,Val_1,Leu_1,Lys_1}$; A_2T-12: $\mathrm{Asp_1,Thr_1,Gly_1,Ala_2,Val_1,Leu_1,Lys_1}$. The basic nature of peptide A_2T-12 at *p*H 6·4 suggests that the aspartic acid residue is in the amide form. Both peptide *AT*-12 and peptide A_2T-12 also contain tryptophan, but this is destroyed on acid hydrolysis. As expected, the difference did not involve a charged amino-acid, but seemed to indicate a replacement of serine by asparagine. However, end-group determination by the dinitrophenol-procedure[11] showed that the situation was more complex than had been realized. Peptide *AT*-12 gave serine and peptide A_2T-12 gave threonine as N-terminal amino-acids. Clearly, we are dealing here with two substitutions, serine → threonine and threonine → asparagine. Further experiments on the sequence of the two peptides are in progress.

Examination of peptide *AT*-25 and A_2T-25 showed a further amino-acid difference. These peptides are indistinguishable in paper electrophoresis; a slight chromatographic difference was observed, when the isolated peptides were compared by paper chromatography in butanol/acetic acid/water (4 : 1 : 5). Amino-acid analysis of the peptides *AT*-25 and A_2T-12, carried out as above, showed a threonine (*AT*-25) to serine (A_2T-25) change in this nonadecapeptide. It is remarkable that such a small difference, involving a single methyl group in a peptide of molecular weight of more than 2,000, should show at all in chromatography. No further studies have yet been made on peptides *AT*-25 and A_2T-25 to determine whether this substitution is the only one in the peptide.

Finally, there is an additional peptide, A_2a. To date, the peptide of hæmoglobin *A*, which corresponds to the tetrapeptide A_2a, has not been found in spite of a careful search. Many other tryptic peptides of A_2 have been analysed quantitatively and found to be similar to their hæmoglobin *A* analogues (Table 1). The peptides examined account for at least 90 amino-acid residues, or about two-thirds of the δ-chain. Of these, only 4 or 5 amino-acids appear to be altered, as discussed above, assuming that for the rest similar amino-acid composition implies similar sequence.

Examination of the trypsin resistant 'core' of hæmoglobin A_2 by chymotryptic digestion and fingerprinting[13] suggested that the core might be different in several of its chymotryptic peptides. However, not all these differences were reproducible; although most of the 'core' fingerprint is similar for hæmoglobins *A* and A_2, the degree of similarity is by no means certain.

An important conclusion to be drawn from the present chemical studies is that the hæmoglobin A_2 from individuals with thalassæmia minor is indistinguishable from that of normal people, within the limits of the methods employed. Most of the analyses and sequences reported in this article were in fact made with thalassæmic hæmoglobin A_2, since this was less laborious to prepare. However, careful comparison of fingerprints and 'dissected fingerprints'[10] of hæmoglobin A_2 from normal and thalassæmic individuals gave us confidence that the two proteins are identical. Furthermore, if the thalassæmia hypothesis[14], discussed here, is correct, then the donor of the thalassæmic blood should be suffering from a β-chain thalassæmia, and the genes controlling his hæmoglobin A_2 would not be affected by this mutation.

We can summarize the chemical findings by saying that the tryptic fingerprints of hæmoglobins *A* and A_2 show four definite amino-acid substitutions and, in addition, the peptide A_2a.

The peptide chains of hæmoglobin A_2 were next separated to ascertain how these five differences are

distributed between them. For this purpose, we used a small-scale modification of Hill and Craig's countercurrent distribution technique[15], employed by them to separate the two types of peptide chain (α and β) of hæmoglobin A. Hunt[16] had shown that in fœtal hæmoglobin, the molecule of which is written $\alpha_2^A\gamma_2^F$, the two α chains are similar, if not identical to the α chains of hæmoglobin A—$\alpha_2^A\beta_2^A$. We find that none of the differences between hæmoglobins A_2 and A is in the α chain, but they are confined entirely to the other type of chain of A_2. This chain should be called the δ^{A_2} chain and the whole molecule, HbA_2 = $\alpha_2^A\delta_2^{A_2}$.

Genetic Control of Hæmoglobin A_2

The reasons for introducing the concept of separate δ chains in hæmoglobin A_2 are several. The observed amino-acid substitutions are at least four in number and probably more numerous. This fact distinguishes these chains from the β chains of the series of abnormal human hæmoglobins, such as the β^S chain of Hb-S the β^C of Hb-C, the β^E chain of Hb-E, etc., all of which differ from the normal β^A chain of Hb-A by a single amino-acid substitution[17]. On the other hand, the chemical similarity between β and δ chains is considerable as evidenced by the possession of the same N-terminal sequence Val.His.Leu . . .[18], by the same C-terminal sequence . . . Tyr.His[8], by the absence of *iso*leucine and by the apparent similarity in many tryptic peptides.

The necessity for their designation as 'δ chains' is confirmed by the genetic evidence that these chains are under genetic control which is separate from that of the β chain. For example, a mutation of the β gene, as in Hb-S or Hb-E, does not result in an altered δ chain ; the hæmoglobin A_2 component remains normal[2].

In addition, it appears that there is an independent series of alleles of hæmoglobin A_2. Ceppellini[19] has discovered an abnormal minor component, hæmoglobin B_2, which has a slower electrophoretic mobility than hæmoglobin A_2. In individuals carrying the B_2 component, the proportion of A_2 is decreased from the normal 2·5 to 1·2 per cent, and B_2 is present in the same amount, that is, the sum of hæmoglobins A_2 and B_2 is the usual 2·5 per cent. Furthermore, in individuals who also have thalassæmia, the level of A_2 and B_2 together was increased to 5 per cent, each being present at a level of 2·5 per cent.

Another abnormally slow A_2 component, described by Huisman and Meyering[20] as A_2', has an electrophoretic mobility which is similar to that of the hæmoglobin B_2 mentioned above. In the family in which it was discovered, it was found always together with thalassæmia, and the sum of A_2 and A_2' was also elevated above the normal level of A_2.

Shooter *et al.*[21] have evidence that the α chains of hæmoglobins A and A_2 are under the control of the same α gene. In a person homozygous for the abnormal hæmoglobin G_{Ibadan}, which differs from hæmoglobin A in the α chain[22], no normal hæmoglobin A_2 was found. Instead there was a new minor component, G_2, which differed in electrophoretic mobility from hæmoglobin A_2 in the same way that hæmoglobin G differs from hæmoglobin A.

We are, therefore, left to conclude that the genetic control of the production of hæmoglobin A_2 is exercised by α and δ genes, whereas hæmoglobin A is controlled by α and β genes. It appears[19], in addition, that the β and δ genes are linked. The hæmoglobins of a normal individual are therefore under the control of four genes: α, β, γ and δ. The α gene is concerned in the manufacture of all three types of hæmoglobin : $F = \alpha_2^A\gamma_2^F$, $A = \alpha_2^A\beta_2^A$, $A_2 = \alpha_2^A\delta_2^{A_2}$. These various hæmoglobins are produced depending on whether or not the β, γ or δ genes are 'active', which in turn seems to depend on the stage of development of the individual.

Hæmoglobin A_2 in Thalassæmia

The work of Kunkel *et al.*[2] and of Gerald and Diamond[23] has shown that hæmoglobin A_2 is involved in some of the thalassæmia diseases, since in many instances the proportion of A_2 rises to about 5 per cent.

We have recently proposed a hypothesis[14] (and an alternative) which suggests that the thalassæmia mutations are similar to those which lead to the single amino-acid substitutions in the recognized abnormal adult hæmoglobins (for example, Hb-S, C, E, etc.). However, thalassæmia is thought to differ from the abnormal hæmoglobin diseases in that the proposed thalassæmia mutations lead to amino-acid substitutions which do not affect the electrophoretic mobility of the hæmoglobin produced, but merely its rate of synthesis. An immediate consequence of this idea is the distinction of different thalassæmias as affecting either the α or the β chain of Hb-A. It has been suggested[24] that the occurrence of high proportions of fœtal hæmoglobin is compensatory in cases which we now describe as homozygous for a β chain thalassæmia. This could not happen for an α chain thalassæmia, since fœtal hæmoglobin uses α chains. Similarly, the observed rise of hæmoglobin A_2 in some thalas-

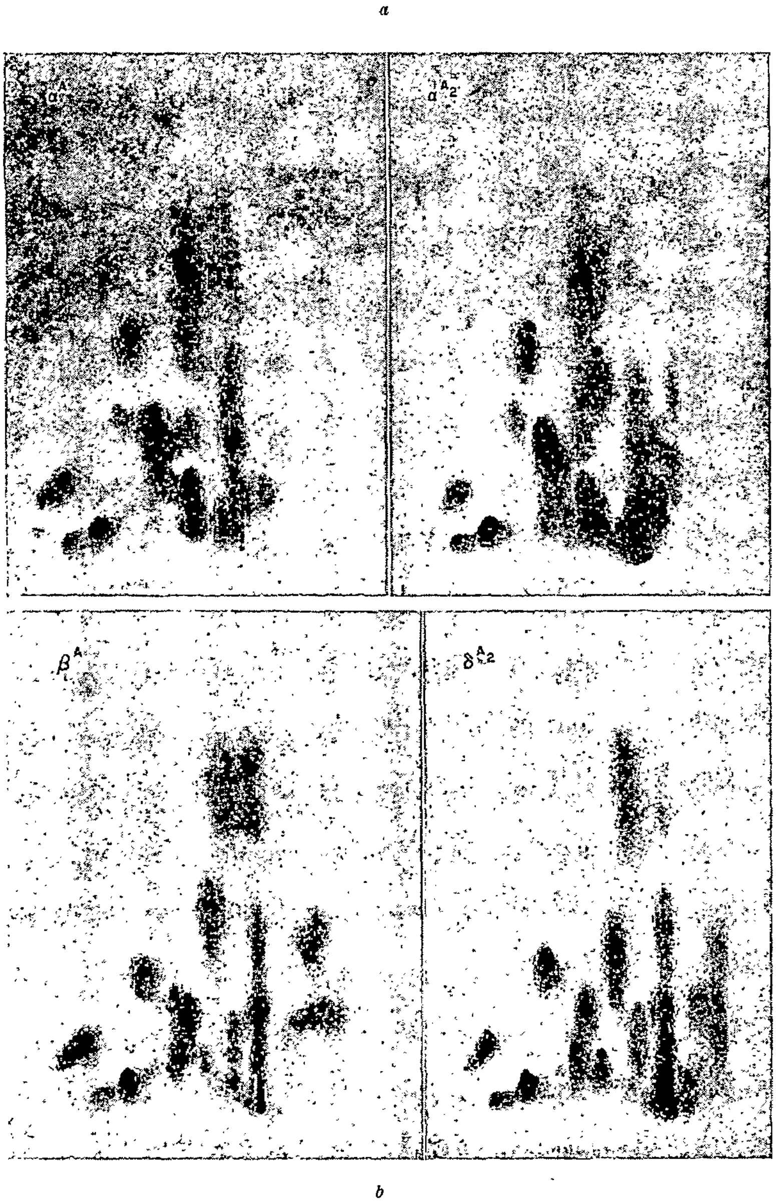

Fig. 4. Fingerprints of tryptic digests of: *a*, α chains of hæmoglobins *A* and A_2; the extra spots in the fingerprint of the α^{A_2} chain are known to be due to contamination with the δ^{A_2} chain; *b*, β chain of hæmoglobin *A* and δ chain of hæmoglobin A_2

sæmia minors can be ascribed to the presence of a β chain defect. In certain cases, this classification of the thalassæmia is borne out of a study of the pedigree[14]. Again, the cases of thalassæmia which do not have increased levels of A_2 (refs. 2, 25, 26) would be classified as α chain thalassæmias.

In the case of an α chain thalassæmia, a rise in hæmoglobin A_2 would not be expected since the relative rates of synthesis of β^{A} and δ^{A_2} chains should be normal. On the other hand, a β chain thalassæmia would decrease the rates of synthesis of the β^{A} chain relative to that of the δ^{A_2} chain, and therefore lead to an increase in the proportion of hæmoglobin A_2.

Evolution of Hæmoglobin A_2

Kunkel *et al.*[3] showed that blood specimens from cattle, horses, pigs, dogs and rabbits failed to show a minor component similar to A_2 hæmoglobin.

However, when they examined specimens from primates, in several cases a hæmoglobin A_2-like component was found. Ten chimpanzees showed such a component, comprising 2·4 per cent of the total hæmoglobin; the mobilities of the major and the minor components were indistinguishable from those of the human counterparts.

The New World monkey, *Cebus capucinus*, also showed the presence of A_2, but at levels of 4–5·5 per cent. No hæmoglobin A_2 was found in several Old World monkeys: *Macacus rhesus*, *M. cynomolgus* and *M. cercopithecus*.

The absence of A_2 in the Old World monkeys is at first sight surprising, since they are often held by zoologists to be more advanced than the New World monkeys. However, it might be that the particular examples studied were exceptions, which had lost the A_2 component during evolution. If all Old World monkeys lack A_2, perhaps this can be taken as a taxonomic criterion, along with the anatomical criteria at present used.

It would be of interest to extend this survey to other primates, to see whether the presence or absence of A_2 has a phylogenetic significance, as is suggested by these preliminary studies. Among the apes, the gibbon, orang-utan and gorilla have yet to be examined. An examination of primitive races of humans, such as aborigines, would also be of interest in this respect.

Although, on the basis of the limited survey that has been made, the A_2 component appears to be confined to the primates, other animal species are known to possess more than one hæmoglobin component. For example, it is possible that the two horse hæmoglobins[27] are related in a similar way as are the human hæmoglobins *A* and A_2.

A satisfactory explanation of the system of genetic control of hæmoglobin A_2 is that comparatively recently in evolution the β gene underwent duplication and that the two genes evolved independently from the original type by mutation to give the presently existing β and δ genes[28]. Gene duplication has been demonstrated in *Drosophila* both by genetic analysis and by cytological investigation of salivary chromosomes (for example, the 'bar' duplication)[29].

A process of duplication followed by divergence has long been considered by geneticists as a possible mode of origin of new genes[30]. While cases of duplication are known, no instance of subsequent independent evolution has been reported. It is believed that hæmoglobin A_2 provides an illustration of this process and that it furnishes evidence as to the way in which genes evolve.

We wish to thank Dr. Park Gerald for supplies of thalassæmic blood and for stimulating discussions.

This work was supported by a grant from the National Science Foundation. One of us (A. O. W. S.) thanks the National Institutes of Health for a fellowship under a training grant.

Addendum. Muller and Jonxis[31] have recently discussed their fingerprints of hæmoglobins A and A_2. Although there is a large measure of agreement between their results and ours, our results differ in that we find no arginine in the neutral tyrosine-containing peptide 5 (which they denote as peptide 2). Also, we find the additional peptide A_2a, which they do not report.

ESTIMATION OF PERCENTAGE NATURAL CROSS-POLLINATION : EXPERIMENTS ON RICE

By E. H. ROBERTS and R. Q. CRAUFURD

West African Rice Research Station, Rokupr, Sierra Leone

AND

F. LE COCHEC*

Centre de Recherches Rizicoles du Koba, Koba par Ouassou, Guinea

IN work on the amount of cross-pollination which occurs under natural conditions in crop plants, the term 'percentage cross-pollination' has not always been clearly defined; consequently it is not always easy to assess the meaning of some of the published values. In many cases this is because the nature of the experimental design used has made it impossible to give a simple definition. Percentage cross-pollination is defined here as the number of seeds produced by all the plants in a plot—excluding those plants at the edge—which are the result of a cross-pollination, expressed as a percentage of the total number of seeds produced by those plants. Our definition of cross-pollination is the fertilization of one plant by another. (Fertilization of one flower by another on the same plant can be considered as self-pollination from the genetical and practical point of view.)

The basis of our design is as follows. Two pure-line varieties are used which have the same duration from sowing to flowering and are similar in most other respects (such as height, tiller number, etc.) except for one character which is genetically dominant in one variety and recessive in the other. We used the rice variety *BG*79, which has a red-pigmented leaf-sheath in the seedling stage (dominant), and Lead 35, which has a green leaf-sheath (recessive). The two varieties are planted as shown in Fig. 1. Assuming that the chance of cross-pollination is the same between plants at the same distance, an examination of Fig. 1 (see also Table 1) shows that any plant has an equal chance of being cross-pollinated by either variety when the eight nearest plants to it are considered. When plants farther away than the nearest eight are considered, it may be assumed that the chance of cross-pollination is less, but the chance of either variety effecting this is still approximately the same. (No information is available concerning the relationship between distance and the chance of cross-pollination; but if one makes the assumption that pollen dispersal is comparable to certain forms of spore dispersal[1], then the chance of cross-pollination would be inversely proportional to the square of the distance; if this is so, then the chance of cross-pollination in any plant near the centre being caused by any plant of the same variety as against any plant of the other variety is approximately 0·485 : 0·515.)

When the plot is ripe, a number of plants of the variety which has the recessive character is gathered from the centre of the plot (in Sierra Leone we chose the nine plants included in the central square shown in Fig. 1). The seed (F_1) from these plants is grown and the number of plants showing the dominant and recessive character noted. Those showing the dominant character provide an estimate of half the number of cross-pollinations which took place.

The main disadvantage inherent in this design is due to the fact that plants with the same character are aligned in rows. In Fig. 1, if the top of the

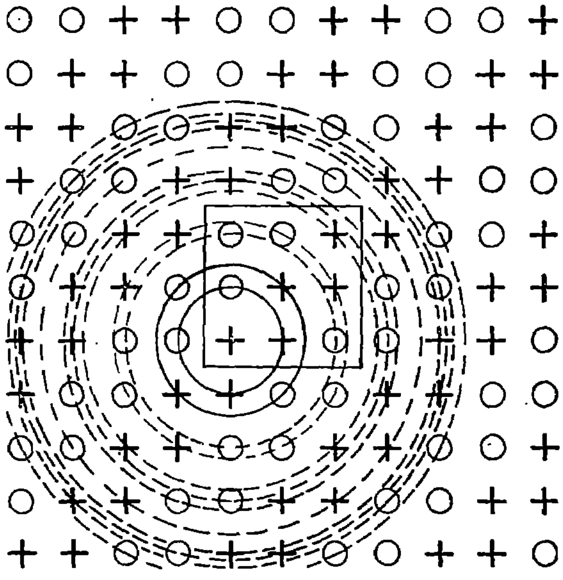

Fig. 1. Planting diagram of cross-pollination experiment. Each small circle represents a plant with the dominant character and each cross represents a plant with the recessive character. Concentric circles have been described round one of the 'recessive' plants to demonstrate those plants which are equidistant from it for the twelve innermost circles of plants. In the immediate neighbourhood of the central plant (solid circles), there is an equal number of each variety equidistant from it

page is considered as north, these lines run from south-west to north-east. Because of this alignment, directional factors are likely to distort the result. (This criticism also applies to a number of popular designs such as those based on a chess-board pattern.) For example, if wind is an important agent for carrying pollen then a prevailing south-westerly or north-easterly wind at the time of pollination would result in an underestimate of the amount of cross-pollination taking place, whereas a wind at right-angles to this would result in an overestimate. However, this apparent disadvantage can be made use of providing replicate trials are laid down with the diagonal rows of plants orientated at right-angles to one another. Such replication should compensate for any directional influences; furthermore, comparison of the differently orientated trials should give an indication as to whether directional influences are important.

We have carried out experiments on rice at two sites near the coast of West Africa—at Rokupr (9° 01′ N., 12° 57′ W.) in Sierra Leone and at Koba (9° 55′ N., 14° 04′ W.) in Guinea. One experiment was carried out at Koba and two at Rokupr within the normal season but planted on different dates. At Koba 75 out of the 14,021 seedlings in the F_1 were found to have a red leaf-sheath; this gives a value of 1·07 per cent cross-pollination. At Rokupr, 1 red leaf-sheath out of a total of 5,210 seedlings was obtained in the first experiment and 1 out of 5,004 in the second. As these results at Rokupr are very similar, they have been grouped together to give a value of 0·04 per cent cross-pollination.

These experiments indicate that the percentage natural cross-pollination in rice in West Africa is low but may vary considerably under different environmental conditions.

This article is published with the permission of the Director of Agriculture, Sierra Leone.

PRIMARY METABOLIC DEFECT SUPERVENING ON VITAMIN B_{12} DEFICIENCY IN THE SHEEP

By HEDLEY R. MARSTON, F.R.S., SHIRLEY H. ALLEN and RICHARD M. SMITH
Commonwealth Scientific and Industrial Research Organization, Division of Biochemistry and General Nutrition, University of Adelaide, South Australia

Résumé of Experimental Findings which led to the Present Investigations

WHEN the concentration of cobalt within the paunch contents of a sheep falls below 40 mμgm. cobalt/gm. (20 μμgm./ml. of the bacteria-free supernatant) a manifest change occurs in the nature of the delicately poised associative growth of micro-organisms which constitutes the rumen flora. Although the rate and course of fermentation of carbohydrates within the rumen remain unaltered by this change, production of vitamin B_{12} and its analogues by the newly established microbial population decreases very materially. In such circumstances, bacterial synthesis of vitamin B_{12} itself falls precipitately from the level of 600–1,000 μgm./day, which normally prevails in the presence of adequate cobalt, to less than 50 μgm./day.

As the efficiency of absorption of the vitamin B_{12} produced by the rumen micro-flora is not more than

3 per cent, the amount of the vitamin that becomes available to the animal's tissues at this lower level of production is insufficient to make good the normal metabolic wastage of the functional vitamin B_{12}-containing complexes. Depletion then ensues.

The sheep suffers no obvious impairment of its physiological function until its complement of the vitamin as indicated by the concentration of vitamin B_{12} in its liver is reduced below 0·15 μgm. vitamin B_{12}/gm.

This is a critical level; depletion beyond it results in a marked loss of metabolic efficiency. The animal, then, can deal no longer with the fermentation products arising from a full feed; its appetite fails progressively as depletion proceeds, food consumption reflecting with remarkable precision the extent of the diminishing vitamin B_{12}-status, until death from inanition supervenes.

At any stage of the syndrome, provision of adequate vitamin B_{12} arrests further decline and dramatically restores normal health.

In the search for this defect of intermediary metabolism, the fact that a shortage of vitamin B_{12} imposes a much more profound metabolic stress on ruminants than on other animals, prompted the experiments reported here.

Unlike other animals, the ruminant derives the major part of its energy requirements from acetic and propionic acids produced by fermentation of the carbohydrates of its fodder. The course of this fermentation is remarkably consistent. The relative concentrations of the volatile fatty acids present in the rumen contents of our experimental sheep vary somewhat, but not greatly, throughout the 24-hr. cycle of rumination. The molecular ratios of the three main fatty acids present in the rumen contents 4 hr. subsequent to feeding are typical. At this stage, acetic acid comprises about 57 per cent, propionic acid 27 per cent and butyric acid 13 per cent of the total volatile acids; the remaining 3 per cent is made up of traces of formic, *iso*butyric and higher acids arising from secondary fermentations of other substrates.

The earliest of our investigations of the metabolic efficiency with which a sheep deals with individual fatty acids injected into its bloodstream demonstrated, unequivocally, that a state of vitamin B_{12}-deficiency seriously impairs the animal's capacity to utilize propionic acid, whereas its capacity to utilize formic and acetic acids remains unchanged.

Normal capacity to catabolize acetic acid becomes reduced occasionally in sheep that have been confined for two years or more to cobalt-deficient rations supplemented by parenteral injection of vitamin B_{12}, and then induced to become vitamin B_{12}-deficient by removal of the supplement. In these very rare cases, a massive parenteral dose of folic acid immediately reinstates normal metabolic function in this respect, leaving unaltered the seriously impaired capacity to metabolize propionic acid as the primary consequence of uncomplicated vitamin B_{12}-deficiency.

The site of the metabolic disability imposed in animal tissues by vitamin B_{12}-deficiency was located, unequivocally, by our work on the relative capacities of homogenates from the livers of normal and of vitamin B_{12}-deficient sheep to effect the catabolism of propionate. The metabolic defect is in the pathway of transformations, described by Flavin and Ochoa[1], through which, in animal tissues, propionate is launched into the Krebs cycle. Precisely, the breakdown arises from failure of the transfer reactions responsible for the intermediate isomeric conversion of methyl malonyl co-enzyme-A to succinate.

Tagging of the functional vitamin B_{12}-containing component by injection of cobalt-58 vitamin B_{12} into deficient sheep facilitated its isolation from their livers. This complex functions as a co-enzyme essential for the conversion of methyl malonate to succinate.

Finally, we have shown this co-enzyme to be identical with the 5 : 6-dimethyl-benziminazole cobamide co-enzyme separated from the cells of micro-organisms. We are very grateful to Dr. H. A. Barker, Department of Biochemistry, University of California, and to Dr. D. Perlman, Squibb Institute for Medical Research, New Brunswick, for gifts of crystalline 5 : 6-dimethyl-benziminazole cobamide co-enzyme prepared respectively from the cells of *Clostridium tetanomorphum* cultured in media containing free 5 : 6-dimethyl-benziminazole, and from *Propioni-bacterium shermanii*.

Our latter experiments were influenced and facilitated by the work of Barker *et al.*[2], on the isomeric conversion of L-glutamate to α-L-β-methyl-aspartate by *Clostridium tetanomorphum*, a transformation shown by them to be dependent normally on a co-enzyme which contains the analogue, Pfiffner's ψ vitamin B_{12} (adenyl cobamide).

Whatever its action *in vitro*, the adenyl cobamide co-enzyme is unlikely to function in animal tissues either in the isomeric conversion of methyl malonate to succinate, or in the metabolism of glutamic acid, which latter takes a course entirely different from that in *Clostridium tetanomorphum*. The animal organism either rejects vitamin B_{12}-analogues or destroys them after absorption. The total vitamin B_{12}-activity in the tissues of a sheep, for example, is due to vitamin B_{12} itself, although very considerable quantities of its analogues are produced along with it in the rumen contents.

Whether the 5 : 6-dimethyl-benziminazole cobamide co-isomerase present in animal tissues is specific only for the transfer reactions involved in the conversion of methyl malonate to succinate is a moot point, however. Whereas the main symptoms of the vitamin B_{12}-deficiency syndrome in the sheep may be attributed unquestionably to the impairment of propionate metabolism, there are subsidiary symptoms that occasionally become evident, especially in long-standing cases of partial deficiency. Outstanding among these are a blood dyscrasia due to a reduced capacity to mature the red cells, and, on occasions as a terminal symptom, a fatty infiltration of the liver, attributable to an impairment of methionine metabolism. Both could arise from partial failures to translocate single carbon atoms, processes dependent either on the vitamin B_{12}-containing methyl malonate co-isomerase or upon similar vitamin B_{12}-containing complexes essential in other transfer reactions. In some of these, folic acid is involved.

The megaloblastic anæmia, which in sheep is a frequent, though not invariable, symptom of vitamin B_{12}-deficiency, responds spectacularly to treatment with either vitamin B_{12} or folic acid, as it does in the human malady, Addisonian pernicious anæmia. Vitamin B_{12} completely reinstates normal metabolic function; in the sheep, apart from reinstating normal erythropoiesis, folic acid has no effect on the course of the deficiency syndrome which progresses to its fatal termination irrespective of the improved oxygen-carrying capacity of the blood.

Details of the experimental work upon which the above outline is based will be submitted for publication elsewhere. Those conducted, *in vivo*, which demonstrated the primary disturbance in the vitamin B_{12}-deficient sheep to be an impaired capacity to metabolize propionic acid, were referred to in the eleventh Annie B. Cunning Lecture delivered to the Royal Australasian College of Physicians in July 1958 (ref. 3). The studies, *in vitro*, which revealed the origin of this disability to be in the intermediary conversion of methyl malonate to succinate, and proved the dependence of this isomeric change on a vitamin B_{12}-containing co-isomerase, were reported in a section of the Tercentenary Exhibition of the Royal Society in July 1960. The following résumés are of some of our findings which concern directly the function of vitamin B_{12} in animal tissues.

H. R. MARSTON

Demonstration, *in vivo*, of the Site of the Metabolic Defect

As the volatile fatty acids are well tolerated, even when injected in considerable quantities into the blood stream; as the sheep's kidney threshold for them is high; and as equilibrium is quickly established between their concentrations in the blood and in the extra-cellular fluids, the criterion adopted to assess the effect of vitamin B_{12}-deficiency on the animal's metabolic efficiency in respect to them was the rate of their disappearance from the circulation after increasing materially their concentration by infusing their sodium salts into the jugular vein.

The best recommendation for this simple approach is the nature of the information it provided. The findings led directly to recognition of the metabolic defect that supervenes on vitamin B_{12}-deficiency.

Merino sheep were employed as experimental animals. They were confined in metabolism cages and fed on cobalt-deficient fodder which provided adequate nutrition in all respects other than the supply of vitamin B_{12}, which was considerably short of normal requirements. In the course of other experiments, we have determined that about 1·5 μgm. vitamin B_{12}/day is absorbed by sheep consuming the full ration (*cf.* legend to Fig. 6 for its composition). A sheep confined to this fodder loses close to 7·5 μgm. vitamin B_{12}/day in the normal course of its metabolism. Thus the overall deficit in these circumstances is about 6 μgm./day.

In some of the determinations, sheep of virtually the same age, size and previous nutritional history were selected and pair-fed. One of each pair was treated, parenterally, with abundant vitamin B_{12}, and its food intake restricted each day to that of the other animal, which was allowed to become depleted over the course of 35 or more weeks until it was in an advanced stage of the deficiency syndrome (Fig. 1). In other determinations, the effects were assessed by measurements made before and after the administration of massive amounts of vitamin B_{12} to deficient animals, food intake being regulated at a constant level during the short (4–7 days) interval between the tests. As vitamin B_{12} status was the only variable, both series of observations provided critical comparisons.

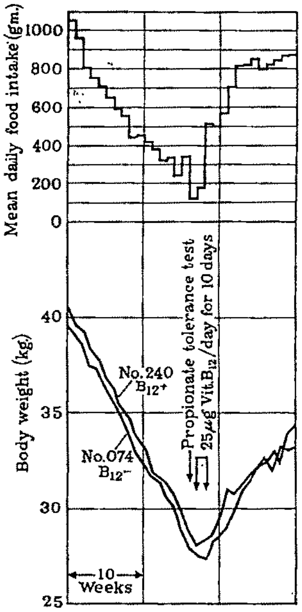

Fig. 1. Performance of pair-fed sheep
The performance of ewes No. 240 B_{12}^+ and No. 074 B_{12}^- used for the experiment illustrated in Fig. 4 is typical of that of the pairs referred to in Figs. 2 and 3. Food consumption of No. 240 was restricted throughout to that of No. 074

For each test, 3·5 m.mol. of the particular fatty acid per kgm. body-weight of the animal fasted for 24 hr., neutralized with sodium hydroxide and diluted to 1 molar concentration, was warmed to 38° C. and transfused steadily over the course of 5 min. into the blood stream via a fine plastic tube implanted temporarily into one of the external jugulars. A series of blood samples was collected at intervals through this tube, and the volume of the blood withdrawn replaced with physiological saline. Coagulation was prevented by washing the tube thoroughly with a solution of 1 : 10^5 heparin in physiological saline between each operation. Volatile fatty acid was determined in aliquots of the tungstic acid filtrates by constant-volume distillation and micro-titration in a stream of nitrogen. Gas–liquid partition chromatography was employed to determine the nature of the volatile acids in the blood.

The results from repeated overall determinations were within a very small experimental error, and left little doubt of the consistency of the underlying phenomena which they reflected. Those reported here are typical.

When raised artificially to abnormally high levels in the blood stream, simple fatty acids rapidly establish equilibrium with the *milieu interieur*, and afterwards their concentrations decrease exponentially to the low levels which normally prevail in the circulation of the fasting sheep.

The rate of this fall in the concentrations of formic acid (Fig. 2) and of acetic acid (Fig. 3), measured in this way, is unaffected by vitamin B_{12}-deficiency, even when the uncomplicated deficiency syndrome has progressed to its terminal stages. The metabolic capacity of the sheep to deal with propionic acid, however, is manifestly impaired by a state of vitamin B_{12} deficiency (Fig. 4). A significant decrease of this function is detectable even in the early stages of the deficiency syndrome, and thereafter it becomes progressively worse as depletion proceeds. Throughout the course of the supervening syndrome the extent of this defect correlates closely with the diminishing vitamin B_{12} status of the animal's tissues.

We conclude, therefore, that vitamin B_{12} is an essential constituent of the enzyme system which constitutes the intermediary channel through which propionic acid passes in normal metabolism.

In ruminants, which, of necessity, deal with relatively large quantities of propionic acid, this metabolic consequence of vitamin B_{12}-deficiency is particularly serious. In the mixed-feeders it is also important, for these animals have to deal with considerable quantities of propionic acid derived from cæcal fermentation of refractory carbohydrates that escape hydrolysis and absorption in the upper levels of the alimentary canal. Moreover, catabolic utilization of protein adds to this. The metabolic degradation of the amino-acids from 100 gm. of wheat gluten, for example, yields 4·1 gm. of propionic acid, which arises as an intermediary product in the degradation of the glucogenic amino-acids, L-valine and L-*iso*leucine.

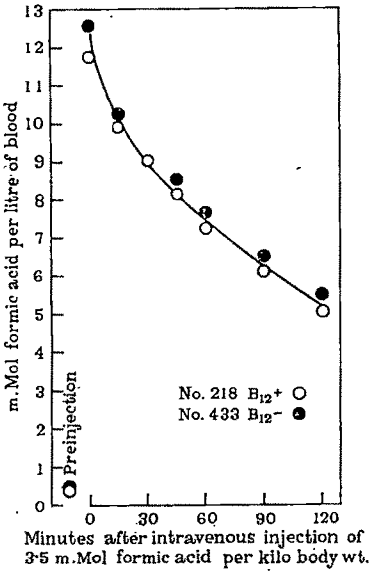

Fig. 2. Lack of effect of vitamin B_{12}-deficiency on the metabolism of formic acid

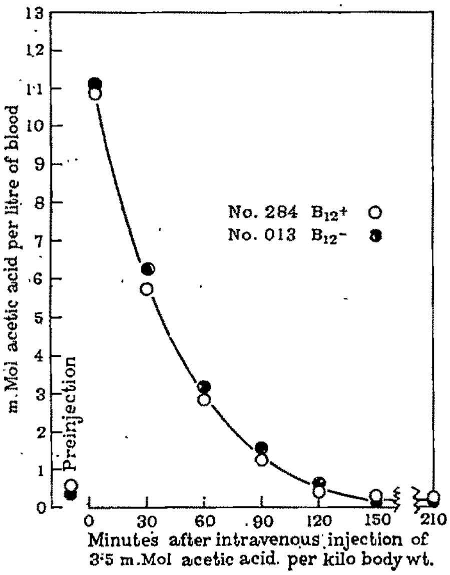

Fig. 3. Lack of effect of vitamin B_{12}-deficiency on the metabolism of acetic acid

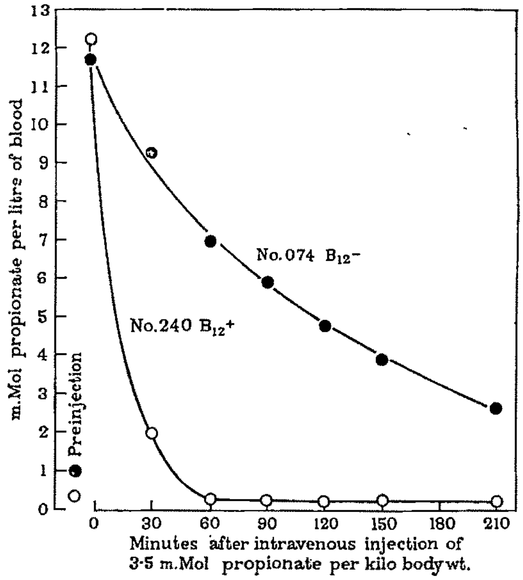

Fig. 4. Effect of vitamin B_{12}-deficiency on the metabolism of propionic acid

The metabolic defect briefly discussed here has been reported[4] as an integral part of a comprehensive investigation of the effects of cobalt deficiency on Merino sheep.

Localization, *in vitro*, of the Metabolic Defect, and Separation of the Vitamin B_{12}-containing Methyl Malonyl Co-isomerase

If provided with carbon dioxide, adenosine diphosphate, and extra cytochrome *c*, homogenates of the livers of normal sheep, prepared to ensure that the mitochondria remain intact, metabolize propionate at approximately the same rate as malate and succinate. Under identical conditions (cf. legend to Table 1) homogenates, prepared in this way from the livers of vitamin B_{12}-deficient sheep, retain their ability to deal with malate and succinate but lose their ability to deal with propionate. Within the small experimental error of the observations, propionate added as a substrate remained unaltered, and there was no increase in oxygen consumption (Table 1).

The capacity of homogenates from deficient livers to metabolize propionate, *in vitro*, however, is strikingly different when the mitochondria are fragmented. Such homogenates, prepared to ensure liberation of the mitochondrial enzymes into the reaction mixture, readily convert propionyl coenzyme *A* to methyl malonyl coenzyme *A* if provided with carbon dioxide and adenosine triphosphate. In these circumstances, methyl malonyl coenzyme *A* accumulates (Fig. 5 (*a*)). Addition of the vitamin B_{12}-containing coenzyme, isolated (*vide infra*) from the livers of normal sheep, reinstates the capacity to effect the isomeric conversion of this intermediate, and as the efficiency of the Krebs cycle is reduced by dispersal of its enzymes in the reaction mixture, succinate accumulates (Fig. 5 (*b*)).

The liver homogenates used in the above experiments were prepared in 0·25 molar sucrose immediately after slaughter of the sheep. Nuclei and larger particles of cell debris were removed at 600 *g* for 10 min. The reaction mixtures comprised: potassium phosphate buffer *p*H 7·4, 2×10^{-2} *M*; sodium bicarbonate, $2·5 \times 10^{-2}$ *M*; potassium chloride, $9·0 \times 10^{-3}$ *M*; adenosine triphosphate, $1·3 \times 10^{-3}$ *M*; cytochrome *c*, $1·1 \times 10^{-5}$ *M*; added substrate, 5×10^{-3} *M*; sucrose added in homogenate about 4×10^{-2} *M*. The mixture, 5 ml., plus 0·5 ml. homogenate (2–3 mgm. nitrogen) was equilibrated in Warburg vessels with 95 per cent oxygen and 5 per cent carbon dioxide, which remained as the gaseous phase, then 0·5 ml. of substrate was added from the side arm. The reaction, at 37° C. for 36 min. with rapid shaking, was terminated by addition of tungstic acid. Volatile acid was estimated in the protein-free filtrate by micro-titration of the distillate in a rapid stream of nitrogen. Oxygen consumption was measured by Warburg's indirect method

The site of the impairment of propionate metabolism is indicated by the failure of the liver homogenate from the vitamin B_{12}-deficient sheep to effect efficiently the conversion of propionate to succinate. This metabolic defect, which, as illustrated in Fig. 5 (*a*), leads to an accumulation of the intermediate, methyl malonyl coenzyme *A*, is made good (Fig. 5 (*b*)) by the addition of a vitamin B_{12}-containing methyl malonyl co-isomerase, isolated from the livers of sheep (*vide infra*). The experimental conditions were essentially as follows.

The homogenate, from the liver of the cobalt-deficient sheep, *A*7–507 (Fig. 6) was prepared in *tris*-hydroxymethylamino-methane buffer under conditions which fragment the mitochondria and disperse their constituents into solution.

Reaction mixture (*a*) comprised propionyl coenzyme *A*, 10^{-3} *M*; *A*7–507 liver homogenate (containing 1·53 mgm. protein); magnesium ions, adenosine triphosphate and glutathione, the whole buffered at *p*H 7·4, *tris*-buffer 0·05 *M*. Two μc. of $^{14}CO_2$ in 10 μmol. carbon dioxide were distributed between the solution and the gas phase above it. Total volume of reaction mixture, 1 ml. Incubated at 30° C. for 20 min.

Reaction mixture (*b*) was identical with (*a*), but contained in addition 5×10^{-7} *M* co-isomerase isolated from the livers of normal sheep. Volume and treatment as above.

At the end of the incubation period, the coenzyme *A* thioesters were hydrolysed with 0·2 ml. 2 *N* potassium hydroxide. The reaction mixture was then adjusted to *p*H 2·0 with sulphuric acid, carrier acids were added, and the whole exhausted with ether. The ether extract was taken to dryness, the residue dissolved in a drop of water and chromatographed on Whatman No. 1 paper with *iso*amyl alcohol saturated with 4 *N* formic acid.

The tracings of radioactivity by a scanning device (Fig. 5) are roughly comparable in arbitrary units.

The critical quantitative determinations of radioactivity due to $^{14}CO_2$ in each spot, reported there as c.p.m. observed, were effected by cutting round the spots developed by brom-phenol blue, and igniting the disks in a combustion furnace from which the whole of the effluent gases was transferred to a high-vacuum manifold essentially of the type described by Glascock[12]. Therein the total carbon dioxide was isolated and, after diluting with the requisite volume of inactive carbon dioxide and the addition of carbon disulphide, transferred quantitatively into a Geiger tube and total radioactivity estimated by modern scaling instruments. Determinations effected by this sensitive procedure are accurate and strictly comparable.

Under the same conditions, homogenates, prepared by this method from the livers of normal sheep, metabolize propionyl coenzyme *A* more readily to succinate without additional co-isomerase, the rate of clearance of the intermediate, methyl malonyl coenzyme *A*, depending on the concentration of co-

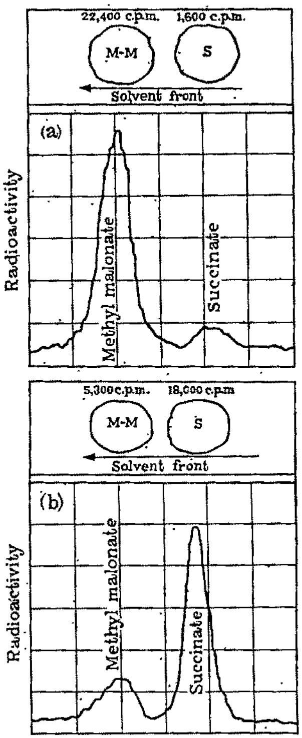

Fig. 5. Influence of added methyl malonyl co-isomerase on the metabolism of propionate by a homogenate from the liver of sheep *A*7–507 (Fig. 6) prepared to ensure fragmentation of the mitochondria. Reaction mixtures (*a*) and (*b*) were identical, other than the addition of 5×10^{-7} *M* co-isomerase to (*b*). The accumulation of methyl malonate in (*a*) indicates the metabolic lesion. For details see text

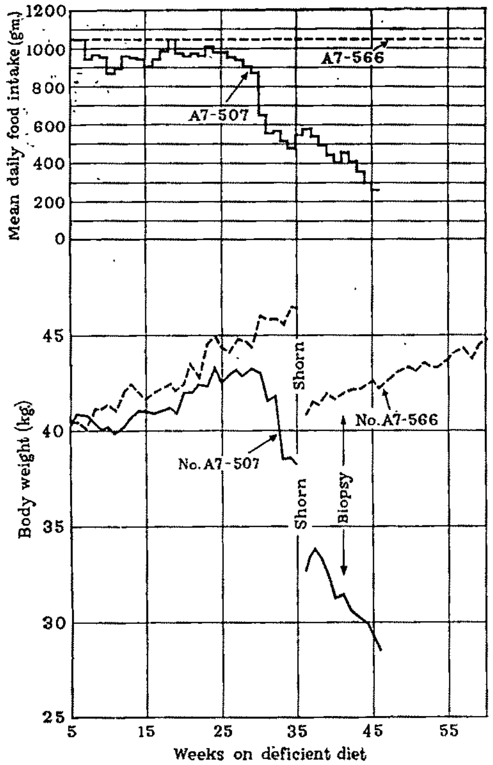

Fig. 6. Course of the vitamin B_{12}-deficiency syndrome in sheep *A*7-507

Criteria employed to assess the state of deficiency of sheep *A*7-507 were, failure of appetite, and the concentration of vitamin B_{12} in the liver and blood.

This animal and its control, *A*7-566, which was treated with adequate cobalt *per os*, were confined in pens and offered each day a cobalt-deficient ration composed of 1 kgm. of chaffed wheaten hay plus 50 gm. of gluten; the mixed fodder contained 0·023 μgm. cobalt/gm. The control animal avidly consumed the whole of the ration throughout. The appetite of the unsupplemented animal, unsteady after 8 weeks, failed progressively after 25 weeks, and thereafter reflected the degree of depletion below the minimum level commensurate with normal function. At 41 weeks, aspiration biopsy samples of the livers of the deficient and control animals contained respectively 0·08 and 1·12 μgm. vitamin B_{12}/gm. wet weight. The rate of depletion indicated by the vitamin B_{12} concentration in the blood was as follows:

Sheep No.	m.μgm. vitamin B_{12}/ml. blood at week number 26	32	41	56
*A*7-507 (deficient)	0·17	0·16	0·032	—
*A*7-566 (cobalt supplemented)	1·9	2·2	2·4	3·4

Sheep No. *A*7-507 was thus in an advanced stage of vitamin B_{12}-deficiency when it was slaughtered at 46 weeks to obtain its liver for the *in vitro* experiments reported in Fig. 5.

isomerase in the liver, as indicated by microbiological assays of the vitamin B_{12} content.

Some measure of further change occurs in both instances. When a $^{14}CO_2$-enriched atmosphere is employed, traces of fumarate and malate, both labelled with carbon-14, may be detected in the reaction mixtures.

As the total carbon dioxide bound in the combined methyl malonate and succinate fractions was observed in all instances to be closely similar, irrespective of additional co-isomerase—in the experiment reported in Fig. 5 they were, perchance, identical—it is clear that the potential efficiency of the propionyl carboxylating enzymes, described by Flavin and Ochoa[1], is not impaired in vitamin B_{12} deficiency.

The virtual stasis in the capacity of the intact mitochondria from the livers of vitamin B_{12}-deficient sheep to catabolize propionate invites comment. In the absence of a necessary quota of methyl malonyl co-isomerase, it is conceivable that conversion of propionate to succinate by an orientated array of enzymes within the mitochondria is stemmed back by local high concentrations of methyl malonyl coenzyme *A* at the reaction site. Such local accumulations of this intermediate as could greatly impede clearance through the propionate → methyl malonate → succinate channel would be relatively minute in terms of concentration within the reaction mixture as a whole. Certainly, sensitive chromatography failed to demonstrate the presence of either methyl malonate or its coenzyme *A* thioester in these reaction mixtures.

The methyl malonyl co-isomerase, employed in the first experiments (Fig. 5), was isolated from sheep's liver by a procedure similar to that employed by Barker and his colleagues[2] for the isolation of the adenyl cobamide coenzyme from *Clostridium tetanomorphum*.

As it was feasible for us to separate only a small quantity of the active vitamin B_{12} component from the liver, the precursor vitamin B_{12} was tagged with cobalt-58 to facilitate its identification during fractionation. On each of four consecutive days, 25 μgm. of vitamin B_{12}, containing 2·92 μc. cobalt-58 vitamin B_{12} was injected subcutaneously into a vitamin B_{12}-deficient sheep. The animal was slaughtered 24 hr. after the last injection. Its liver, which contained 14·3 per cent of the total radioactivity administered as cobalt-58 vitamin B_{12}, was finely ground, together with sufficient normal sheep's liver to yield 2 kgm. of minced tissue. After extraction with 80 per cent ethanol and preliminary purification, the major radioactive peak of the *p*H 6·4 eluate of the material adsorbed on a 'Dowex-50' *p*H 3·0 column was collected, extracted with phenol and re-extracted finally into 18·6 ml. of water. This solution contained 30 per cent of the cobalt-58 present in the original liver-mash. Addition of potassium cyanide to a sample of it changed the absorption spectrum to a curve, with maxima at 350, 367 and 581 mμ, that is characteristic of the cobamides. Microbiological assay (*Lactobacillus leichmannii*) of this sample indicated a concentration of $7 \cdot 9 \times 10^{-6}$ molar co-isomerase in the final solution.

The relationship between the concentration of the coenzyme and the rate of conversion of propionate to succinate by homogenates of the livers of vitamin B_{12}-deficient sheep under the conditions outlined in the legend to Fig. 5 agreed tolerably well with the requirements, *Km.*, of the Michaelis–Menten equation[5]. This criterion was employed for the comparison of the sample separated from liver with the two samples of 5:6-dimethylbenziminazole cobamide coenzyme kindly presented by Dr. Barker and Dr. Perlman. In the experiments employed for this purpose the concentration of the former was assessed from its vitamin B_{12} content: the concentrations of the crystalline samples were determined spectrophotometrically[6]. The apparent *Km.* values of all three ranged closely about 9×10^{-9} *M*. Thus there is little doubt that the coenzyme reported in Fig. 5 was in fact identical with the crystalline preparations.

R. M. Smith

Lack of Influence of Vitamin B_{12}-Deficiency on the Sheep's Capacity to metabolize Glutamate

Barker *et al.*[7] fixed attention on the essential function assumed by derivatives of vitamin B_{12} and its analogues in transfer reactions concerned with isomeric change by demonstrating that *Clostridium tetanomorphum* metabolizes L-glutamate via α-L-β-methylaspartate to mesaconate, and proving that the isomeric conversion of L-glutamate to α-L-β-methylaspartate is normally dependent on a coenzyme form of pseudo-vitamin B_{12} (adenyl cobamide).

In animal tissues L-glutamate is usually considered to be catabolized by simple oxidative deaminization to α-ketoglutarate[8], with which it forms an equilibrium, thence via the Krebs cycle. An alternative pathway in which aspartate and oxaloacetate are involved has recently been suggested[9].

The sheep's capacity to deal with glutamate is uninfluenced by vitamin B_{12} deficiency.

The procedure adopted in the experiment reported here is typical of the series in which comparative determinations were made on the same animal before and after correction of the imposed deficiency by injection of vitamin B_{12} (Fig. 7).

Glutamate in the blood plasma was estimated, after precipitation of the proteins[10] with picric acid and removal of the excess picric acid from the filtrate on a column of the chloride form of 'Dowex 2-X8', by separation[11] from other amino-acids on a column of the acetate form of 'De-Acidite *FF*' and estimation with ninhydrin.

As the peak of the concentration of glutamate in the blood stream immediately subsequent to the infusion of 3·5 m.mol. of glutamate/kgm. body-weight was somewhat above renal threshold, about 20 per cent of the glutamate injected was passed in the urine during the course of 5 hr. The findings, however, leave little doubt that, in sheep, vitamin B_{12} does not enter into any of the metabolic transactions involved in the catabolism of glutamic acid (Fig. 8). Under the conditions of the experiment the defect in the metabolism of propionate is clearly revealed (Fig. 9).

S. H. Allen
H. R. Marston

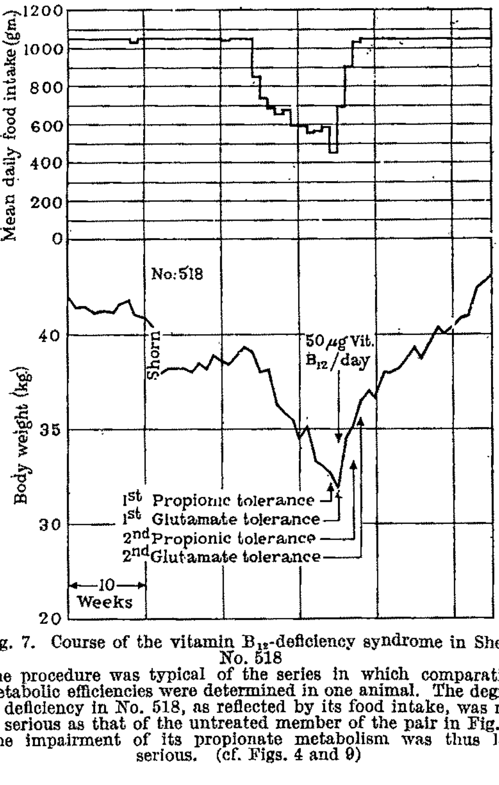

Fig. 7. Course of the vitamin B_{12}-deficiency syndrome in Sheep No. 518

The procedure was typical of the series in which comparative metabolic efficiencies were determined in one animal. The degree of deficiency in No. 518, as reflected by its food intake, was not so serious as that of the untreated member of the pair in Fig. 1. The impairment of its propionate metabolism was thus less serious. (cf. Figs. 4 and 9)

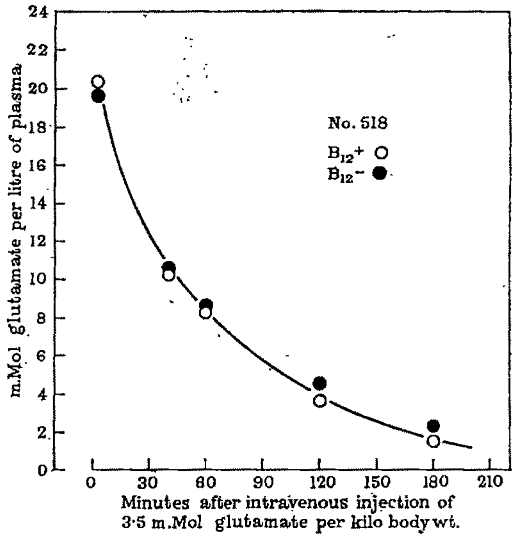

Fig. 8. Lack of effect of vitamin B_{12}-deficiency on the metabolism of glutamate

The concentrations of glutamic acid prior to injection were about 0·07 m.mol. per litre of plasma

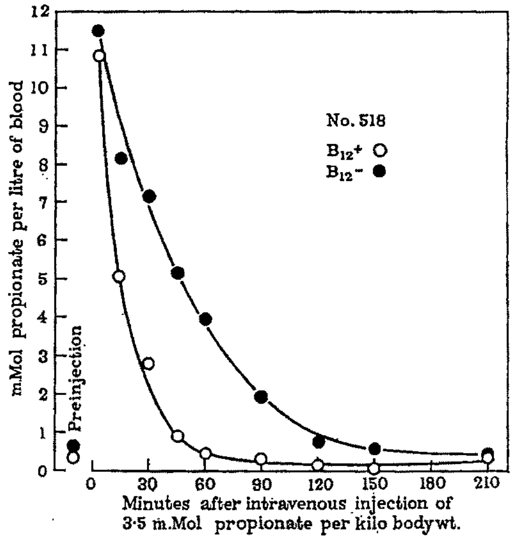

Fig. 9. Effect of vitamin B_{12}-deficiency on the metabolism of propionate

LETTERS TO THE EDITORS

HISTORY OF SCIENCE

Observation in the Year 1648 of Diffraction through a Lattice

In the first half of the seventeenth century there worked in Bohemia the naturalist, physician and philosopher, Ioannes Marcus Marci (1595–1667), professor of the Faculty of Medicine in the University of Prague. It is known that Marci published in 1639 his book "De proportione motus", wherein he defined the laws governing impact of spherical bodies.

Besides other works in the field of physics, mathematics, medicine and philosophy he also wrote a book *Thaumantias. Liber de arcu coelesti deque colorum apparentium natura, ortu et causis* in the year 1648, in which he dealt with the origin and qualities of rainbow and "fictitious" (spectral) colours.

The book is remarkable in that Marci described in it certain observations of phenomena in the field of physical optics, about which published reports appeared only much later. Marci described, but without correct knowledge of the causes of these phenomena, the colour of thin plates (p. 241) and diffraction (pp. 103, 111, 119, 138, 178). In these chapters Marci did not speak only of diffraction on a wire, edge and aperture, but spoke directly (p. 119) about the system of apertures, which he called the lattice ("reticulum"):

"If you put the lattice before a light source, you will see as many rainbows, as there are apertures", as translated from the original, namely, "... si reticulum opponas luminoso, nam totidem irides, quot foramina, videbis".

Marci spoke of the lattice also on p. 138. "Itaque cancelli reticulatim intersecti ad singula foramina suas irides habent proprias."

Furthermore, Marci also mentioned the observation of spectral colours on the apertures formed by meshes of wires or threads (p. 103):

"Or plate with the apertures in the form of grating or twisted wires (threads) develops as many rainbows as one has apertures or slits through which light penetrates. Individual glasses in window frames behave in a similar way. But if we put a net in front of one of them, again there appears as many rainbows as there are apertures", from the original, namely: "Quin lamella in modum reticuli pertusa, aut filamenta convoluta totidem irides procreant, quot foramina seu rimae luci perviae. Ita quoque orbiculi vitrei fenestrarum singuli suas irides habent. Atque si illorum uni reticulum obtendas, rursum totidem irides quot foramina procreabis".

These quotations from Marci's book "Thaumantias" allow us to date the first known report about diffraction through lattices to the year 1648, that is, to the year of issue of his book.

I thank Dr. Ladislav Křivský, scientific worker of the Czechoslovak Academy of Sciences, for his support.

PHYSICS

Concentration of Atmospheric Radon and Wind Direction

It is usually assumed that atmospheric radon comes from the Earth's crust by a slow diffusion process[1,2]. We may expect that radon concentration will change with wind direction at the time of sampling, according to the geographical and geological configuration near the sampling station.

The situation of our laboratory, in Lisbon, near the sea, is therefore excellent to test any probable relationship between radon concentration and wind directions since only half the possible wind directions are continental ones, therefore corresponding probably to higher radon concentrations. In order to study any correlation, the concentration of radon in air has been measured, by a method described in ref. 3. The wind directions have been recorded as is usually done in meteorology (sixteen directions).

Table 1 shows the number of observations for each direction and radon concentration data grouped in ranges of 5 × 10^{-14} c./l. In Fig. 1 the mean value of radon concentration corresponding to each wind direction is plotted in polar co-ordinates centred in Lisbon, over a chart of Portugal. From this we can conclude:

(1) Continental winds are generally related to higher concentration-levels of atmospheric radon.

(2) Sharp maxima are observed in those directions passing over the regions where uranium ores are present in great quantities.

Variations of radon concentration with wind direction have already been observed by Tanaevsky and Vassy[4], and Stierstadt[5]. In the present work we can, furthermore, correlate higher concentration-levels with those directions corrsponding to well-established situations of uranium ores.

The above conclusions should be kept in mind when we intend to use the variation of radon concentration in the atmosphere as a sign of temperature inversion, particularly in those places where the geographical situation may explain radon variations by any other reason, as for example in Lisbon, as we found.

Electrical Conductivity and Thermoelectric Power of Calcium Oxide

During recent years a number of experimental investigations of the physics of the oxide-coated cathode have taken the form of determinations of the thermionic and electrical properties of the individual alkaline earth oxides. The work reported in this communication represents part of a programme of research on calcium oxide, a component of some commercial mixed oxide coatings which has received but little attention.

The electrical conductivity of samples of calcium oxide has been determined in an experimental arrangement in which the oxide, in a layer about 100μ thick, is contained between two nickel cathode buttons. Each button is provided with an independent heater and the temperature of the nickel base may be determined by the use of a tungsten–nickel thermocouple attached to it. The assembly is attached to a glass pinch and is contained within a glass envelope, attached to a vacuum system. The oxide sample is prepared by the pyrolysis of a carbonate suspension, and after the usual techniques of breakdown, outgassing and activation (by applying 4 V. d.c. between the nickel buttons at 1,100° K., with frequent reversals of polarity, for a period of up to 12 hr.) the tube is sealed off from the system and an active barium getter is fired.

Measurements of the electrical conductivity of the calcium oxide sample as a function of temperature are made by setting both nickel buttons to the desired temperature T and determining the conductivity current when potentials of up to 500 mV. are applied between the buttons. For small applied voltages, the current-voltage characteristics are linear, the gradient providing a measure of the conductivity σ of the sample. Graphs of log σ versus $1/T$ show the characteristic form associated with conduction in the porous sample: a typical curve is shown in Fig. 1. Following the interpretation of Loosjes and Vink[1] the linear portion at lower temperatures (up to about 800° K. in this case) is associated with semiconduction through or over the surface of the crystallites making up the sample; the gradient of the low-temperature portion corresponds to an activation energy of 0·72 eV. for this process, for the particular state of sample activation under investigation. A second linear portion occurring between about 800° K. and 1,000° K. is associated with the thermionic emission of electrons within the pores of the sample. The activation energy of this high-temperature process, corrected for the parallel low-temperature mechanism, is 1·27 eV. Deviation from linearity at higher temperatures may be due to the current density in the pores becoming large enough for space-charge effects to be important. The most active samples gave an average low-temperature activation energy of about 0·7 eV., and an average corrected high-temperature activation energy of about 1·2 eV. Measurements in the low-temperature region were often hampered by the effects of thermal

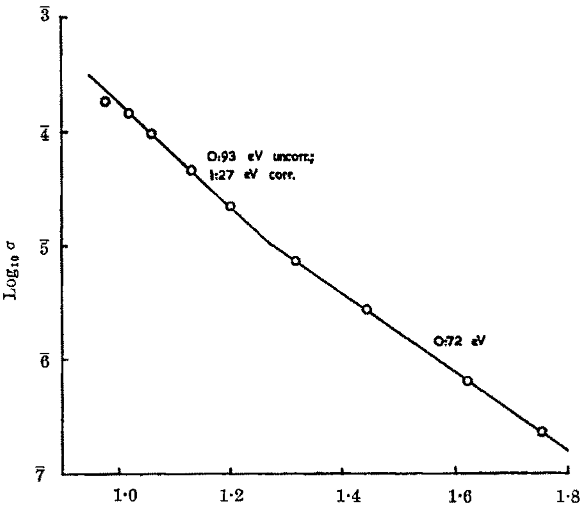

Fig. 1. Electrical conductivity of activated calcium oxide as a function of temperature. The conductivity σ is expressed in ohm^{-1} cm.$^{-1}$

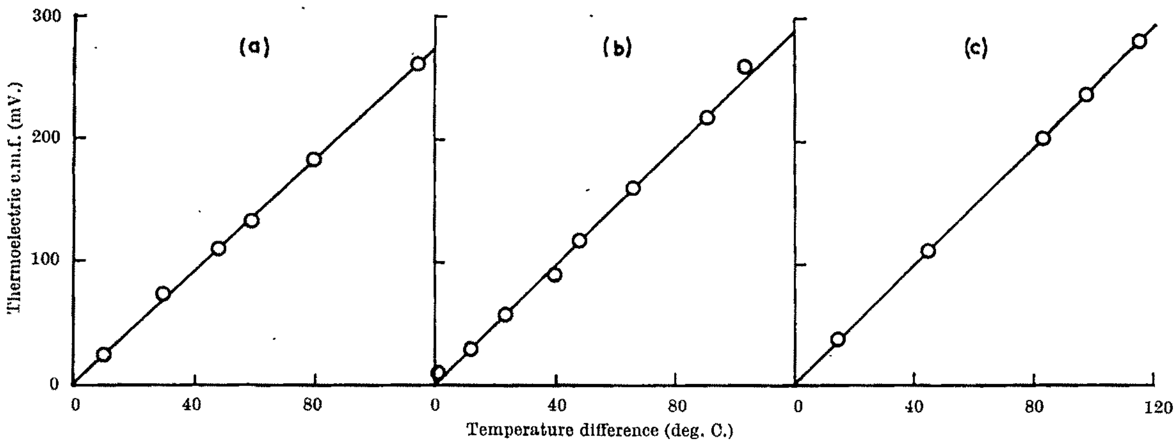

Fig. 2. Thermoelectric e.m.f. versus temperature difference characteristics for calcium oxide. *a*, $\bar{T}$ = 896° K., thermoelectric power = 2·30 mV. °C.$^{-1}$; *b*, $\bar{T}$ = 823° K., thermoelectric power = 2·41 mV. °C.$^{-1}$; *c*, $\bar{T}$ = 749° K., thermoelectric power = 2·43 mV. °C.$^{-1}$

expansion in the sandwich system ; slight changes in the area of contact of the crystallites would be expected to have a considerable effect on the component of the conduction current due to true semiconduction, but only a small effect on the thermionic emission component. The average activation energies are in reasonable agreement with the values quoted by Hopkins and Vick[2] (0·8 and 1·3 eV.) from measurements of the electrical conductivity of calcium oxide with a different sample geometry.

The experimental arrangement adopted allows, in addition, the measurement of the thermoelectric power of the oxide. If the buttons are maintained at different temperatures, a thermoelectric e.m.f. is set up between the faces of the sample which may be measured with a vibrating condenser electrometer of effectively infinite impedance. It is convenient to increase the temperature of one button and decrease that of the other so that the mean temperature $\bar{T}$ is approximately constant. It is found that the thermoelectric e.m.f. thus produced is approximately proportional to the temperature difference between the buttons (at least for temperature differences of up to about 120° C.), and the gradient of the thermoelectric e.m.f. versus temperature-difference characteristic defines the thermoelectric power of the specimen at the mean temperature $\bar{T}$. A typical series of characteristics for a particular sample of calcium oxide is given in Fig. 2. Although in many cases the thermoelectric power shows a tendency to increase with decreasing mean temperature, the experimental error involved in individual measurements of thermoelectric power is too great to allow an accurate determination of the temperature variation. Metson and Holmes[3], in a study of the thermoelectric power of the mixed oxide (BaSr)O, suggest that in the high-temperature range the thermoelectric power is in fact constant, the apparent temperature variation being due to experimental inaccuracies. On this assumption an average thermoelectric power for calcium oxide in the temperature-range 700–1,200° K. has been calculated from determinations on a number of oxide samples : the value obtained is 2·4 ± 0·2 mV. deg. C.$^{-1}$.

Modification of Spectrophotofluorometer for Scanning Paper Strips

THE spectrophotofluorometer is a potent addition to biochemical investigations[1]. The apparatus, at present available from commercial sources, is designed for analysis of liquid solutions. By modifications of the basic design of the spectrophotofluorometer, as indicated in Fig. 1, the spectrophotofluorometric analysis can be applied conveniently to paper strips.

A mirror (*A*) deflects the pathway of the activating light which focuses at the point (*B*) on the paper strip which is mounted on the drum (*C*).

The paper strip used is obtained by high-potential paper electrophoresis. An example of such a result is shown in Fig. 2, for separation of three indolic compounds. The paper strips, resulting from the high-potential electrophoretic process, were dried and mounted on the drum (*C*) of the instrument by means of black insulation tape. There are, on the surface of the drum, six guides to accommodate six strips of paper 23 × 3/4 in. on six levels. By means of the lock mechanism of the shaft (*D*) supporting the drum, each of the six levels corresponding to the six strips can be brought into the focus of scanning without opening the lid of the drum chamber. The drum is set into rotation by a motor (*E*) at any level synchronously with the recorder.

Although the instrument can be applied to paper strips obtained by one-dimensional paper chromatography, the sharpness of separation obtained by high-potential electrophoresis makes the latter better suited to this technique.

The data so far available with reference to fluorescence of compounds of biological interest refer mainly to fluorescence of solutions. These data cannot be simply extrapolated to the fluorescence phenomena under discussion, because the compounds separated on the paper under scanning are in a solid state.

In the experiment such as Fig. 2, the best settings for fluorescence under these conditions, for most of the indolic compounds tested, are 2900 Å. for the activation wave-length, and 3400 Å. for the fluorescence. These data are not very different from those given for the fluorescence in water solution for tryptophan (*p*H 11), serotonin (*p*H 2) and tryptamine (*p*H 7) (ref. 2). It is expected, however, that data reported by other investigators, with regard to fluorescence of compounds of biological interest, in

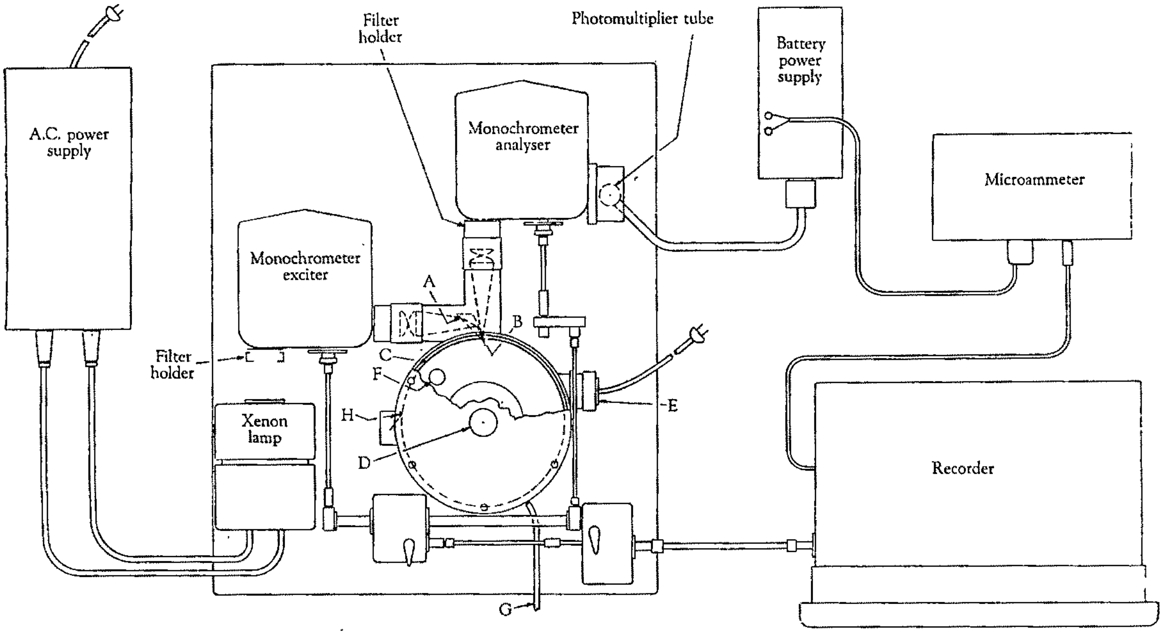

Fig. 1. Modification of spectrophotofluorometer for the spectrofluoro-phoretogram

solutions at various *p*H are not necessarily in agreement with the fluorescent data under discussion. Similarly, other salient features of fluorescence of compounds in solution such as quenching by chemical means or change induced by freezing would have to be retested. The drum in the basic part of this instrumentation serves not only for the purpose of scanning with least danger of contamination of the sample, but also to provide cooling of the paper, by introducing liquid nitrogen through one of the inlets (*F*), while the system is flushed with dried nitrogen-gas, introduced through the inlet (*G*) for prevention of fogging. The temperature of the paper surface is defined by the reading of the thermocouple making switching contact on the paper at point (*H*).

In view of the above-mentioned combination of high-potential paper electrophoresis and spectrophotofluorescent scanning technique, and because the fluorescence is of compounds in the solid state rather than in solution, the term spectrofluoro-phoretogram (SFPG) is proposed to specify the data (as in Fig. 2) obtained by scanning the paper electrophoretic pattern by means of this apparatus.

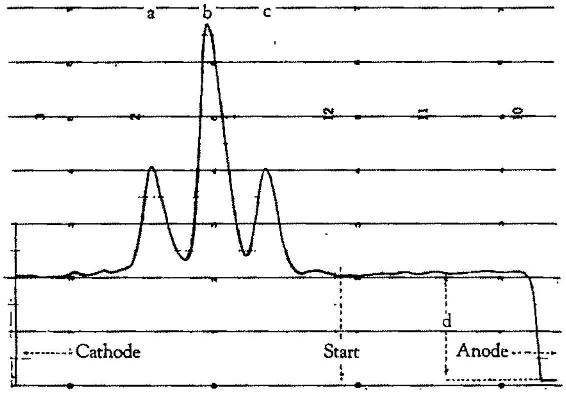

Fig. 2. Spectrofluoro-phoretogram (SFPG) of separation of L-tryptophan, serotonin and tryptamine. *a*, Tryptamine (equivalent to 4γ); *b*, serotonin (equivalent to 3γ); *c*, L-tryptophan (equivalent to 2γ); *d*, 'background fluorescence' of the paper strip. Axial Migration of Particles in Poiseuille Flow

IT was reported recently[1] that rigid spheres concentrate into a thin annular region when an initially uniform suspension undergoes laminar flow through a straight circular tube at particle Reynolds numbers between 10^{-3} and 6×10^{-2}; while not completely explained, the phenomenon was attributed to the Magnus inertial effect.

We have conducted similar experiments with single spheres, rods and disks at much lower Reynolds numbers ($<10^{-6}$), and have found that migration of the particles away from the walls occurs only when the particles are deformed in the shear field. The rotation of rigid particles in spherical elliptical orbits and the deformation of fluid drops into prolate spheroids agreed well with the corresponding theories of Jeffery[2] and Taylor[3] for Couette flow.

The experiments were rigorously controlled to prevent sedimentation of the particles and to exclude convection currents. The suspending fluid flowed through a vertical precision-bore tube of radius $R =$

0·4 cm. and isolated particles were observed (without optical distortion) in the median plane of the tube normal to the viewing axis of an electrically driven travelling microscope. Reproducible flow was produced by an automatic infusion-withdrawal pump which moved the liquid back and forth through the tube.

Continuous experiments were conducted over periods up to 24 hr. at flow-rates Q varying from 3·5 to 7·0 × 10^{-2} cm.^{3} sec.$^{-1}$ using rigid polystyrene spheres (radius $b = 0{\cdot}01$ cm.) and disks ($b = 0{\cdot}04$ cm., particle axis ratio $r_p = 0{\cdot}20$) and 'Dacron' rods (length $l = 0{\cdot}04$ cm., $r_p = 30$). Even when the particle centres were within $2b$ or l of the wall, no measurable migration occurred after the particles travelled over distances between 350 and 3,500 cm.

In striking contrast, liquid drops and tiny threads undergoing shear-deformation[4,5] migrated towards the tube axis. With liquid drops the rate of migration $-(\mathrm{d}r/\mathrm{d}t)$ increased with increasing b, Q and radial distance r from the tube axis.

An analysis of the forces operating on a fluid sphere has shown that when the velocity gradient G in the suspending fluid varies from one side of a particle to the other, there is a net force driving the particle in the direction of diminishing G. In Poiseuille flow, the gradient varies linearly with radial distance r from the tube axis:

$$G = -kr \qquad (1)$$

where

$$k = 4Q/\pi R^4 \qquad (2)$$

The net radial force on a fluid drop is calculated with the aid of Taylor's theory[6] for small deformations to be:

$$F_{rr} = \pi^2 b^3 \eta_2 D f_1(p) \qquad (3a)$$

where D is the deformation given by[6]:

$$D = \frac{Gb\eta_2(19p + 16)}{\gamma(16p + 16)} \qquad (3b)$$

p being the viscosity ratio (suspended phase)/(suspending phase) $= \eta_1/\eta_2$, and γ the interfacial tension. Assuming that the drop is propelled radially with Stokes velocity (corrected for internal circulation[2]) the migration velocity becomes:

$$-\mathrm{d}r/\mathrm{d}t = \frac{\pi\eta_2}{48\gamma} f_2(p) k^2 b^3 r \qquad (4a)$$

where

$$f_2(p) = \frac{(19p + 16)(8p^2 + 39p + 30)}{3(16p + 16)(3p + 2)} \qquad (4b)$$

Integration of equation (4) yields:

$$\log_e\left(\frac{r_0}{r}\right) = \frac{\pi\eta_2}{48\gamma} f_2(p) k^2 b^3 t \qquad (5)$$

r_0 being the radial distance at time $t = 0$.

It should be noted that this theory predicts that no migration occurs with rigid spheres ($D = 0$) in Poiseuille flow and with deformable spheres in Couette flow ($k = 0$), in accord with experiment.

The variation of r with t for water drops (b = 0·02 to 0·04 cm.) in 50 poise silicone oil was measured in a range of values of k (1·8–7·1 cm.$^{-1}$ sec.$^{-1}$). When plotted according to equation (5) the experimental points fell on a single curve initially linear and then curving as the particle approached the tube axis. The mean measured/calculated slope of the linear portion was 0·3. In view of the neglect of wall proximity on the Stokes velocity and other approximations, the agreement with theory is good.

The phenomena reported here provide one possible mechanism for the development of a particle-free peripheral zone adjacent to the wall observed in the laminar flow of suspensions of deformable wood-pulp fibres[8] *in vitro* and of deformable red blood cells *in vivo*[9,10]. At the finite concentrations prevailing in these systems, however, axial migration of the peripheral particles may be expected to stop when the radial force F_{rr} is resisted by the elastic compression of the central core of particles, as actually observed in fibre suspensions.

Details of the theory and experiments will be published elsewhere.

This investigation was supported (in part) by U.S. Public Health Service research grant *H*–5911 from the National Heart Institute of the United States Public Health Service.

GEOPHYSICS

Dispersions of Multiple-Stroke Whistlers

THE dispersions of 233 multiple-stroke short whistlers recorded during the International Geophysical Year at Durban (geomagnetic co-ordinates 31° 34′ S., 93° 04′ E.) have been measured from sonagrams. Dispersions were determined graphically using the Eckersley[1] dispersion law $t^2 = D^2/f$, where t is the time-interval between the lightning flash producing the whistler and the arrival at the observer of the component of radiated energy of frequency f; D is a measure of the dispersion of the whistler. The linear relationship between $f^{-1/2}$ and t was plotted for each whistler, the dispersion being obtained from the slope.

Those whistlers with two components only were classified into three groups in which the intensity of the second component was (*a*) significantly greater than, (*b*) approximately equal to, and (*c*) significantly less than, that of the first component. In each case the mean value of the ratio D_2/D_1 of the dispersion of the second component to that of the first was calculated. The results are shown in Table 1.

Table 1. DISPERSION RATIOS OF COMPONENTS FOR WHISTLERS WITH TWO COMPONENTS ONLY

Intensity of second component	No. of records	No. with $D_2/D_1 > 1$	No. with $D_2/D_1 < 1$	Mean value of D_2/D_1
(*a*) Greater than first	43	39	4	1·10 ± 0·02
(*b*) Approximately equal to first	53	36	17	1·04 ± 0·01
(*c*) Less than first	34	24	10	1·07 ± 0·02
All groups	130	99	31	1·064 ± 0·009

Calculation of the 95 per cent confidence limits for the mean value of the dispersion ratio for all groups indicated that the probability of this ratio being less than or equal to unity is less than 1 in 10,000.

For those multiple-whistlers with three or more components the ratios of the dispersions of successive components are given in Table 2.

Table 2. DISPERSION RATIOS OF SUCCESSIVE COMPONENTS FOR WHISTLERS WITH THREE OR MORE COMPONENTS

Dispersion ratio	D_2/D_1	D_3/D_2	D_4/D_3	D_5/D_4	D_6/D_5	D_7/D_6
Mean value of ratio	1·04 ± 0·01	1·07 ± 0·01	1·05 ± 0·02	1·09 ± 0·04	1·05	1·07
No. of records	103	103	39	15	4	1

Although the number of records available for the values given in the last three columns of Table 2 is too small for these particular figures to be reliable, the overall analysis indicates a 4–6 per cent increase in the dispersion of successive components of a multiple-stroke short whistler.

It is interesting to note that this result may indicate support for the current-jet hypothesis of whistler generation proposed by Hoffman[2]. If a stream of energetic electrons passes upwards through the top of the thundercloud during each interval of time between successive strokes to ground, an accumulative process of enhancement of electron density in the whistler path may be expected, with a consequent increase in the dispersion of successive whistler components. Furthermore, if such a process were responsible for the enhancement of energy in successive whistler components, it would be expected that for those records in which the second component is the more intense the dispersion ratio would be greater than for those records in which the second component is less intense. That this is the case can be seen from Table 1. In group (*a*) the mean value of the ratio is 1·10 ± 0·02 with 90 per cent of the records giving $D_2/D_1 > 1$, while in group (*c*) a lower mean value of 1·07 ± 0·02 is obtained and only 70 per cent of the records give $D_2/D_1 > 1$.

Palæomagnetism and the Ancient Radii of the Earth

Cox and Doell[1], applying an earlier idea of mine[2], have determined a probable value of the Permian palæo-radius of the Earth. That communication was commented upon by S. W. Carey[3]. In all probability, Carey's contention that the distance of the sampling localities has since increased due to tectonical events is correct. However, to estimate the amount of the increase in distance as suggested by Carey means substituting one hypothesis by another, since Carey's theory is itself a hypothesis which awaits detailed proof and which will perhaps be found invalid in its present formulation. Since the application of palæomagnetic measurements to the determination of palæo-radii is just a way of proving the expansion of the Earth without auxiliary assumptions, the introduction of such assumptions certainly detracts from the value of the method as a proof.

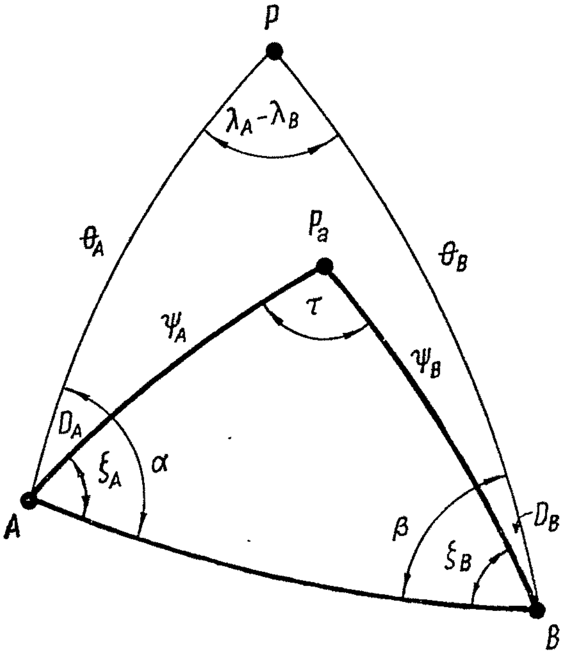

Fig. 1

Instead of the procedure suggested by Carey, I should like to propose a further refinement of the method employed by Cox and Doell as follows:

(1) In a given age, the radius was practically the same for the whole Earth: consequently, it would be possible to treat together the data concerning separate stable blocks in a given period, diminishing thereby the statistical error.

(2) Plotting the data for radii for the individual periods against time, and applying a least-squares adjustment by assuming a linear variation with time, it would become possible to use almost all palæomagnetic data in determining the trend and rate of increase of radius. This would further decrease the statistical error.

Otherwise, I am convinced that the increase of radius can be considered linear and steady to a good approximation for at least the past 3 × 10^9 years and that the rate of increase is less than 1 mm. a year. In my opinion Carey's value is exaggerated.

(3) Undoubtedly, the method of determining palæo-radii is subject to the fewest possible errors if it is applied to sampling localities along the same palæo-meridian, but a very simple generalization permits the utilization of sampling localities not on the same meridian, and thus covers the bulk of the data. The palæomagnetic measurements on a given stable block and for a given geological period yield the inclinations I_A and I_B and declination D_A and D_B for two localities A and B. The distance $AB = d$ is also known for the present. The ancient pole position P_a and the points A and B form the apices of an ancient spherical triangle; the sides $AP_a = \psi_A$ and $BP_a = \psi_B$ are known ($\text{cotg}\,\psi_A = \frac{1}{2}\tan I_A$; $\text{cotg}\,\psi_B = \frac{1}{2}\tan I_B$) and it is possible to calculate the angles situated at the apices A and B, ζ_A and ζ_B ($\zeta_A = \alpha - D_A$ and $\zeta_B = \beta - D_B$, where α is the angle subtended by the present meridian through A and the segment AB and β the angle subtended by the present

meridian through B and the segment AB). Now we have:

$$\sin \alpha : \sin (\lambda_A - \lambda_B) = \sin \theta_B : \sin \Delta$$

$$\sin \beta : \sin (\lambda_A - \lambda_B) = \sin \theta_A : \sin \Delta$$

$$\cos \Delta = \cos \theta_A \cos \theta_B + \sin \theta_A \sin \theta_B \cos (\lambda_A - \lambda_B)$$

where Δ is the present-day central angle subtended by the segment AB, θ_A and θ_B are the present colatitudes of the points A and B and λ_A and λ_B are the present longitudes.

If now the values of ψ_A, ψ_B, ζ_A, ζ_B and d are known, then from the relations:

$$\cos \psi_A \cos \psi_B + \sin \psi_A \sin \psi_B \cos \tau = \frac{b}{a} + \frac{1}{a} \cos \tau = \cos \Delta_a$$

$$\frac{\sin \zeta_A}{\sin \psi_B} \sin \Delta_a = c_1 \sin \Delta_a = \sin \tau$$

$$\frac{\sin \zeta_B}{\sin \psi_A} \sin \Delta_a = c_2 \sin \Delta_a = \sin \tau$$

we have:

$$\begin{array}{l} \cos \tau = a \cos \Delta_a - b \\ \sin \tau = c \sin \Delta_a \end{array} \quad \text{where } c = \sqrt{c_1 c_2}$$

Whence:

$$(a \cos \Delta_a - b)^2 + c^2 \sin^2 \Delta_a = 1$$

Thus we have the equation:

$$(a^2 - c^2) \cos^2 \Delta_a - 2ab \cos \Delta_a + (b^2 + c^2 - 1) = 0$$

which determines Δ_a.

The value of the palæo-radius is:

$$R_a = \frac{d}{\Delta_a}$$

GEOLOGY

Hafnian Zircons

AMONG quadrivalent trace elements, hafnium is a constant and inseparable associate of the more common zirconium. All zirconium and zirconium-bearing minerals contain appreciable amounts of hafnium; zircon ($ZrSiO_4$), one of the most common accessory constituents in rocks, particularly those of granitic composition, is the main carrier of this element.

The highest hafnium content, as recorded recently by Levinson and Borup[1], is 22–24 per cent HfO_2. This was observed in zircons intergrown with the rare mineral thortveitite, $Sc_2Si_2O_7$, from a granite pegmatite in the Iveland area of Norway.

In connexion with geochemical studies of pegmatites in Uganda, Southern Rhodesia, Mozambique and South-West Africa, hafnium has been determined by X-ray fluorescence in zircons from various pegmatites and, for comparison, in zircons from other environments. The hafnium contents thus found have varied from 1 per cent HfO_2 in a zircon from the Sukulu carbonatite in Uganda, to 31 per cent HfO_2 in a zircon from a lithium-bearing pegmatite near Karibib, in South-West Africa.

It has been observed that zircons high in hafnium occur in certain lithium-bearing pegmatites rich in tantalum and carrying a typical suite of minerals such as tantalite, manganotantalite, microlite, cassiterite, amblygonite, manganoapatite, rose-coloured beryl, topaz, etc., which represent a late phase of pegmatite crystallization.

Coherent pairs of elements, that normally occur together, may be enriched during successive stages of crystallization, and in some cases even separate to form independent minerals. Niobium and tantalum—the odd-numbered neighbour elements of zirconium and hafnium—are in many ways geochemically similar. Thus, on one hand, zirconium and niobium, and on the other hafnium and tantalum, are found to be enriched in the same geological environments. Whereas tantalum may separate from niobium to form independent minerals, hafnium only becomes enriched relative to zirconium. According to Rankamä and Sahama[2], this may be explained partly by the abundance ratio of niobium/tantalum (11·4) being less than that for zirconium/hafnium (48·9).

Some lithium-bearing pegmatites constitute an example where almost complete separation of tantalum from niobium has occurred and tantalum minerals, for example, tantalite, manganotantalite, stibiotantalite, bismutotantalite, simpsonite, and a number of microlite varieties, have been formed[3]. If zirconium and hafnium are present in these pegmatites, the hafnium/zirconium ratio may well increase, and strongly enriched hafnian zircons, in which the weight percentage of hafnium may well exceed that of zirconium, are to be expected.

During the present work, two hafnian zircons have been examined in more detail, one from Mtoko in Southern Rhodesia, containing 21 per cent HfO_2, and the other from Karibib in South-West Africa, with 31 per cent HfO_2. In both cases the zircons are associated with the later tantalum-rich phase of mineralization. The Mtoko zircon forms small, mauve-coloured, independent crystals in the albitic zone of the pegmatite, and is associated with manganotantalite, microlite and bismutite. The zircon from Karibib occurs in larger reddish-brown masses, partly intergrown with minute manganotantalite crystals and set in a matrix of lithium-bearing mica, albite, quartz and kaolinized feldspar. Some crystals show dominant pyramid faces, with a suppressed prism.

The following properties have been determined for the hafnian zircons:

Mtoko zircon	sp.g. 4·91	R.I.ω = 1·920	ε = 1·972
Karibib zircon	sp.g. 5·2	R.I.ω = 1·92	ε = 1·97

Both zircons exhibit an intense golden-yellow fluorescence in ultra-violet light. The zircon from Karibib was found to be only weakly radioactive. A qualitative spectrographic analysis gave the following results:

Major: silicon, zirconium, hafnium.
Trace: beryllium, magnesium, aluminium, calcium, manganese, iron, tin.
Yttrium and rare-earths, if present, were below the limit of detection.

The zircon from Karibib was also chemically analysed, and the results obtained were as follows:

SiO_2	TiO_2	$\underbrace{ZrO_2 \quad HfO_2}$	Al_2O_3	Fe_2O_3	MnO	CaO	MgO	H_2O+	Total
29·20	0·0	70·20	trace	0·17	trace	0·0	0·0	0·23	99·80

The hafnium content as determined by X-ray fluorescence was found to be 31 per cent HfO_2.

X-ray powder data of the two zircons agree on the whole with the data given for zircon in the A.S.T.M. *X-ray Powder Data File.* As with many zircons, heating produces a more defined pattern for the Karibib zircon. Compared with low-hafnium zircon, *d*-values of the unheated Karibib mineral are distinctly larger, while the heated zircon has rather smaller values. (The radius of the Zr^{4+} ion is 0·82 Å. and of Hf^{4+} ion 0·78 Å.). The difference in spacing is, however, too small to be of any practical value in distinguishing hafnian from normal zircons. An interesting feature, perhaps significant for hafnian zircons, was noticed in the relative position of the three lines representing the indices (532), (424) and (523, 620). In the hafnian zircon from Karibib the centre line of this triplet is clearly displaced toward the low-angle one; in the hafnian zircon from Mtoko it lies in a median position and in normal zircons is distinctly displaced towards the high-angle line.

Some recent data on the geochemistry of hafnium in granite pegmatites have been given by Vainshtein *et al.*[4]. Their views concerning hafnium enrichment in the late pegmatite crystallates are in good agreement with those presented in this communication.

We are indebted to Dr. R. S. Bradley and Dr. D. C. Munro of the School of Chemistry in this University for provision of facilities and for helpful advice in connexion with the X-ray fluorescence analysis, and to Miss J. M. Rooke for the spectrographic analysis of zircon.

Salinity Response of Trace Element Concentration in *Crassostrea virginica*

In a search for ecologically significant variations in elemental concentrations in marine invertebrate skeletons, the concentrations of several trace elements in shells of *Crassostrea virginica* have been investigated. Samples of 71 specimens from 11 stations along the American coast between Massachusetts and Texas were analysed spectrographically for magnesium, strontium, manganese, sodium, boron, and copper. Correlations between elemental concentrations and the temperatures and salinities at which the oysters grew were assessed statistically.

At least five shells were sampled from each station. Wedge-shaped cross-sections were cut just behind the hinge region so that all periods of shell-growth, except the earliest, were represented, since reproducibility among shells from the same station was greatest in such samples. Ideally, average annual temperatures and salinities for periods of shell-growth should have been used, but precise data were not always available, so averages that include periods of several years not coinciding with shell-growth had to be used for some stations. Salinity data and mean concentrations ($\bar{X}$) and standard errors (*S.E.*) of several elements in all shells examined from each station are presented in Table 1.

Significant correlations were found between some elemental concentrations and salinity, although no correlations with temperature were apparent and neither strontium, magnesium, boron, nor copper was significantly related statistically to either temperature or salinity. For the results summarized here, a correlation coefficient (r) of 0·219 is significant at the 5 per cent confidence level. Significant correlations between elemental concentrations and salinity were found for manganese ($r = -0{\cdot}453$) and sodium ($r = +0{\cdot}356$). If individual strontium ($r = -0{\cdot}054$) and magnesium ($r = -0{\cdot}214$) concentrations are combined and then correlated with salinity, the coefficient is a significant $-0{\cdot}253$.

A multiple correlation of magnesium, magnesium plus strontium, manganese, and sodium with salinity has a coefficient of 0·533, higher than for any element alone. Taking into consideration the analytical accuracy and range of variation encountered in measured elemental concentrations among members of the same population, it appears that multiple regressions based on these four elements without transformation of raw data allow prediction, from concentrations in a single shell, of average salinity of waters in which shell-growth occurred, with a standard error of 5·3 parts per thousand. The accuracy of prediction may be enhanced by increasing the number of stations from which raw data are assembled and by increasing sample size. Furthermore, the multiple correlation coefficient is improved and standard error reduced when calculations are based on an assumption that the diadochic elemental correlations are logarithmic. Evidently the simple correlations are not linear. To certify their forms and assess fully their significance requires knowledge of elemental concentrations in the sea-water of shell-growth, which is not available.

Elements correlated negatively with salinity are those that are presumably diadochic with calcium in the calcite structure. Discrimination of *C. virginica* against these diadochic elements thus decreases in

waters of low salinity. Perhaps the lowered concentration of the preferred calcium ions stimulates acceptance of less desirable ions for shell construction. On the other hand, sodium is probably interstitial, and thus reflects salinity directly.

As characteristic differences in tolerance for trace element concentrations are found among even closely related taxa[1,2], the responses of other pelecypods are still conjectural. However, trace elements in fossil shells of *Crassostrea virginica* may be studied with the aim of establishing palæosalinities. Presumably, the accuracy of palæotemperature determinations by the oxygen isotope method may be enhanced by palæosalinity corrections.

This research was supported in part by a grant from the Petroleum Research Fund administered by the American Chemical Society, for which we are grateful.

Geological Age of the Sandringham Sands

THE Sandringham Sands, up to 100 ft. thick, form the basal member of the Cretaceous System in Norfolk and rest unconformably on the Jurassic (Kimmeridge Clay); their position in the Cretaceous time-sequence and their stratigraphical relations with other early Cretaceous deposits have hitherto remained in doubt owing to lack of palæontological data. Excavations near Abbey Station, West Dereham, Norfolk (Nat. Grid Ref. 53/65549969), made in connexion with the Fenland Flood Relief Scheme, have provided new sections in the Sandringham Sands from which officers of the Geological Survey and Dr. G. P. Larwood of the Sedgwick Museum, Cambridge, have collected a large suite of fossils indicative of a Berriasian (Infra-Valanginian) fauna new to Britain.

The fossils occur as clustered moulds in nodular masses of hard, grey-brown, glauconitic sandstone with carbonized plant debris, about 30 ft. above the base of the formation. Twenty-eight genera of Mollusca have been identified, mostly lamellibranchs, *Astarte* (*Neocrassina*), *Pholadomya*, *Panopea*, *Hartwellia*, *Isocyprina*, *Thracia*, *Myophorella* and *Isodonta* predominating. Cephalopods are represented by well-preserved examples of the ammonite *Hectoroceras*, described by Spath[1] in 1947 from S.W. Jameson Land, East Greenland, and by numerous hollow moulds of belemnite guards, including those of *Acroteuthis*. Some of the lamellibranch and belemnite species occur also in the Spilsby Sandstone (Berriasian) and superjacent Neocomian strata in Lincolnshire; others, such as the species of *Hartwellia*, *Isocyprina* and *Isodonta*, have their closest parallels in the Upper Jurassic (there is no previous record of *Isodonta* in the British Cretaceous, for example). Many of the shells were ravaged by the boring polyzoan *Graysonia*, only recognized recently in the Cretaceous faunas of Britain[2].

The fossiliferous sandstone is followed within a few feet by the Lower Greensand (Aptian–Lower Albian), this determination being suggested by a rolled specimen of the ammonite *Deshayesites* found among the excavated material. This means that any equivalent of the Snettisham Clay (Barremian) of north Norfolk or the Valanginian–Hauterivian sequence of Lincolnshire is either absent or is present only in greatly attenuated form.

It is now clear that the Sandringham Sands are wholly or in part of Berriasian age and that in the West Dereham area the hiatus at their top is probably as great or greater than that at their base. It is not yet possible, however, to say precisely where this fossil band in the Sandringham Sands fits in with the fragmentary Berriasian successions in Lincolnshire and Yorkshire. In the Spilsby Sandstone there are three distinct ammonite-levels, all characterized by forms of *Subcraspedites*; the lowest, with the sub-genus *Paracraspedites*, is thought to be more or less contemporaneous with the basal Berriasian of East Greenland[3]. *Subcraspedites* is found both above and below *Hectoroceras* in East Greenland, so that the most likely position of the Norfolk *Hectoroceras* fauna is a horizon within or just above that of the Spilsby Sandstone.

Dr. Larwood is preparing a preliminary stratigraphical account of the section. The Geological Survey material referred to above is being further examined.

AGRICULTURE

Evaluation of Effective Rainfall and Irrigation from Ground-water Measurements

A FRACTION of the total rainfall that reaches the ground water-table is called the effective rainfall[1]. Where there is irrigation, a fraction of the irrigation water also has been found to contribute to the rise of the water-table[2]. Effective values of rainfall and irrigation are usually determined using lysimeters[3]. The lysimeters, however, need correction for their size and the indications obtained from them are often high. A general figure found at Amsterdam dune water works, where there was no run-off, indicated that 61 per cent of a total rainfall of 659 mm. per annum was effective[1]. An actual determination of the rise in water-table over large areas has also been carried out by means of open well water measurements[4,5]. The effective values of rainfall and irrigation, however, do not seem to have been arrived at. An analysis of the changes in the ground-water level has therefore been taken up in this investigation, and the effective values of rainfall and irrigation were evaluated from the (fortnightly) measurements of the water-levels recorded for the past 20 yr. in thirteen wells randomly distributed over 565 acres of irrigated farm area of the Indian Agricultural Research Institute, New Delhi.

Fig. 1 gives the mean water-table levels on July 1 of each year, from 1940 to 1950, just before the beginning of the monsoons. This period is selected to be suitable as the water would reach a stable level just before the monsoons start[6]. The trends in the rise of

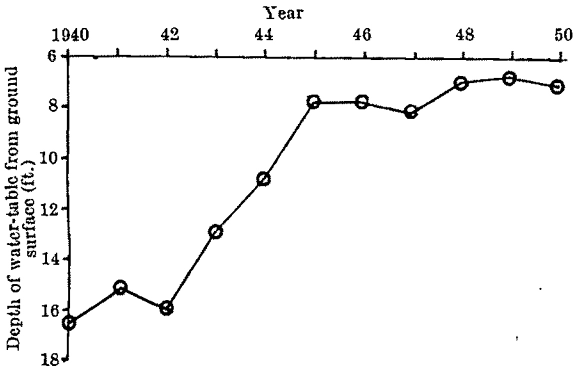

Fig. 1. Average water-table readings on July 1 each year

the water-table, however, remain the same irrespective of the period selected. As there is no conspicuous change in the level of the water-table after 1948, presentation of further data was not found necessary. The results indicate that during the years 1940–42 the increase in the ground-water level is small. During 1942–45, however, the rise in ground water is quite steep. This steep rise may be due to the fact that the drains then existing for the run-off provided on the farm area since 1936 were closed in 1942 with the view of conserving the rain water. In fact, the run-off became negligible in that period. The almost linear rise in the ground-water level permitted the evaluation of the effective values of rainfall and irrigation.

Table 1. WATER-TABLE RISE IN MONSOON PERIOD AT THE FARM AREA OF THE INDIAN AGRICULTURAL RESEARCH INSTITUTE, JULY 1–DECEMBER 31

Year	Rainfall R (in.)	Irrigation I (in.)	Well-water levels (ft.) on July 1	Well-water levels (ft.) on Dec. 31	Rise in ground-water level G (in.)
1942	21·24	15·97	15·97	12·80	38·04
1943	14·09	18·27	13·06	10·91	25·80
1944	22·82	22·86	10·93	6·53	52·80

Table 1 gives the rise in water-level in inches during the moonsoon period (July 1–Dec. 31), during which some of the rainfall or irrigation seeps down to the ground-water level. The other period, Jan. 1–June 30, is mostly a dry period at Delhi with scanty rainfall that just wets the top layers, but is not sufficient to saturate the top capillary zone and percolate down to the ground-water level.

The effective rainfall, aR, the effective irrigation bI, and the rise in the ground-water level, G, are related by the equation: $aR + bI = P.G$, where R and I are the values of the total rainfall recorded and the total irrigation given during the monsoon season, and P the fractional pore space at the ground-water level. A solution of the three resulting equations arrived at by the principle of least squares is:

$$a = 1{\cdot}69\,P \text{ and } b = 0{\cdot}36\,P$$

The first 4·5 ft. depth of the soil is sandy loam with about 50 per cent porosity, while the layers below this are characterized by the presence of *Kankar* (calcium carbonate), the concretions becoming more and more calcareous downwards[7]. Such a compact soil usually has a porosity varying from 25 to 30 per cent. Using these values for P, the values of effective rainfall and effective irrigation turn out to be 42 per cent–51 per cent and 9 per cent–11 per cent, respectively. The values of the effective rainfall seem to agree fairly well with the observations made earlier in refs. 8–10 on Indian sandy loam soils. The effective percolation from rainfall seems to be much more than that from irrigation. This is a tribute to the irrigation management, since the design avoids excessive percolation.

In balancing the ground-water rise, the lateral movements of ground water, if any, have not been accounted for. The effective values are thus the minimum values possible. Work is in progress on the effect of lateral movement on the ground-water balance.

We thank Dr. B. P. Pal for his interest in the progress of this investigation.

CHEMISTRY

Odour and Molecular Vibration

THE low-frequency vibrations of organic molecules are largely unexplored, so that it is difficult to test directly the hypothesis that odours may be correlated with them[1]. An indirect test was therefore devised.

The low-frequency Raman lines of nitrobenzene and methyl salicylate are reported[2] to be:

Nitrobenzene	183			408 cm.$^{-1}$
Methyl salicylate	185	263	356	423 cm.$^{-1}$

If these values are correct and complete, then, on the above hypothesis, their odours should be basically similar but with the odour of methyl salicylate altered from almond-like to wintergreen by the additional frequencies not possessed by nitrobenzene. It follows that a small amount of methyl salicylate added to nitrobenzene should be perceived by the nose more easily than a small amount of nitrobenzene added to methyl salicylate, provided due allowance is made for the different absolute thresholds of the two substances.

The olfactory threshold concentration of each substance when dissolved in 'Nujol' was determined by a modification of the American Public Health Association method[3]. A dilute solution of each substance in 'Nujol' was prepared, serial dilutions were made, and 10 ml. of each solution were placed in a series of *B. O. D.* bottles. (These are 250-ml. bottles with ground stoppers and a funnel-like enlargement of the neck. They were washed and baked overnight at 105° C. before use.) Other bottles contained 10 ml. additions of pure 'Nujol'. The bottles were numbered but otherwise unmarked. Each bottle containing a solution was placed with two blanks, and the observ-

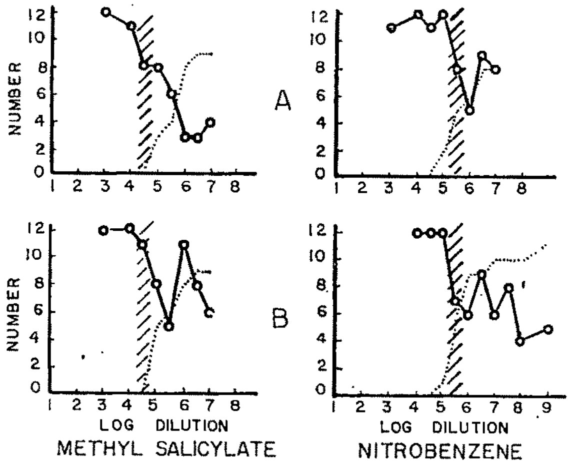

Fig. 1

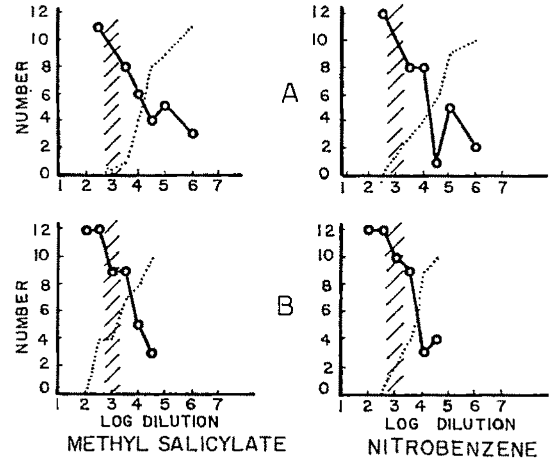

Fig. 2

ers were asked to smell all three and try to identify the 'one that was different'. The same twelve observers were used in all the experiments (except the last, Fig. 2*B*, when one new subject was used), which were all carried out in the same way and in the same room, and on four different days spread over a period of 10 weeks. The observers were given 45 sec. to smell each set of three bottles, 15 sec. to record the result, and then rested 60 sec. before smelling the next three. The strongest solutions were smelled first followed by the weaker ones in order, and all the solutions were made very dilute to minimize olfactory fatigue. The observers were told to guess if necessary, and to mark the guessed results.

The results of threshold determinations made on different days are shown in Fig. 1, *A* and *B*. The solid line shows the number of correct identifications of the 'odorous' bottle, and the dotted line the number of admitted guesses. The threshold concentration of methyl salicylate in 'Nujol' (indicated by the shaded area) is about 1 in 30,000, and that of nitrobenzene is about 1 in 300,000.

For the next experiment, a stock solution containing nitrobenzene in 'Nujol' at a concentration of 1 in 10,000 (= 30 × threshold) was made up and used in the pairs of blank bottles. The third bottle in each set contained the same base solution with a small addition of methyl salicylate. In a similar way, a base solution of methyl salicylate was made up containing 1 part in 1,000 (= 30 × threshold) and given small additions of nitrobenzene.

The observers then tried to determine the threshold concentration of one odorant in the presence of a constant amount of the other, with the results shown in Fig. 2, *A* and *B*. The threshold concentration for the perception of methyl salicylate in the presence of nitrobenzene was about 1 in 1,000, or 30 × the threshold for methyl salicylate by itself. For nitrobenzene to be smelled against a background of methyl salicylate, the threshold concentration was again about 1 in 1,000, but this is 300 × the threshold concentration for nitrobenzene alone.

Thus the wintergreen odour of methyl salicylate conceals the almond odour of nitrobenzene 10 times more effectively than the almond odour conceals the wintergreen odour. The effect is not large; but it is distinct, and it is in the direction predicted by the vibrational theory of odour.

I wish to thank Prof. E. S. W. Belyea and his students in the Department of Psychology of the University of British Columbia for carrying out the smelling tests.

The Relation between Theoretical and Experimental Diamagnetic Susceptibilities for Aromatic Hydrocarbons

IN calculations of the π-electron diamagnetic susceptibility of aromatic hydrocarbons by the method due to London[1], it is assumed that the calculated susceptibility χ^L is equal to the experimental anisotropy $\Delta\chi$. χ^L is, in fact, the susceptibility, due to delocalization of the π-electrons, in a direction perpendicular to the plane of the ring, which will be called the z-direction. In the semi-classical treatment due to Pauling[2] the same assumption was made, but Pauling went on to add to his calculated susceptibility the value obtained from Pascal constants[3] for the susceptibility in the plane, and he thus obtained the total susceptibility in the z-direction, χ_z. He compared his χ_z with the experimental values obtained from measurements of crystal susceptibilities. Later workers[4] have followed London rather than Pauling and sought to calculate $\Delta\chi$, not χ^L.

The identification of χ^L with $\Delta\chi$ has been criticized recently (refs. 4*a*, 4*b*), and Hoarau (ref. 4*b*) has suggested that the total anisotropy $\Delta\chi$ should be written:

$$\Delta\chi = \Delta\chi^\sigma + \Delta\chi^p + \chi^L \qquad (1)$$

where $\Delta\chi^\sigma$ and $\Delta\chi^p$ are the anisotropies due to the σ-bonds and the isolated $p\pi$-electrons, respectively. Support for Hoarau's view may be found in the work of Itoh, Ohno and Yoshizumi[5], who, in a calculation by the method of antisymmetrized molecular orbitals, obtained a value for χ^L equal to 49·6 per cent of the observed anisotropy for benzene, although Lykos and Parr[6] have suggested that most of the difference can be attributed to the approximation used in evaluating the resonance integral. A recent calculation I have carried out[7] using the simplified self-consistent molecular orbital method[8] gave a value of χ^L of $-33 \cdot 26$ (all susceptibility values quoted are $\times 10^{-6}$ c.g.s.e.m.u./mole) for benzene compared to the observed anisotropy[11] of $-59 \cdot 7$. A contribution to the π-electron susceptibility in the z-direction, χ_z^π, cf $-1 \cdot 35$ per carbon atom was also obtained. This is due to the effect of the field on the isolated $p\pi$-electrons. Thus, for an aromatic hydrocarbon containing n carbon atoms, χ_z^π can be written :

$$\chi_z^\pi = -33 \cdot 26\rho - 1 \cdot 35n \qquad (2)$$

where ρ is the ratio of χ^L for the given hydrocarbon to χ^L for benzene. Values for ρ obtained by London[1] and by McWeeny (ref. 4c) may be used in equation (2), which provides a simple way of approximating to a full self-consistent molecular orbital calculation.

It is well known that diamagnetic susceptibilities can be written as the sum of a semi-classical term and a paramagnetic or high-frequency term of opposite sign[10]. The high-frequency term can be calculated for a polyatomic molecule only by making severe approximations[11], and its occurrence in $\Delta\chi$ makes the latter a difficult quantity to calculate. χ_z^π, however, does not contain a high-frequency term, and an empirical value for χ_z^π can be obtained from the experimental value for χ_z by using the equation :

$$\chi_z^\pi = \chi_z - \sum_i \chi_i \qquad (3)$$

where χ_i is the Pascal constant[3] for the ith atom, $-6 \cdot 0$ for carbon and $-2 \cdot 9$ for hydrogen. The high-frequency term occurs in Pascal's scheme for conjugated hydrocarbons as the constitutive correction for a carbon–carbon double bond[3], $+5 \cdot 5$, which is, for this reason, not included in equation (3).

Table 1. ANISOTROPY ($\Delta\chi$) AND π-ELECTRON SUSCEPTIBILITY ($\chi_z\pi$)

Substance	$-\Delta\chi$ Exp.	$-\Delta\chi$ Calc.	$-\chi_z$ Exp.	$-\chi_z^\pi$ Exp.	$-\chi_z^\pi$ Calc.
Benzene	59·7[a]	(59·7)	94·6[a]	41·2	41·4
Naphthalene	114·0[b]	131[c]	169·0[d]	85·8	86·3
Anthracene	182·6[b]	206[c]	251·8[d]	139	134
Phenanthrene	166[b]	190[c]	240[b]	127	125
Pyrene	232·9[b]	266[c]	313·5[b]	189	170
Coronene	390[e]	585[f]	480[e]	301	358
Biphenyl	118·6[b]	112[f]	182[b]	81	78·4
p-Terphenyl	178·8[b]	163[f]	271·3[d]	123	115
p-Quaterphenyl	256[b]	214[f]	372[d]	176	152

Table 1 shows calculated and experimental values for χ_z^π obtained from equations (2) and (3) respectively. For comparison the results of calculations of the London type for the anisotropy are compared with the experimental values. The agreement between theory and experiment for χ_z^π is clearly better than for $\Delta\chi$, thus supporting the views expressed here.

A more satisfactory treatment of anisotropies would be possible if experimental values for the contribution of the high-frequency term were known for some conjugated hydrocarbons. This contribution can be obtained from the rotational magnetic moment[12], and an interesting comparison of theoretical and experimental susceptibilities has been made for certain systems[13] the rotational magnetic moments of which are known. At present, however, for conjugated hydrocarbons the comparison of χ_z^π suggested here would seem to be more satisfactory than an attempt to calculate anisotropies.

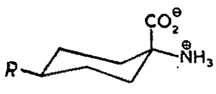
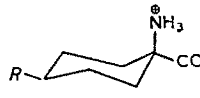
Alkylcyclohexanones in the Strecker and Bucherer Hydantoin Syntheses

THE reaction of 2- and 4-alkylcyclohexanones in the Strecker and Bucherer hydantoin reactions leads to geometrically isomeric alkylcyclohexane-1-amino-1-carboxylic acids. Paper chromatographic analysis shows that the crude product of the Strecker reaction consists of one isomer only, while the main product from the Bucherer reaction has the alternative configuration. Assuming the configuration of the 4-alkyl derivatives to be indicated by the sluggish hydrolysis of the 1-amino-4-tert-butylcyclohexylcyanide hydrochloride[1] in the Strecker synthesis, then the Bucherer products must have the opposite configuration.



Strecker product



Bucherer product

The evidence for the difference in identity is briefly : (i) The 4-methyl-, 4-ethyl-, 4-iso-propyl-, 4-tert.-butylcyclohexane-1-amino-1-carboxylic acids produced by the Strecker synthesis crystallize anhydrous from aqueous acetic acid, whereas the corresponding Bucherer products crystallize as hemi-hydrates from the same solvents. (ii) The melting points of the amino-acids and their derivatives are different :

Table 1

Cyclohexane carboxylic acid	Strecker product (melting point, ° C.)	Bucherer product (melting point, ° C.)
1-Amino-4-methyl-	356–360 (subl.)	305–310 (subl.)
1-Acetylamino-4-methyl- *	220–222	223–224·5
1-Benzoylamino-4-methyl-	209–210	234–236
4-Methyl-1-spiro-5′-hydantoin	215–216	281–282
1-Amino-2-methyl-	355–360	298–300
1-Acetylamino-2-methyl-	220–221	181–181·5
1-Benzoylamino-2-methyl-	174–175	196 (ref. 2)

* Mixed melting point, 170–185°

(iii) The infra-red spectra (in potassium chloride disks) are markedly different, particularly in the 6μ region, where the Strecker products alone give particularly well-resolved (amino-acid) bands. (iv) Different R_F values on Whatman No. 3*MM* paper using normal butanol–acetic acid–water as eluant.

These results indicate that the hydantoin synthesis does not proceed through the same intermediate amino-nitrile involved in the Strecker synthesis, as suggested by Bucherer[3].

Further work is in progress to confirm the configurations of these amino-acids and to elucidate the mechanisms of the reactions involved in their synthesis.

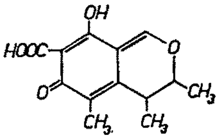
Chemical Structure of Citrinin

In our search for new antibiotics from fungi we have isolated a substance, *S*-52, a metabolic product of an unidentified *Penicillium*. From the results of paper-chromatographic investigations and from its other properties we believed the substance to be identical with citrinin. This has proved correct, since the infra-red spectra of the pure substance *S*-52 and of an authentic sample of citrinin (kindly provided by Dr. P. W. Brian, Akers Research Laboratories, Welwyn, Herts) were identical.

The measurement of the infra-red absorption spectra was carried out on a double-beam spectrophotometer *UR*-10 (*IR*-10), Zeiss, Jena. Sodium chloride cells 1·030 mm. thick were used and the concentration of citrinin was 4·5 gm./litre carbon tetrachloride.

Brown *et al.*[1] and Cramm[2] have proposed a chemical structure for citrinin according to the chemical reactions of this substance as follows:



(I)

The infra-red spectrum of citrinin (Fig. 1) indicates that the structure of citrinin differs from that proposed by these authors. Should citrinin have a free carboxylic group, this would be shown by an intense absorption band in the region above 1,700 cm.$^{-1}$, but this absorption band is absent.

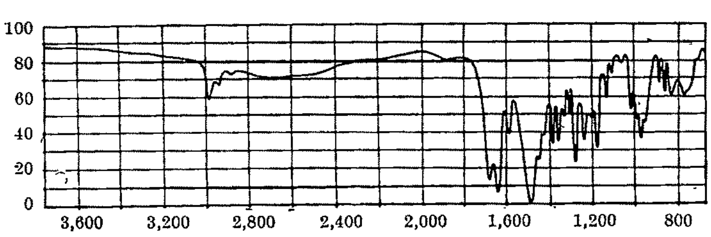


Fig. 1. Infra-red spectrum of citrinin. Ordinates, percentage absorption ; abscissæ, wave-lengths

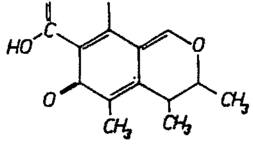
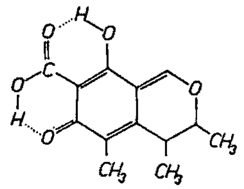
The absorption band in the region of 1,685 cm.$^{-1}$ belongs to the stretching vibrations of the C=O bond in the carboxylic group forming a strong chelate bond with the hydroxylic group situated in the ortho position[3,4]:



(II)

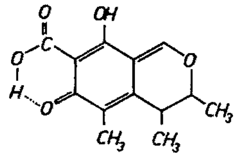
This is indicated also by the small intensity of the absorption band in the region of 3,700 cm.$^{-1}$. This is similar to the infra-red absorption spectrum of salicylic acid[3], where the absorption band in the region of 1,685 cm.$^{-1}$ belongs to the stretching vibrations of the C=O bond, forming a chelate bond. Salicylic acid can form only one chelate ring, but in the case of citrinin two can be formed:



(III)

The formation of one chelate ring as indicated by formula (II) would result in a weakening of the —OH bond in the carboxylic group and in this case there would be a relatively intensive absorption band in the region of 950 cm.$^{-1}$ belonging to the bending vibrations of the —OH group in the carboxylic group.

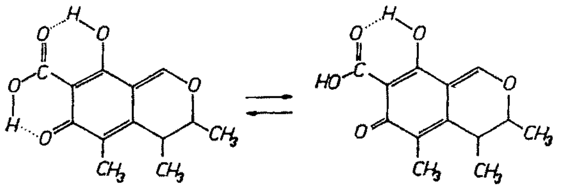
Should only one chelate ring, as indicated by formula (IV), be formed, the dilution of the electrons on the carbon atom of the carboxylic group would be compensated by the π-electrons of the double bond of the ring.



(IV)

In this case the —OH group on the ring would show itself by its +C-effect. By this the acidity of the hydrogen atom in the hydroxylic group would, of course, be greatly enhanced, and on the infra-red absorption spectrum a relatively intense absorption band would arise in the region of 3,600 cm.$^{-1}$.

As a relatively small absorption band is found in the region of 950 cm.$^{-1}$, and on the other hand a relatively broad absorption band belonging to the stretching vibrations characteristic for an intramolecular hydrogen bond appears in the region of 3,200 cm.$^{-1}$, we presume that citrinin is represented by formulæ (II) and (III) which are in equilibrium (V):



(V)

Table 1. CHARACTERISTIC INFRA-RED FREQUENCIES OF CITRININ

Frequency (cm.$^{-1}$)	Group	Nature of vibration
3,200		ring vibration (chinoid system)
2,935, 2,870	CH_3—	stretching C—H
1,685	C=O	stretching C=O
1,640	C=C	stretching C=C
1,600	C—H	stretching C—H (unsaturated)
1,480	C—H	bending C—H (asymmetrical)
1,380	C—H	bending C—H (symmetrical)
1,310	C—O	stretching C—O
1,180	=C—O—C	stretching =C—O—C
1,130	—O—	ring vibration
950	—OH	bending (in —COOH group)

The characteristic vibrations of the individual groups of atoms in the molecule of citrinin are presented in Table 1.

BIOCHEMISTRY

Imidazole Acrylic Acid Excretion in Kwashiorkor

CHILDREN who are suffering from severe kwashiorkor (protein-calorie malnutrition) lose a large proportion of their tissue solids[1]. Earlier work[2] has shown that in spite of a very low protein intake a relatively large amount of nitrogen is still excreted in the urine. The amount increases with the severity of the illness, which strongly indicates an endogenous origin. A considerable part of the nitrogen cannot be accounted for as urea, ammonia, free amino-acids, peptides, creatine, creatinine or uric acid. Evidence was obtained for the presence of nitrogenous material which absorbed ultra-violet light in the region 268–274 mμ. The fractionation of the material and the isolation of one of its components form the basis of this communication.

Initial separation was achieved by paper chromatography. 50–100 μl. of urine were applied to Whatman No. 1 paper and the chromatogram was run in *n*-butanol/formic acid/water (77 : 10 : 13). After drying, the chromatogram was examined in ultraviolet light by the method of Markham and Smith[3], and ten abnormal compounds were detected which appear in the urine of severe cases of kwashiorkor and disappear on successful treatment. The compound with the largest absorption, temporarily called *F*, has been isolated by the following method and identified.

Two litres of urine were shaken for 30 min. with 100 gm. of activated charcoal. After washing with 2 l. of distilled water, the absorbed material was eluted twice with 2 l. of 50 per cent v/v acetic acid. The eluate was concentrated by distillation under reduced pressure at 60° C. and finally in a vacuum desiccator. The resultant dark brown tar was redissolved in ammonium formate at *p*H 11 and aliquots were applied to a 'Dowex-1' formate column. The column was first eluted with 0·01 *M* ammonium formate at *p*H 6 followed by 0·01 *M* formic acid which gave a good separation of the compound *F*. The fractions were combined, concentrated by distillation under reduced pressure and taken to dryness *in vacuo*. The material still contained some tarry impurity and was therefore passed again through the 'Dowex-1' column. The product was analysed by paper chromatography, which showed that it contained in addition to the major component a small amount of a further compound. The material was dissolved in hot acetic acid and insoluble substances removed by filtration. The filtrate was evaporated to dryness and redissolved in 4 ml. 20 per cent v/v acetic acid. On addition of diethyl ether, almost colourless needle-shaped crystals were obtained. Recrystallization from water gave a chromatographically pure product.

The crystals contained carbon, 52·3; hydrogen, 4·42; nitrogen, 20·2 per cent, indicating the formula $(C_3H_3ON)_x$. Unfortunately the material was too insoluble in camphor for a molecular weight determination. The ultra-violet absorption spectra (absorption maxima 268 mμ in 0·1 *N* hydrochloric acid and 287 mμ in 0·1 *N* sodium hydroxide) had suggested that compound *F* might be a substituted xanthine, but the minimum molecular formula for a purine on the pattern (C_3H_3ON) would be $C_{12}H_{12}O_4N_4$ and the molar extinction coefficient for this compound in hydrochloric acid would be $3{\cdot}8 \times 10^4$, which is very high. A compound that was known to have a high molar extinction coefficient was imidazole-acrylic acid (urocanic acid), and its formula would fit the analysis of compound *F* if the molecular weight corresponded to twice the empirical formula.

The ultra-violet spectra of the isolated material were identical with those of a sample of imidazole-acrylic acid obtained from Roche Products, Ltd. (Table 1). The material melted at 224° C. and the reference sample at 225° C.; the mixed melting point was 224·5° C. The infra-red spectra of both substances in potassium chloride powder were identical, and they had the same R_F values when chromatographed

Table 1. ULTRA-VIOLET ABSORPTION OF COMPOUND *F* AND IMIDAZOLE-ACRYLIC ACID

Solvent	Compound *F*		Imidazole–Acrylic acid	
	Absorption maximum (mμ)	$E^{0{\cdot}001\%}_{1\text{ cm.}}$	Absorption maximum (mμ)	$E^{0{\cdot}001\%}_{1\text{ cm.}}$
0·1 *N* hydrochloric acid	268	1·49	268·5	1·49
Water (*p*H 6·6)	265	1·26	265	1·24
Water (*p*H 8·1)	278	1·40	278	1·38
0·1 *N* sodium hydroxide	286·5	1·18	287	1·17
N sodium hydroxide	307	1·51	307	1·50

on paper in four different solvents: (1) *n*-butanol saturated with water, containing 1 per cent ammonia (s.g. 0·880), R_F 0·06; (2) *n*-butanol/acetic acid/water (63 : 10 : 27), R_F 0·47; (3) *n*-butanol/formic acid/water (77 : 10 : 13), R_F 0·50; (4) *iso*propanol-hydrochloric acid[4], R_F 0·64.

Although imidazole-acrylic acid has been tentatively identified in trace amounts in human urine[5], it has not previously been isolated from urine. In 12 severe cases of kwashiorkor, the average amount excreted was 28 mgm./12 hr. (range 10–80 mgm.). Only very small amounts have been found in the urine of early cases, and none in cases that have been successfully treated for a week or ten days.

Imidazole-acrylic acid is a known metabolite of histidine, and, in rats treated with ethionine[6], the acid has been found in the urine after intraperitoneal injection of L-histidine-2-^{14}C. The origin in the children with kwashiorkor has not yet been determined. It may be histidine that is released by tissue breakdown: if the breakdown is excessive, the enzyme system normally responsible for metabolism beyond the stage of the acid may be overwhelmed.

The possibility of using the presence of the acid as an aid to the diagnosis of kwashiorkor, and other details of clinical significance, will be described elsewhere.

Micellar Solubilization of Fatty Acids and Monoglycerides by Bile Salt Solutions

Bile salts were recognized as detergents some years ago[1], but few investigations have been done on their detergent properties under physiological conditions. Aqueous solutions of detergents are known to form molecular aggregates called micelles[2]. These form above a critical micellar concentration (CMC) and can solubilize water-insoluble materials. Using synthetically prepared[3], chromatographically pure[4] bile salts, I have investigated the micellar solubilization of pure fatty acids and monoglycerides in bile salt solutions, under conditions simulating those present in human small intestinal content during fat absorption[5].

For lipids with melting point above 37°, an excess of radioactive material was incubated in bile salt solution with shaking, and the amount of solubilized lipid determined after filtration. For lipids, such as α-mono-olein, which form liquid crystalline suspensions with bile salts when present in excess, the maximum amount of lipid which could be solubilized was determined turbidometrically[6]. All incubations were done at 37°, for 96 hr., with bile salt solutions 0·15 *M* (sodium ions), at a *p*H of 6·3, and at physiological concentrations[7]. The resulting micellar solutions were stable and transparent, without turbidity or opalescence.

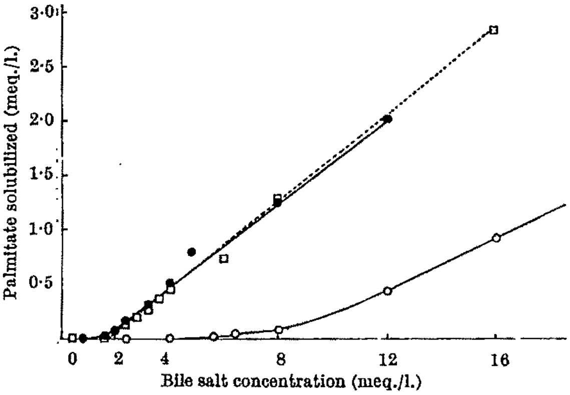

Fig. 1. Solubilization of palmitate by conjugated bile salts; *p*H 6·3, 37° C., 0·15 *M* sodium ions. □, taurodeoxycholate; ●, glycodeoxycholate; ○, taurocholate

Under these experimental conditions and in the absence of bile salts, no ordinary carboxylate soap is sufficiently soluble to form a micellar solution. The unconjugated bile salt deoxycholate is quite insoluble at this *p*H and sodium concentration, and cholate forms unstable solutions from which cholic acid precipitates. Thus stable micellar solutions under conditions normally present in small intestinal content seem possible only with conjugated bile salts (and possibly lysolecithin). Conjugation of deoxycholate and cholate with glycine or taurine lowers the *pK* and increases the solubility under these experimental conditions.

Palmitate solubilization begins at a well-defined bile salt concentration, the critical micellar concentration, and the amount solubilized rises linearly with increasing bile salt concentration (Fig. 1). The critical micellar concentration is about 7 meq./l. for the trihydroxy-bile salt, taurocholate, and about 1·6 meq./l. for the dihydroxy-salts, taurodeoxycholate and glycodeoxycholate. For a fixed bile salt concentration, the amount of fatty acid solubilized is directly proportional to the sodium ion concentration.

α-mono-olein solubilization begins at a lower critical micellar concentration than palmitate (Fig. 2) and the solubilization curves rise much more steeply. The critical micellar concentration for α-mono-olein solubilization is about 5 meq./l. for taurocholate and 0·8 meq./l. for glycodeoxycholate and taurodeoxycholate. α-Mono-olein and α-mono-linolein form myelin figures in bile salt solutions, which diffuse into the bile salt solution, rapidly forming a transparent micellar solution rich in lipid. α-Mono-palmitin, however, does not form myelin figures, and the critical micellar concentration and amount solubilized are almost identical to those of palmitate under these conditions.

A bile salt solution containing previously solubilized α-mono-olein dissolves far more palmitate than in the absence of mono-olein, and solubilization begins at a much lower bile salt concentration.

These results seem relevant to the observation that β-mono-glycerides and fatty acids are the normal end-products of pancreatic lipolysis during fat digestion[8], and that the β fatty acid of most dietary triglycerides is unsaturated[9]. Micellar solubilization by conjugated bile salts of unsaturated mono-glycerides and fatty acids may be the usual pathway of the products of pancreatic lypolysis, and it is possible that lipids may

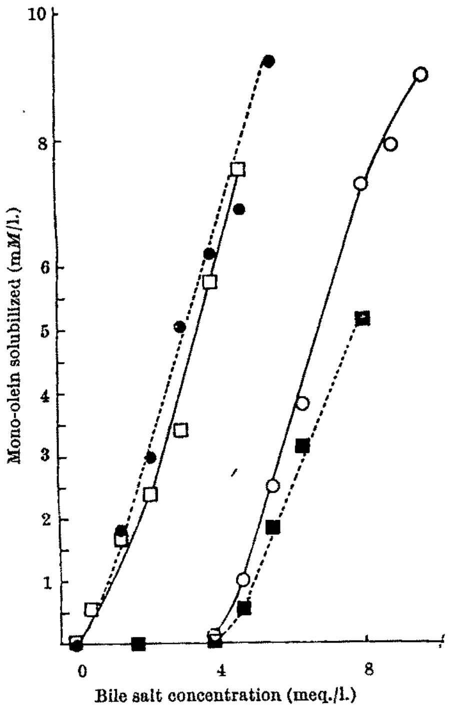

Fig. 2. α-Mono-olein solubilization by bile salts; pH 6·3, 37° C., 0·15 M sodium ions. ●, glycodeoxycholate; ○, cholate; □, taurodeoxycholate; ■, taurocholate

be absorbed in this form. It is of interest that the critical micellar concentrations of the bile salt solutions in these simple *in vitro* systems correspond closely to the lowest bile salt concentrations enhancing triglyceride synthesis in the work of Dawson and Isselbacher, who used preparations of intact small intestine[10].

I wish to thank Prof. Bengt Borgström for his interest and invaluable advice. This work was done with financial help from a National Foundation Postdoctoral Fellowship, and the Scientific Council of the Swedish Dairies' Association.

Origin of the Potential Difference in the Intestinal Epithelium of the Turtle

WHILE we were looking for a suitable preparation to investigate the absorption of amino-acids in the digestive tract, we were impressed by the fact that the potential difference across the epithelium of the small intestine of various species is consistently lower (around 1 mV.) than the potential difference existing across the gastric mucosa or the colon (about 30 mV.). In order to throw some light on this observation we have first measured the flux of sodium across the isolated epithelium of the small intestine and the colon of the turtle *Testudo hermanni* J. F. Gmelin. We have chosen this species because it is quite easy to strip the muscle layers off the epithelium. The method used is described elsewhere[1]. Both sides of the isolated epithelium are bathed with saline having the following composition : sodium chloride 113 mM ; potassium chloride 1·9 mM ; calcium chloride 0·45 mM ; phosphate buffer pH 7·0, 1·5 mM. Table 1 gives the results obtained. It can be seen that there is an active transport of sodium from the mucosal to the serosal side of the preparation in both small intestine and colon. The fact that the values of the short-circuit current are smaller than the values of the net flux means that a cation must be transported actively from the serosal to the mucosal side, or that an anion must be transported actively in the opposite direction. It is also interesting to note that the values of the flux are higher in the small intestine than in the colon and that dinitrophenol inhibits, at least partially, both influx and outflux in the small intestine. This could indicate that part of the outflux of sodium across the small intestine is due to active transport. Let us examine now the effect of a modification in sodium and potassium concentrations on the potential difference across both intestine and colon (Table 2). In these experiments chloride is generally replaced by an equivalent amount of the non-penetrating sulphate anion. Na/10 means a saline containing 10 times less sodium than the physiological saline. Sodium is then replaced by an iso-osmotic amount of sucrose. K × 10 means a saline containing 10 times more potassium than the physiological saline. It can be seen that :

Table 1. INFLUX AND OUTFLUX OF SODIUM ACROSS THE ISOLATED EPITHELIUM OF THE SMALL INTESTINE AND THE COLON IN THE TURTLE *Testudo hermanni* J. F. GMELIN

The epithelium is bathed with a physiological saline on both sides. Results obtained when 2,4-dinitrophenol (DNP) is applied are also given. The fluxes, the net flux and the short-circuit current are expressed in m.coulomb cm.$^{-2}$.H^{-1}. *C*, control. Dinitrophenol concentration, 0·1 mM. Experimental periods, 1 hr.

	50·2	50·2	13	0

(1) The replacement of chloride by sulphate is without any effect on the potential difference across the small intestine, contrary to the situation in the colon where the potential difference increases. A decrease in sodium concentration in the mucosal solution results in the inversion of the potential difference across the small intestine. In the colon we observe a decrease in potential difference (experiment *B*).

(2) If one then increases the potassium concentration, the potential difference decreases in the small intestine, while it stays constant in the colon (experiment *H*).

Table 2. EFFECT OF SODIUM AND POTASSIUM CONCENTRATIONS ON THE POTENTIAL DIFFERENCE ACROSS THE ISOLATED EPITHELIUM OF THE COLON AND THE SMALL INTESTINE IN THE TURTLE *Testudo hermanni* J. F. GMELIN
The sign refers to the serosal side

Experiment	Small intestine		Potential difference (mV.)	Colon		Potential difference (mV.)
	Mucosal	Serosal		Mucosal	Serosal	
B	RCl	RCl	1	RCl	RCl	20
	RSO_4	RSO_4	1	RSO_4	RSO_4	45
	RSO_4–Na/10	RSO_4	−26	RSO_4–Na/10	RSO_4	25
C	RSO_4	RSO_4	1	RSO_4	RSO_4	30
	RSO_4	RSO_4–Na/10	30	RSO_4	RSO_4–Na/10	60
H	RSO_4	RSO_4	1	RSO_4	RSO_4	57
	RSO_4–Na/10	RSO_4	−26	RSO_4–Na/10	RSO_4	48

I	RSO_4	RSO_4	1·5	RSO_4	RSO_4	13
	RSO_4	RSO_4–Na/10	20	RSO_4	RSO_4–Na/10	21
	RSO_4	RSO_4–Na/10–K×10	12	RSO_4	RSO_4–Na/10–K×10	19

(3) In sulphate saline, a decrease in sodium concentration in the serosal solution increases the potential difference across both small intestine and colon (experiment *C*). If the potassium concentration is then increased, the potential difference decreases in both small intestine and colon (experiment *I*).

The observations reported in Table 2 suggest the following conclusions. As the replacement of chloride by sulphate in the solutions bathing both sides of the colon produces an increase in potential difference, it is clear that this epithelium is relatively impermeable to sulphate. The epithelium of the small intestine is equally permeable to chloride and sulphate, since the replacement of chloride by sulphate has no effect on the potential difference. This result could also be explained if one postulates that the epithelium, although impermeable to sulphate, is permeable to potassium and sodium. This possibility is most likely to be correct as the other results demonstrate that the epithelium is permeable to sodium and potassium. Moreover, using sulphur-35 as tracer, we have been able to show that the permeability coefficient for sulphate in frog skin, turtle colon and intestine are of the same order of magnitude (unpublished results). Nevertheless, as we have found that the replacement of chloride by sulphate does not affect the magnitude of the potential difference appreciably when the sodium concentration is modified, this would suggest that the passive permeability of the small intestine to chloride is low.

The small spontaneous potential difference existing across the small intestine is related to the concentrations of sodium and potassium in the mucosal and serosal solutions: it is thus clear that both mucosal and serosal sides of the epithelium are permeable to these ions. On the contrary, in the colon the mucosal side is permeable to sodium, but impermeable to potassium, while the serosal side is permeable to both ions.

It is obvious from the results reported here that the distribution of the permeability characters in the small intestine is different from that in the colon. The organization and the distribution of the permeability characters is therefore an important aspect of cell differentiation. A purely speculative scheme has been proposed to explain the possible evolution of the permeability characters in the epithelial tissues[2]. According to this hypothesis, the primitive stage would be characterized by a mechanism of active transport located at both inner and outer borders of the cell. The cell would then evolve toward an asymmetry by losing the active transport mechanism at one of the borders. The results reported here give some experimental support to this conception.

Constituents of *Lagerstroemia Flos-reginae* Retz.

FOR many years people of the Philippines have used certain parts of a tree (*Lagerstroemia Flos-reginae* Retz.) as an aid in the lowering of blood sugar[1,2]. The drug, commonly called 'banaba', is usually administered in the form of an aqueous 20 per cent decoction prepared from the leaves. While the drug has been employed for many years and pharmacological studies have been made using extracts of the drug[3,4], very little information has appeared in the literature concerning its constituents.

Dried leaves, obtained from an authentic source, were used in this investigation. To ensure that our material possessed physiological activity, 20 per cent decoctions were prepared. These, with and without tannins, were administered orally via stomach tube to rabbits. The dose was 10 ml. of 20 per cent decoction per kgm. of body-weight. Following administration of the drug, blood sugar determinations were made at 2-, 4-, and 6-hr. intervals using the Nelson–Somogyi procedure[5]. Results revealed that the leaves possessed hypoglycæmic properties as the average blood sugar was lowered 25 mgm. per cent after 4 hr., which was the peak time of activity. The results were essentially the same regardless of the presence or absence of tannins.

Determinations for the presence of therapeutically active compounds commonly found in plants were carried out. Alkaloid analysis was performed using Wall's method[6,7]. Flavonol determinations were carried out using Bryant's method[8], rutin being used as a control. Analysis for sterols was carried out with Liebermann–Burchard and Salkowski tests. Several methods of analysis for glycosides were employed, including (*a*) acid hydrolysis of an 80 per cent alcohol extract and subsequent analysis for reducing sugars;

(*b*) hydrolysis of an aqueous extract with β-glucosidase; (*c*) the use of ion exchange according to the method of Khym and Zill[9]. Results of the preceding tests were negative for the presence of alkaloids, glycosides, sterols and flavonols. The presence of tannins in banaba as indicated by Garcia was substantiated, and we have done some work on the nature of the tannins present.

It was suggested by Garcia[1] that perhaps some type of 'insulin-like' material might be responsible for the hypoglycæmic activity. Therefore we checked carefully for the presence of amino-acids in our extracts. Aqueous extracts were purified by Plaisted's method[10], which involves a desalting technique using ion exchange. Portions of the purified extracts were then spotted on Whatman No. 1 filter paper for chromatographic analysis. Four solvent systems proved to be the most efficient. These were: (1) *n*-butanol/glacial acetic acid/water (12 : 3 : 5); (2) *n*-butanol/pyridine/water (1 : 1 : 1); (3) *tert.* butanol/methylethylketone/diethylamine/water (2 : 1 : 2 : 2); (4) phenol/water (4 : 1). The presence of amino-acids was detected with ninhydrin. Amino-acids found were alanine, *iso*leucine, α-aminobutyric acid and methionine, the latter present in much higher amounts than the others. Purified extracts were also subjected to paper chromatographic analysis using the method of Moffat and Lytle[11]. Results of the latter procedure confirmed the presence of the above-named amino-acids.

From the results obtained it appears that constituents responsible for hypoglycæmic activity are not from those classes of secondary constituents commonly found in plants.

This investigation was aided in part by funds from the Smith, Kline and French Foundation, Philadelphia, Pennsylvania.

A New Photo-reaction between some Furocoumarins and Flavin Mononucleotide

THE photosensitizing properties on the skin of some furocoumarins have been studied extensively by us since 1953[1] and later by other workers[2]. While the relationships of chemical structure to photodynamic effects are well known, the mechanism of action of these substances is at present not clear, in spite of the fact that xanthotoxin is used therapeutically for leucodermia. Recently, Pathak and Fellman[3] pointed out interesting relationships between activating and fluorescent wave-lengths and the photodynamic properties of many furocoumarins. Furthermore, we have been able to show[4] that furocoumarins do not operate by a photo-oxidative process on a protein substrate as do other known photodynamic substances (hæmatoporphyrin, hypericin, erythrosin, rose bengal, benzpyrene, etc.[5]).

We report here the results of research work which started from the observation, about a year ago, that some furocoumarins react with flavin mononucleotide on ultra-violet irradiation. A preliminary report of this work was given on May 22, 1960, at the meeting of the Istituto Veneto di Scienze, Lettere ed Arti, Venice.

Aqueous ethanolic solutions of equimolecular mixtures of flavin mononucleotide and of a furocoumarin (psoralen, xanthotoxin or bergapten) were irradiated by a Philips lamp (*HPW* 125) of principal wave-length 3655 Å. By paper chromatography with *n*-butanol/acetic acid/water (4 : 1 : 5) as eluant, new spots are detectable, which do not appear when flavin mononucleotide and furocoumarins are irradiated separately. There are spots of yellow colour and yellow fluorescence at low R_F values (0·15–0·22), and spots with violet or blue-violet fluorescence at high R_F values (0·85–0·90). The intensity of these new spots increases up to a maximum with the time of irradiation.

The ethereal extract containing the derivatives with violet and blue-violet fluorescence, which are formed on irradiation of a mixture of flavin mononucleotide and bergapten, was chromatographed on a column of silica gel, using water as the stationary phase and benzene or benzene–ethyl ether mixtures as the moving phase. So far three new compounds have been isolated in small quantity: substance *a*, $C_{14}H_{14}O_6$, melting point 153°, with violet fluorescence; substance *b*, $C_{12}H_{10}O_6$, melting point 178°, with violet fluorescence; substance *c*, $C_{12}H_8O_5$, melting point 208°, with grey-blue fluorescence. Compound *a* is an ethyl ester giving, by saponification, an acid identical to compound *b*. All these compounds appear to have coumarinic structure, showing that the furanic ring of the bergapten undergoes modifications. Further work is in progress for the elucidation of these substances and of those formed in the photoreaction between flavin mononucleotide and psoralen or xanthotoxin.

It seems that this photo-reaction does not take place appreciably when flavin adenine-dinucleotide is used. In fact, the irradiation of solutions of the latter containing equimolecular quantities of psoralen, xanthotoxin or bergapten did not give significant variations in the activity of flavin adenine-dinucleotide as coenzyme for D-amino-acid-oxidase, when determined by Warburg and Christian's method[6].

It has not been possible, hitherto, to say if the *in vitro* reaction between flavin mononucleotide and some furocoumarins could explain the mechanism of the photodynamic activity on the human and guinea pig skin by furocoumarins. However, the following results have to be considered carefully:

(1) We found a strict parallelism between chemical reactivity and biological action, that is, only the photodynamically active furocoumarins (for example, psoralen, xanthotoxin, bergapten, allobergapten, angelicin, 4′-methyl-psoralen, 5-*iso*propyloxy-psoralen, 3-methyl-xanthotoxin, 3,4′-dimethyl-xanthotoxin, 4,5′-dimethyl-xanthotoxin, 4,4′-dimethyl-psoralen) gave new compounds when irradiated with solutions of flavin mononucleotide, as observed by paper chromatography. No new spot is detectable when photodynamically inactive derivatives were

used (isopimpinellin, xanthotoxol, bergaptol, 4′,5′-dihydropsoralen, 4′-phenyl-4-methyl-psoralen, 3,4-dihydropsoralen, 4′,5′-dihydrobergapten, 4-methyl-5′-phenylxanthotoxin, thioxanthotoxin, erniarin, citropten, seselin, ethyl ester of psoralen-5-oxyacetic acid, etc.).

(2) There are also indications that flavin mononucleotide could give some protection *in vivo*: a batch of guinea pigs (average weight 450 gm.) was treated with bergapten (200γ/4 cm.^{2} of area); an Osram *HWA* 500-W. lamp was used as a source of radiation, with a total exposure of 60 min., and the distance between the lamp and the irradiated skin was kept constant at 30 cm. A very large dose of flavin mononucleotide (50 mgm. immediately after irradiation and 4 doses of 20 mgm. each at 12-hr. intervals) was injected subcutaneously at a distance from the place of application of bergapten and the irradiated zone. In a few cases erythema did not appear, in some animals a lighter erythema occurred, and in others erythema was delayed, compared with a control group of guinea pigs, irradiated in the same conditions and not injected with flavin mononucleotide. We emphasize that the amount of flavin mononucleotide necessary to give some protection was accompanied by a toxic effect.

Thanks are due to Dr. N. Zonta, Dr. F. Baccichetti, Dr. U. Fornasiero and Dr. F. Dall 'Acqua for their practical assistance.

Gastric Esterases of Pigs

THERE has been considerable controversy as to the existence of a gastric lipase since Volhard[1] discovered the breakdown of fat in the stomach. Many authors have ascribed this phenomenon to regurgitated pancreatic or duodenal activities, but others believe that the stomach produces a factor which is active in the normal breakdown of fats.

During investigations of the esterolytic activities of tissues of the alimentary tract of pigs[2], using a *p*H-stat method, it was shown that the fundic mucosa had no ability to hydrolyse triolein, which is a typical lipase substrate. This confirms the findings of Cherry and Crandall[3] and of Schonheyder and Volqvartz[4]. It thus seems likely that the reported gastric hydrolyses of fats are not due to an enzyme produced in the fundic mucosa.

Preliminary investigations revealed that the fundic mucosa had low activity towards simple esters, such as 'Tween 20', ethyl acetate and triacetin. The *p*H optima of the hydrolyses of these three compounds were 8·8, 6·5 and 7·3, respectively. Such high *p*H optima suggest that these enzymes are of no practical use in the normal digestive processes of the animal, since the normal *p*H of the stomach content is much below this figure.

Detailed investigations of the behaviour of these systems in the presence of inhibitors were prohibited by the very low activities present. It was not found possible to use homogenates of the fundic mucosa containing more than 200 mgm. wet tissue/ml. because of the high viscosity of the extracts, and triacetin, which was hydrolysed at the greatest rate by this tissue, only produced 5 micro-moles of acid/min./gm. wet tissue.

However, we were able to show that the hydrolyses of all three substrates were inhibited by NN′ di-*iso*-propyl phosphodiamidic fluoride (mipafox), and that the hydrolyses of ethyl acetate and triacetin were also inhibited by *p*-chloromercuribenzoate (*p*-C.M.B.) (see Table 1).

Table 1. INHIBITION OF HYDROLYSIS OF TRIACETIN (PER CENT)

Inhibitor	Concentration	'Tween 20'	Inhibition ethyl acetate	Triacetin
Mipafox	$2 \times 10^{-4} M$	100	—	—
	$1{\cdot}5 \times 10^{-4} M$	—	74	49
p-C.M.B.	$2 \times 10^{-4} M$	0	—	—
	$1{\cdot}5 \times 10^{-4} M$	—	5	22

The inhibition of the hydrolysis of triacetin by mipafox and *p*-C.M.B. was additive, suggesting action on two active centres, and possibly indicating the participation of two enzymes.

Calcium ions activate the hydrolysis of 'Tween 20', but inhibit the hydrolysis of ethyl acetate and triacetin. This inhibition can be lessened by adding ethylenediamine tetraacetic acid, which removes calcium ions.

Effect of Water-soluble Polymers on Nitrate Reductase Activity

SEVERAL years ago Whitaker[1] observed that the presence of small quantities of bovine serum albumin, β-lactoglobulin, and other proteins enhanced the activity of a cellulase preparation obtained from culture filtrates of *Myrothecium verrucaria* when insoluble substrates were used. Tracey[2] found a similar effect in the stimulation by cow serum of chitin hydrolysis by chitinase. More recently, activation by polymers has been observed in homogeneous aqueous enzyme systems. The action of liver diaphorase has been reported[3] to be enhanced by bovine serum albumin and polyvinylpyrrolidone while polysaccharides, particularly starch, have been shown[4] to increase the activity of horse-radish peroxidase. These findings suggest that the *in vitro* enhancement of enzymic activity by non-catalytic polymeric materials may be a phenomenon of broad biological significance.

We discovered a new example of this 'polymer effect' while studying the metabolism of inorganic nitrogen. It was observed that the enzymic activity of nitrate reductase preparations obtained from the mould *Neurospora crassa* (5297*A*) and purified by ammonium sulphate fractionation and column chromatography on hydroxyl apatite[5] is stimulated appreciably by several polymeric materials, notably by methyl cellulose and polyvinylpyrrolidone. We also tested the effect of several chelating agents, sugars, amino-acids, and other low-molecular-weight additives on the activity of the chromatographed enzyme. Reagent-grade materials were used wherever possible. Nitrate reductase activity was determined by colorimetric analysis of the rate of enzymic nitrite formation at 25° C. under zero-order reaction conditions. All additive materials were tested for interference with this analysis[7] and appropriate corrections made where necessary in calculating the nitrate reductase activities listed in Table 1.

Table 1. EFFECT OF ADDITIVES ON THE ACTIVITY OF PURIFIED NITRATE REDUCTASE

Additive	Concentration of enzyme protein (μgm./ml.)	Relative enzyme activity
None	122	100
Egg albumin	61	94
Dextran, clinical	61	94
Gelatin	61	140
Gum acacia	61	108
Methyl cellulose (100 cp.)	61	164
Polyvinylpyrrolidone (*K*-30)	61	149
Soluble starch	61	125
DL-Alanine	122	93
Creatine	122	89
L-Cysteine	122	80
Adenosinetriphosphate	122	47
L-Leucine	122	74
Ethylene dinitrilotetraacetic acid	122	105
Sucrose	122	90
D-Glucose	122	89
Glycerol	122	85
Sodium deoxycholate	122	116
Tris(hydroxymethyl)aminomethane	122	80
Reduced glutathione	122	110
Diglycylglycine	122	98

Assay mixtures: 0·50 ml. additive in 0·1 *M* phosphate, final *p*H 7·0 ; 0·08 ml. 1·25 × 10^{-4} *M* flavin adenine dinucleotide ; 0·02 ml. 1·0 *M* potassium nitrate ; nitrate reductase (specific activity 300–1,000) dissolved in 0·32 ml. neutral phosphate, 0·1 *M*. Assay reaction initiated by adding 0·08 ml. 2 × 10^{-3} *M* reduced triphosphopyridine nucleotide.

Concentrations of additives (polymers : 5 mgm./ml., other additives: 10^{-2} *M*) were chosen arbitrarily. Subsequent observations indicated that for methyl cellulose, at least, maximal enhancement of nitrate reductase activity is obtained by considerably lower polymer concentrations.

Among the polymers tested, egg albumin and dextran are conspicuous in their failure to enhance the reaction-rate of nitrate reductase. Thus it appears that a macromolecule must be endowed with specific physico-chemical characteristics in order to exercise a 'polymer effect' on a given enzyme system.

With the exception of sodium deoxycholate, none of the low-molecular-weight substances examined produced a significant enhancement of enzymic activity. At the concentrations used, most of these materials were in fact inhibitory. The 'polymer effect' is exerted by the polymer molecule and not by its monomers. This is seen by comparing the action of glucose, alanine, cysteine and leucine with that of starch and gelatine, respectively.

Since neither ethylenediamine tetraacetic acid nor *tris*(hydroxymethyl)aminomethane at concentrations of 10^{-2} *M* enhances nitrate reductase activity, chelation of inhibitory trace metals possibly present in the assay mixtures does not provide a basis for the 'polymer effect'. A kinetic explanation (Kamen, M. D., personal communication) has been suggested based on the premise that certain polymer materials may be capable of reversing a possible product-inhibition of the enzyme by physicochemical interaction with the nitrite ions formed. Kinetic studies[5] have shown, however, that at concentration-levels usually reached during assay, nitrite ion has no effect on the zero-order reaction-rate of the enzyme.

The well-known property of dissimilar polymeric materials to form binary aqueous systems[8] has been considered as a possible basis for the 'polymer effect'. The interfaces of such systems may exert an orienting effect on the enzyme molecule which could result in a more efficient catalytic system. Mixtures of methyl cellulose (5 mgm./ml.) and semi-purified nitrate reductase protein (8 mgm./ml.) slowly separate on standing into two aqueous phases. This phase separation is not observed when bovine serum albumin is substituted for the enzyme. At concentration-levels (50–200 μgm. protein/ml.) prevailing during enzyme assay such a phase separation was not found spectrophotometrically nor was it expected on the basis of Albertsson's results[9] on the composition of aqueous binary polymer systems.

Whitaker[2] noted that with less-pure preparations of cellulase the stimulation given by extraneous proteins is reduced. He attributed this observation to the presence of non-enzyme protein in the enzyme preparation. We encountered the 'polymer effect' on nitrate reductase activity only after the enzyme had undergone considerable purification.

These observations suggest to us that purification removes auxiliary substances normally associated *in vivo* with these enzyme systems, which provide a physicochemical environment permitting maximal catalytic activity. Such a physicochemical environment is provided apparently *in vitro* by certain polymer materials.

It may be argued that the presence of macromolecules such as methyl cellulose helps to prevent surface denaturation of the enzyme. Protective effects of this kind are well known, as exemplified by the protection of glutathione reductase activity by bovine serum albumin[10]. We observed, however, that the percentage increase in apparent nitrate reductase activity due to the presence of a fixed amount of methyl cellulose remains constant over a considerable range of enzyme-levels, down to protein concentrations of less than 4 μgm./ml. Furthermore, the presence of methyl cellulose has no effect on the gradual loss of enzyme activity observed when dilute purified nitrate reductase preparations are exposed to room temperature. Thus the 'polymer effect', as demonstrated by the example of methyl cellulose, promotes, but does not protect, enzymic activity.

In view of this evidence, we are inclined to believe that many macromolecules of varied structure possess physicochemical characteristics which render them capable of enhancing the *in vitro* catalytic activity of a number of enzyme systems. While the mechanism of this enhancement is still the subject of speculation[4], 'polymer effects' on enzymic efficiency should no longer be regarded as isolated phenomena. Their existence must be taken into consideration when dealing with purified enzyme systems.

Further work is in progress, and a detailed report will be published later.

Activation of Hurain by Bivalent Iron

Hurain[1], the active principle of the sap of jabillo trees (*Hura crepitans*) which is responsible for its proteolytic action, apparently represents a proteinase with special chemical properties differing from those so far known for this class of enzymes. During purification and assay of the enzyme, it was found that the enzymatic activity of hurain is greatly affected by metal ions.

Experimental results, to be described in this preliminary communication, have been performed with crude enzyme obtained as a dry, almost white powder from the tree sap by cutting the bark and centrifuging, dialysing and freeze-drying the pooled samples. Proteolytic activity was determined by present techniques[2-5]. The enzyme preparation shows certain activity on hæmoglobin and egg albumin (Fig. 1), gelatine and Witte's peptone[1], without further additions; maximal activity is reached, however, only when bivalent iron ions are added (Table 1).

The crude hurain preparation was found to act also on a synthetic substrate. Hurain slowly hydrolyses benzoyl-L-arginine-methylester, and the velocity of hydrolysis is increased by the addition of Fe^{2+} (Fig. 2). It appears that hurain does not act on the corresponding amide. The effect of bivalent iron appears to be specific, since Ca^{2+}, Mg^{2+}, Mn^{2+} and Fe^{3+} had no influence on hurain activity; Zn^{2+}, Cd^{2+} and Ni^{2+} inhibit the enzyme action. The mechanism of activation by bivalent iron is not produced by reduction of S–S to SH-groups of the protein. Hurain is not affected by cysteine or other reducing agents[1], and *p*-chloromercuribenzoate.

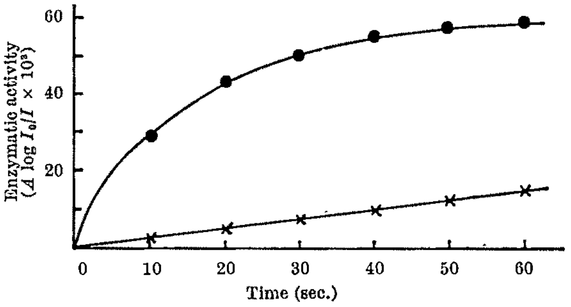

Fig. 2. Activity of crude hurain on benzoyl-L-arginine-methylester without —×— and with —●— addition of Fe^{2+}. Method, ref. 4

Apparently, active hurain represents a reversibly dissociating iron complex, in which Fe^{2+} can be displaced by inhibiting ions as Zn^{2+} or by complexing agents such as ethylenediamine tetraacetic acid (EDTA) (Table 1). The bivalent iron is firmly bound by the protein moiety, at least more firmly than the inhibiting ions. An excess of Zn^{2+} is required to displace the iron from its site of binding. Other evidence for the strong binding of Fe^{2+} is shown by the fact that after 48 hr. of dialysis against EDTA the preparation has 2·2 mgm. per cent iron, that is, about 10 per cent of its original iron content (23·5 mgm. per cent), calculated for dry weight. The amount of iron present in the preparation after dialysis of the crude extract is sufficient to activate partly the hurain.

Terminology of Protein Structure

I WISH to suggest a revision in the practice of discussing proteins in terms of primary, secondary, and tertiary structures. This terminology, introduced by Linderstrøm-Lang in his Lane Memorial Lectures[1], served well in the few years since it was invented, and has thoroughly permeated the literature. Developments since that time have lessened its usefulness. Arguments to demonstrate this, and suggestions for a more useful general terminology, are the substance of this communication.

One difficulty connected with the terminology is that there is major and widespread disagreement on definitions. For example, in refs 2–4 disulphide bridges are called primary structures, while in refs. 5–7 they are known as tertiary. Disagreement can also be anticipated with other covalent chain-branches and cross-links. Further, there is confusion about secondary structures: some writers accept only helices as secondary structures[6,7,9], others go a step further and include pleated-sheet models[2,4] and some few[5] maintain that a peptide chain segment or loop may have a meaningful non-random structure in the absence of peptide hydrogen bonding; for example, for steric reasons. Furthermore, it is not generally agreed whether tertiary structure is to mean "the way in which primary and secondary structures are packed together in the molecule"[2] and the resultant molecular shape[2,5,7,8]; or whether tertiary structure should direct attention to the multiple forces maintaining the particular folding of α-helices or other chain conformations in a protein[3,9].

The designations, primary, secondary, and tertiary, tend to connote relative importance which can be misleading. I do not disagree with the primacy of covalent bonds in proteins, but there is no compelling evidence that peptide hydrogen bonds contribute more strongly than side-chain interactions to conformational stability; in fact, there are numerous suggestions to the contrary[2,5,8,10].

Finally, there is a sequential connotation in the primary, secondary, tertiary terminology. While present hypotheses of protein biosynthesis support the notion that formation of peptide bonds in an ordered sequence precedes the change to the three-dimensional structure of the protein, there is little knowledge of processes involved in this transformation. The same issue arises in the reversible denaturation of proteins. It is uncertain whether side-chain interactions lead or follow formation of peptide hydrogen-bonds, or whether, as is my view, there may be an advantage in considering the transformation to be a concerted, co-operative process.

To summarize, considerable ambiguity exists at present in the application of the primary, secondary, tertiary terminology. Further objections to this terminology are that it tends to connote relative importance and a sequence of formation of structural elements. Although it is conceivable that general agreement on definitions might be achieved, the other objections remain. I therefore recommend that use of this terminology be discontinued entirely.

In fact, a general move in this direction has already been noted: a recent symposium on protein structure and function[11] ran its full three-day course with scarcely a reference to secondary and tertiary structure. Apparently several other investigators concerned with protein structure have recognized shortcomings in this terminology. If my present arguments do not succeed in persuading writers to abandon the primary, secondary, and tertiary terminology, I hope that it will at least lead some to a greater awareness of its limitations.

I suggest that protein structure can be discussed generally in terms of amino-acid sequences of peptide chains, called chain sequence, and the ways in which peptide chains and side-chains are arranged in space, called chain conformations. (It has already been noted[12] that configuration has often been used synonymously with conformation. This is undesirable, since configuration traditionally has applied to optically asymmetric centres, and should be reserved for this use We should speak of the configuration of an amino-acid residue, and of the conformation of a peptide chain.) It appears desirable to subdivide the latter term into side-chain conformations and peptide chain or backbone conformations, without implying that these two subdivisions are mutually exclusive, and certainly without implying rank or sequence of development. Taken together, chain sequences and chain conformations are sufficient to define a structure, which is the three-dimensional location of all the atoms and covalent bonds of a molecule. The factors determining a structure, such as covalent bond lengths and angles, rotational barriers, steric repulsions, hydrogen bonds, electrostatic forces, 'hydrophobic bonds', etc., should not be confused with the structure itself. No general designation seems necessary for the arrangements of protein sub-units into aggregate molecules, as in insulin, hæmoglobin, collagen, the caseins, etc. However, if such a term must be employed, 'sub-unit array' seems preferable to 'quaternary structure'[13].

Finally, I wish to emphasize that I have intended criticism only for general ways of discussing protein structure; no criticism is meant for terms describing specific structural elements, such as α-helices, pleated-sheets, polyglycine II type structures and constrained non-hydrogen-bonded backbone loops.

Since there is nothing intrinsically proteinaceous in the designations 'chain sequence' and 'chain conformation' (main and side-chain), these terms may be applicable in structural discussions of chain polymers in general.

I am grateful for discussions of this matter with Dr. E. R. Blout, Prof. L. C. Craig, Prof. J. T. Edsall and Prof. D. Waugh.

PHYSIOLOGY

Korotkov's Sounds : a Function of the Skeleton to Transmit 'Pulsactor' Signals

WORK upon Korotkov's sounds led me[1] to the conclusion that the arterial system could be regarded as an energy transmission line, into which the heart launches energy at two levels, namely, waves with a frequency of 3–15 c.p.s. and waves with a frequency of 256–512 c.p.s. The theory required that the sound waves, resulting from forces of cavitation, be transmitted throughout the arteries, with a velocity much higher than that of the waves of low frequency, to explain the development of arterial stationary waves.

Sound waves are indeed transmitted by arteries, Kerr and Harp[2] giving velocities of the order of that of the pulse-wave, 4–5 m./sec. Comparable results are found in fluid-filled elastic tubes where, however, should the wave arise from a unit impulse function, longitudinal waves may occur, transmitted with a velocity of 30 m./sec., as reported by Citters[3]. Landowne[4], moreover, has shown that externally produced impact waves are propagated along living arteries with an average velocity of 17·1 m./sec. These velocities, however, are not sufficiently high for the theory, and, certainly on transmission in fluid-filled elastic tubes, sound waves, especially of higher frequencies, undergo rapid attenuation.

Now bone is an excellent conductor of sound, the velocity of transmission is about 3,900 m./sec. and bone conduction of the heart sounds occurs *in vivo* : Turrettini[5], for example, observed that the murmur of mitral regurgitation was audible over the sacrum. McKusick[6] describes conduction of heart sounds, via the ribs rather than directly through the chest, as "circumferential transmission", when auscultation is performed over the back.

In aortic stenosis, loud systolic murmurs may be heard with the aid of a stethoscope, or microphone, applied to the olecranon : it was discovered by Levine and Likoff[7] that this sound is unaffected by occlusion of the brachial artery with a pressure cuff, so proving that the sound is conducted by bone. These workers also reported a case where a diastolic murmur, due to syphilitic aortic incompetence, was audible on auscultation over the skull.

The above observations support the following amendment to the original theory :

The sternum acts as a sounding board that resonates to the heart sounds, the body of the sternum being more favourably placed to resonate to the first sound ; the manubrium to the second. The clavicle conducts the sounds to the scapula by which they are transmitted to the bones of the arm. The ribs conduct the sounds to the vertebral column by which they are conducted upwards to the skull, which acts as a cavity resonator, and downwards to the sacrum and so to each hip bone by which they are transmitted to the bones of the leg.

Conduction at joints is by the ligaments, which are so attached that they act as matching devices. In the case of the costal cartilages, the sound may be conducted by the perichondrium. The clicking nature of the noises arising in joints suggests that sound waves of frequencies up to, say, 10,000 c.p.s. are involved : frequencies even higher should be considered.

What function could such a phenomenon subserve ? Probably the following : the skeleton acts as an aerial, broadcasting the heart sounds throughout the body, the sound being conducted, finally, from bone to soft tissue by fibrous, ligamentous and muscular attachments. Each sound acts as a signal, imparting a slight jolt to the branches of the vascular system, analogous to the effect of pulsactor circuits employed in radar and utilized to overcome initial and terminal high impedance of other circuits in which momentary flow of current is required.

A similar concept was introduced by me[8] in connexion with blood flow in the coronary arteries, applying the term 'to overcome thyxotropism'. Since the transmitted sound waves are likely to have the further effect of synchronizing pulsation of the peripheral arteries, they may be described as 'pulsactor signals'. In turn, the action of the heart, initiating these, may be termed that of a 'synchronizing signal generator'.

An Effect of Glucose on Acetate Metabolism in Sheep

RUMINANTS derive their energy requirements essentially from lower fatty acids (acetic, propionic and butyric) and thus differ from non-ruminating animals. The concentration of glucose in the blood of sheep, which is extraordinarily low when compared with that of non-ruminants, is probably an expression of the sparsity of the exogenous glucose available in the metabolism of these animals[1,2].

It is unlikely, however, that glucose plays no important part in the metabolic pathways in the sheep. Certainly glucose has an important role[3] in the young lamb. In adult sheep glucose, though in limited supply, might well be implicated in aiding the metabolism and utilization of acetate by the tissues. It is the purpose of this communication to examine this hypothesis.

In this work estimations of the rate of disappearance of acetate after intravenous injection were used as a measure of the sheep's ability to 'utilize' acetate.

Six well-trained Merino wethers, aged 2 years, were fed in pens for 6–8 weeks on 800 gm. of chaffed wheaten hay plus 7 mgm. cobalt chloride once a week to ensure adequate vitamin B_{12} status. Four of the six animals were used in the experiments without change of diet, while two were given, 2 days before the observations were made, a ration of 500 gm. of chaffed wheaten hay plus 300 gm. of chaffed lucerne hay.

Estimations on the rate of disappearance of acetate from the blood were made by determinations of the concentration of volatile fatty acids in the blood at 30, 60 and 90 min. after an injection of 5 mM/kgm. of acetic acid neutralized to *p*H 7·0 with caustic soda and diluted to 75 ml. with distilled water. The injection was made through a polythene tube inserted and fixed into the jugular vein and usually was completed within 3–5 min.

A few days following the determination of the rate of disappearance of the acetate by this means an injection of glucose (1·0 gm./kgm.) was given, followed half an hour later by an injection of acetate, and the rate of disappearance of acetate was then again determined. The injection of glucose resulted in a profound hyperglycæmia, the blood sugar-level being elevated throughout the experimental period by at least 100 mgm./100 ml. blood over the normal control-levels. After 2–3 days had elapsed control observations (without glucose injections) were again made. The results are presented in Table 1.

Table 1. CONCENTRATION OF VOLATILE FATTY ACIDS IN BLOOD (m*M*/L.) AFTER THE INJECTION OF ACETATE (5 m*M*/KGM.)

Minutes after acetate injection	Wheaten hay chaff (mean of 4 animals ± *S.E.*)			Wheaten hay chaff+ lucerne chaff. Data from 2 animals		
	Acetate only	Glucose then acetate	Acetate only	Acetate only	Glucose then acetate	Acetate only
0	0·38 ±0·13	0·50 ±0·11	0·51 ±0·08	0·45 0·35	0·53 0·51	0·32 0·70
30	7·24 ±0·11	6·02 ±0·26	6·99 ±0·24	5·65 6·30	4·28 4·91	6·25 5·96
60	3·46 ±0·10	1·54 ±0·16	3·27 ±0·34	2·03 1·06	0·73 0·62	1·96 1·88
90	1·77 ±0·19	1·29 ±0·11	1·49 ±0·17	0·95 1·07	0·58 0·60	0·87 0·80

It is apparent from Table 1 that prior administration of glucose led to a more rapid rate of removal of acetate from the blood than occurred in control experiments in which no exogenous glucose was given. The results emphasize the importance of diet in this respect, for the incorporation of lucerne chaff in the diet, although only for so short a period as 2–3 days before the experimental observations, significantly changed the rate of 'utilization' of acetate. The importance of the nature of the diet has previously been stressed[4,5]. It might thus be considered that an interrelationship exists, not between acetate and glucose itself but between acetate and the glucose precursor, propionate. When the rations are comprised largely of crushed maize an enhanced production of propionate results, and, then after being introduced intravenously, both glucose and acetate disappear from the blood more rapidly than from the blood of control animals on standard diets[4]. Recent work[5], however, does not favour the direct implication of propionate, and from the work reported here, it is suggested that glucose, as in non-ruminants[6], may be important in aiding in the 'utilization' of acetate which is so essential to the metabolism of the sheep.

Evidence of Secretion of an Aldosterone-stimulating Substance by the Kidney

HÆMORRHAGE causes a two-fold increase in aldosterone secretion in hypophysectomized dogs[1]. We have found recently that nephrectomized hypophysectomized dogs fail to show this rise, and that saline extracts of dog kidney contain an aldosterone-stimulating substance.

Ten male mongrel dogs (average weight, 12·1 kgm.) were subjected to left nephrectomy. Five or more days later, the dogs were anæsthetized with pentobarbital and the right kidney removed (5 dogs), or an adjustable ligature placed around the renal artery and vein (5 dogs). The right lumbo-adrenal vein of each dog was then cannulated and the animals hypophysectomized via the transbuccal route. One hour later, a control adrenal venous blood sample was collected from each of the five dogs with a ligature around the vessels of the remaining kidney. The ligature was tightened and two more adrenal vein samples were collected at 20-min. intervals. In the dogs in which the remaining kidney had been removed, two specimens of adrenal venous blood were collected starting 1 hr. after hypophysectomy. All dogs were then bled by removing 15 ml./kgm. body-weight of femoral arterial blood over a 6-min. period. Adrenal venous blood samples were collected 10, 40 and 70 min. after the start of hæmorrhage. In five instances, the experiment was continued by re-infusing the shed blood over a 6-min. period and collecting adrenal venous blood 10 and 30 min. thereafter. Four of these dogs were given 1 I.U. of adrenocorticotrophic hormone intravenously and an adrenal vein sample collected starting 5 min. after the injection. Ten similarly studied hypophysectomized dogs with intact kidneys (average weight, 12·9 kgm.) served as controls.

Extracts of tissues were made by dicing normal dog kidney or spleen, mixing the tissue with 50 or 100 ml. of isotonic saline, straining through cheesecloth, and centrifuging at approximately 3,000 r.p.m. for 15 min. The supernatant was injected intravenously over a 1-min. period into hypophysectomized–nephrectomized dogs and adrenal venous blood was collected starting 5 min. after each injection. The dose of extract used in each case was equivalent to 1 kidney or ½ spleen. Control injections of an equal volume of isotonic saline were performed in 3 dogs. All hypophysectomies were found to be complete by gross examination at autopsy. Blood pressure was monitored continuously, using a Statham strain gauge manometer and Grass model 4 polygraph. The adrenal venous blood samples were centrifuged promptly, and the plasma frozen for subsequent analysis of aldosterone content by the double isotope derivative method[2] and 17-hydroxycorticoid content by the method of Silber and Porter[3].

The results are summarized in Tables 1 and 2. There was a slight, but statistically significant, fall in aldosterone secretion following ligation of the renal vessels, and the control values in the nephrectomized–hypophysectomized dogs were significantly lower than those of the hypophysectomized dogs. Following hæmorrhage, aldosterone secretion-rates rose at least 5 mμgm./min. in all 10 hypophysectomized dogs, while no rise occurred in 8 out of 10 nephrectomized–hypophysectomized dogs. The mean values for aldosterone secretion after hæmorrhage were significantly higher in the dogs with intact kidneys. Adrenal responsiveness to adrenocorticotrophic hormone was

Table 1. Changes in Aldosterone Secretion-rate following Haemorrhage

Table 2. Changes (mean ± *S.E.*) in Adrenal Secretion and Blood Pressure after Injection of Kidney and Spleen Extracts and Saline

The aldosterone and 17-hydroxycorticoid values are the difference between the rate following injection and the control value immediately before injection. Blood pressure values represent the maximum value after injection minus the value before injection

	Kidney extracts (9 exp.)	Saline (3 exp.)	Spleen extracts (2 exp.)
Mean change in aldosterone secretion-rate (mμgm./min.)	+26·7 ± 7·2	+1·7 ± 2·4	−5·8
Mean change in 17-hydroxycorticoid secretion-rate (μgm./min.)	+2·0 ± 0·6	+0·1 ± 0·1	−0·4
Mean change in systolic blood pressure (mm. mercury)	+72·8 ± 10·8	+16·7 ± 8·8	−2·5
Mean change in diastolic blood pressure (mm. mercury)	+66·7 ± 7·4	+11·7 ± 7·3	+2·5

retained in the dogs without kidneys, as indicated by the slightly greater response to adrenocorticotrophic hormone in this group. Except after adrenocorticotrophic hormone injection, 17-hydroxycorticoid secretion was less than 3 μgm./min. in all dogs and was unaffected by hæmorrhage and retransfusion. After adrenocorticotrophic hormone, 17-hydroxycorticoid values were 8·1 ± 1·1 μgm./min. (mean ± *S.E.*) in the nephrectomized dogs and 5·9 ± 0·9 μgm./min. in the controls.

Injection of the saline extract of 1 normal dog kidney caused a large rise in aldosterone secretion in 8 out of 9 instances (Table 2), with a mean increase of 26·7 mμgm./min. 17-hydroxycorticoid values also increased slightly. Systolic and diastolic blood pressure rose markedly. Control injections of equal volumes of saline had no effect on the secretion of either hormone, although they did cause a 10–15 mm. mercury rise in blood pressure. Spleen extracts (2 dogs) had no effect on adrenal secretion or blood pressure.

Similar experiments have been carried out independently by Davis *et al.*[4], and similar results obtained. The fact that aldosterone secretion rises after hæmorrhage in hypophysectomized dogs indicates that some non-pituitary factor is involved. A renal source for this factor is suggested by the absence of the response in nephrectomized animals and the presence of an aldosterone-stimulating substance in kidney extracts.

The nature of this aldosterone-stimulating substance is uncertain. Richards and Sayers[5] found that extracts of normal rat kidneys caused adrenal ascorbic acid depletion in hypophysectomized rats and assumed that the material giving the response was adrenocorticotrophic hormone. A slight rise in 17-hydroxycorticoid secretion followed the injection of extracts of normal kidneys in the present experiments, and it is possible that adrenocorticotrophic hormone extracted from the kidneys was responsible for the observed effects on aldosterone secretion. However, doses of commercial adrenocorticotrophic hormone which produce 17-hydroxycorticoid responses of this magnitude have no effect on aldosterone secretion in the hypophysectomized dog[1].

In 1951 Deane and Masson[6] reported that renin injections led to hypertrophy of the zona glomerulosa of the adrenal. Recently, Genest *et al.*[7] and Laragh *et al.*[8] have reported that injection of synthetic angiotensin into normal humans caused an increase in aldosterone secretion. Preliminary experiments by us indicate that synthetic angiotensin increases adrenal secretion of aldosterone and 17-hydroxycorticoids when injected into hypophysectomized–nephrectomized dogs in very small doses. Since hæmorrhage causes an increased secretion of renin[9], the present results are consistent with the hypothesis that the renin–angiotensin mechanism is responsible for the increase in aldosterone secretion following hæmorrhage in hypophysectomized dogs.

Isolation and Partial Characterization of a Growth-control Factor

A growth-promoting factor in liver extracts has been reported in work on a chemically defined medium for the axenic cultivation of the nematode, *Caenorhabditis briggsae*[1]. An active fraction has now been isolated from horse liver by salt precipitation and column chromatography. The purified material emerged from the column as a discrete protein peak. By electrophoretic analysis (through the courtesy of Dr. Arthur Karler, Karler Laboratories, Berkeley, California) on cellulose acetate strips and ultracentrifugal analysis (through the courtesy of Dr. F.

Lindgren, Donner Laboratory, University of California, Berkeley), it appeared to be essentially a single component. Twelve amino-acids have been demonstrated in a hydrolysate of the active fraction.

Freshly excised liver was cut into small pieces and autolysed for 24 hr. at 4° C. All subsequent procedures were carried out in the cold. A 1 : 1 homogenate was made in water, and after centrifugation the residue was discarded. Ammonium sulphate was added to the supernatant fluid to obtain the material which precipitated between 40 and 60 per cent saturation at *p*H 7·0. This precipitate was dissolved in distilled water and reprecipitated with ammonium sulphate between 45 and 60 per cent saturation. After centrifugation, the precipitate was redissolved and dialysed to remove ammonium sulphate. This material was then applied to a column of hydroxylapatite[2] and eluted with successive increases in concentration of phosphate buffers. The eluates contained six discrete protein peaks. These six fractions were sterilized by filtration ('Millipore', size *G.S.*) and assayed with *C. briggsae*. Only one of them was found to be biologically active.

The growth-promoting property of this protein fraction for *C. briggsae* was tested in a chemically defined basal medium[3] which is protein-free. In the basal medium, young larvæ survived but increased in size only to a limited extent. But, in medium to which the fraction had been added, maturation and reproduction occurred. The purified protein material showed the freeze-activation phenomenon described previously[4]. When freeze-activated, 39 μgm. of protein (optical density 280/260) per ml. of culture medium was found to be adequate for maturation and reproduction. A higher level (158 μgm. protein per ml.) was selected for prolonged maintenance, and seven generations were afterwards subcultured. Successive inocula were first-generation larvæ of respective preceding cultures.

None of the other fractions from the column was active in the nematode assay, either before or after freeze-activation treatment.

In other experiments, this fraction was tested as a replacement for the serum requirement of a tissue culture cell line (McCoy, originally obtained through the courtesy of Dr. C. M. Pomerat). Stock cultures of McCoy cells were maintained in a medium composed of mixture 199 (Microbiological Associates), lactalbumen hydrolysate, and calf serum[5]. Cultures were trypsinized, washed, and resuspended in a deficient medium composed of mixture 199 plus antibiotics. Aliquots were dispensed into Leighton tubes and were incubated for 4–6 hr., at which time the rounded cells had become attached to the glass. The medium was decanted and replaced according to the following schedule: series 1—complete serum medium plus adenylic acid; series 2—serum-deficient medium plus adenylic acid; and series 3—serum-deficient medium plus fraction (79 μgm. protein per ml. freeze-activated in adenylic acid) to be assayed. After 18 hr. incubation, the cell sheet of series 1 was confluent and individual cells were like epithelium. Cells in series 2 were enlarged slightly and for the most part were still round, with little evidence of differentiation or multiplication. A small number of these cells showed evidence of fibroblast-like growth. In series 3, most cells had proliferated into fibroblast-forms and some into epithelial-forms. Although the cell sheet did not attain the confluent aspect observed in the serum controls, it far surpassed the growth and differentiation obtained in the deficient medium.

The findings of these experiments suggest that this purified protein fraction may play a general regulatory part in growth and differentiation.

Œstrogen Protection against Acute Digitalis Toxicity in Dogs

Grinnell and Smith[1] have demonstrated that castrated female dogs prophylactically treated with œstradiol-17β are much more resistant to a toxic intravenous dose of digoxin than are untreated castrated controls.

In an extended search for a medicinal agent which would duplicate the protective effect of the ovarian hormone without œstrogenicity, a large list of steroids fabricated on the naturally occurring œstratriene nucleus have been studied. Among such steroids our best compound so far is 1,3,5(10),16-œstratetraen-3-ol methyl ether. This highly active steroid was prepared both by the methylation of 1,3,5(10),16-œstratetraen-3-ol and by the pyrolysis[2] of the *p*-toluenesulphonate of 3-methoxy-1,3,5(10)-œstratrien-16β-ol[3]. It has a melting point of 68° and an optical rotation of $[\alpha]_D^{24} = +115° \pm 2$ ($c = 0{\cdot}615$ in chloroform). Apparently a crystalline modification melting at 71–72° exists[3].

After many endocrine studies we do not yet know the physiological mechanism(s) involved in steroidal protection against digitalis toxicity. Adult, female, mongrel dogs weighing 7–14 kgm. were ovariectomized by a technique which included hysterectomy and then permitted a minimal period of 4 weeks for post-operative recovery. The test substance was dissolved in sesame oil and administered intramuscularly at a dose-level of 0·5 mgm./kgm. daily for 7 days, with vaginal smears being taken prior to and at intervals during the administration. Food was withheld from all animals for a period of 18–24 hr. before the acute experiment, but water was allowed *ad libitum*. On the eighth day of the experiment anæsthesia with pentobarbital sodium (30 mgm./kgm.) was induced and a cathode-ray electrocardiograph was installed for continuous observation of the electrocardiogram, lead aV_F being used regularly. Permanent tracings of this lead were made at frequent intervals with a Sanborn twin-viso electrocardiograph. After a 30-min. control period during which the normal electrocardiographic pattern was recorded, digoxin (0·15 mgm./kgm.) was administered intravenously. The electrocardiogram was observed continuously and the time of appearance of the arrhythmia was recorded (the term 'arrhythmia' refers to a complete atrioventricular block with idioventricular tachycardia).

Table 1

Steroid used in prophylactic treatment	Time of onset of arrhythmia (min.)	State of œstrus
1,3,5(10),16-œstratetraen-3-ol methyl ether	> 60	Anœstrus
	> 60	,,
	38	,,
	> 60	,,
	30	,,
None	21	Anœstrus
	19	,,
	24 (av. 20)	,,
	18	,,
	18	,,

If this arrhythmia did not occur within a time-limit of 60 min., protection against the digoxin intoxication was arbitrarily considered to be 100 per cent, as survival has always been indefinite with this degree of protection.

In Table 1 are recorded the results with 5 castrated female dogs prophylactically given 1,3,5,(10),16-œstratetraen-3-ol methyl ether against the results with 5 similar animals untreated. Not only was this steroid non-œstrogenic in our experiments, but it also demonstrated a markedly superior protective action. Curiously, the free phenol—1,3,5(10),16-œstratetraen-3-ol[4]—is not as potent as its 3'-methyl ether; and the free phenol, furthermore, produces œstrus in our routine experiments.

We have never observed augmentation of digoxin toxicity by an œstrogen or œstrogen-like steroid. Such steroids, if protectively inactive, demonstrate onset of arrhythmia at time-intervals identical to those of controls within experimental error.

Hyaluronic Acid in the Uterine Wall of the Guinea Pig during the Sexual Cycle

The amount and function of acid mucopolysaccharides in the mammalian uterus are not yet known. A metachromatic staining material has been described in the endometrial stroma of the human uterus[1–3] during the proliferative phase of the sexual cycle, and recently the presence of a periodic acid–Schiff positive material in the uterus of swine during the sexual cycle has been established[4]. Nothing definite has been found in the literature concerning the possible importance of hyaluronic acid in the physiology and pathology of the uterus. Investigations concerning the acid mucopolysaccharides of the uterus have been undertaken, since alteration in the quantity or quality of the ground substance may prove to be important in the pathogenesis of uterine infections and possibly in other disorders.

Forty mixed coloured virgin female guinea pigs, 3–5 months of age, were used in this investigation. They were kept at a relatively constant temperature, between 68° and 72° F., and fed with a standard ration; fresh water was given *ad libitum*. The sexual cycle was followed by daily examination of vaginal smears, stained by Papanicolaou's method. Using this method, it was possible to kill animals in a given phase of the sexual cycle, that is, pre-œstrus, œstrus, post-œstrus, and di-œstrus. A small block of tissue was removed from each uterus approximately 1 cm./ distal to the bifurcation, and this was fixed in 10 per cent formol-alcohol. The remainder of the uterus was put in acetone immediately, and stored at -20° C. for future chemical examination. Paraffin sections were prepared from the block of tissue and stained as follows: Hale colloidal iron method for mucopolysaccharides as modified by Rinehart and Abul-Haj[5]; period acid–Schiff method of McManus; and 0·5 per cent aqueous toluidine blue.

Hyaluronic acid was extracted from the remainder of the uterus by the method described by Hayashi *et al.*[6], with the slight modification that an additional filtration was done at the end of the dialysis procedure. The extract, proved to be free of protein and sulphur, was dissolved in 1–2 ml. of 0·1 *M* veronal-acetate buffer at *p*H 6. One drop of the solution of each extract was spread over an area 0·5 cm. in diameter on a glass slide. The dried smears were then stained with toluidine blue[6], at *p*H 6·9; 4·1; 2·5 and 1·0. Some of the dried smears were treated with hyaluronidase for 1, 2 and 3 hr. at 37° C. before staining, using a concentration of 100 VR units per ml. The enzyme was dissolved in 0·1 *M* acetic buffer *p*H 4·7, containing 0·15 *M* sodium chloride. Controls were incubated at the same time with the buffer solution only. Dried smears of chemically pure hyaluronic acid, chondroitin sulphate and heparin were also used as controls.

The smears of the uterine extracts showed a significant metachromasia at *p*H 6·9 and 4·1 with diminished metachromasia at *p*H 2·5 and none at *p*H 1·0. Treatment of the smears with the hyaluronidase for 60–90 min. caused a complete loss of metachromasia. The smears of known chondroitin sulphate and heparin showed distinct metachromasia in all ranges of *p*H tested, including *p*H 1·0, while the known smear of hyaluronic acid gave results similar to the experimental extracts of the uterus. Hayashi *et al.*[6] reported that metachromatic staining with toluidine blue at *p*H 1·0 is highly specific in differentiating non-sulphate acid mucopolysaccharides from the sulphated form. On this basis, our results suggest that the acid mucopolysaccharide from the uterus is hyaluronic acid. An attempt was made to extract chondroitin sulphate from the uteri of other guinea pigs, using the method described by Hayashi[6], with negative results.

Histochemical examination of the uterine sections showed the presence of an acid mucopolysaccharide which was distinctly blue (with the Hale method of staining) and metachromatic with toluidine blue, but only slightly positive with the periodic acid–Schiff method. This material was seen in both the endometrial epithelium and stroma. The histochemical observations varied during the different phases of the sexual cycle. In particular, the amounts of demonstrable acid mucopolysaccharide were notably increased during œstrus and, at this time, the periodic acid–Schiff staining reaction became more strongly positive.

The results reported suggest that hyaluronic acid is the major mucopolysaccharide in the uterine wall of the guinea pig, and that either the amount or quality of this ground substance material varies with the phase of the sexual cycle, being maximal, as judged by histochemical methods, during œstrus. Quantitative and qualitative investigations are now being completed on the uterine extract and will be published.

Electrical Excitability of Isolated Frog Skin

In the course of investigating the electrical properties of frog skin with short current pulses, it was discovered that this preparation is capable of exhibiting electrical excitability. The present communication is concerned with a description of this phenomenon.

The abdominal skin of the frog *Rana pipiens* was removed and immediately mounted between two cylindrical 'Lucite' compartments, 6·5 cm. long, 1·15 cm.^{2} cross-sectional area. There were holes at the far end of each compartment for the silver/silver chloride stimulating electrodes, and at each end adjacent to the skin was a small hole for the bridges (polyethylene tubes containing saturated potassium chloride in agar solution) going to the recording calomel electrodes. Each compartment was filled with Gray–Ringer solution (71·75 m*M* NaCl; 5·00 m*M* KCl; 2·50 m*M* $CaCl_2$; 1·60 m*M* $MgCl_2$; 20·00 m*M* $NaHCO_3$; 1·03 m*M* Na_2HPO_4; 0·12 m*M* NaH_2PO_4; 0·26 m*M* glucose. Solution is saturated with a 97 per cent O_2, 3 per cent CO_2 gas mixture), and within 1 hr. a steady state value of the resting potential across the skin obtained (25–60 mV., inside surface positive). Current through the skin and voltage across it were recorded on a Tektronix 502 dual beam oscilloscope (input impedance 10 MΩ); the square waves of current were obtained from an AEL laboratory stimulator through a 100-kΩ series resistance.

Fig. 1 shows a typical set of responses of the skin to square waves of current of 35 m.sec. duration. At low values of inward (depolarizing) and outward (hyperpolarizing) current (by an inward current is meant a current produced with the cathode in the solution bathing the inner surface of the skin and the anode in the solution bathing the outer surface; the reverse is the case for an outward current) (Fig. 1*a*) the voltage responses are almost symmetrical and phenomenologically identical to the behaviour of a network consisting of a resistance and capacitance in parallel (RC network). The observed resistance was from 0·5–1·0 kΩ/cm.^{2}; capacitance from 2–5 μF./cm.^{2}. As the magnitude of the current pulse is increased, the potential changes begin to show non-linearity and rectification (Fig. 1*b*). At still higher current density the system is very non-linear, and for an outward current pulse, overshoot occurs (Fig. 1*c*). As the magnitude of the current pulse is continually increased, a value is eventually reached at which the skin is near threshold. At this point, if the magnitude of the current pulse is increased slightly, the skin responds with an action potential for inward current pulses, while continuing to give an overshoot for outward currents (Fig. 1*d*). (The overshoot response for outward current pulses as seen in Fig. 1*c* seems to be a 'poor' action potential, for in some skins an action potential with a sharp threshold and a form essentially the mirror image of the type shown in Fig. 1*d* occurs.)

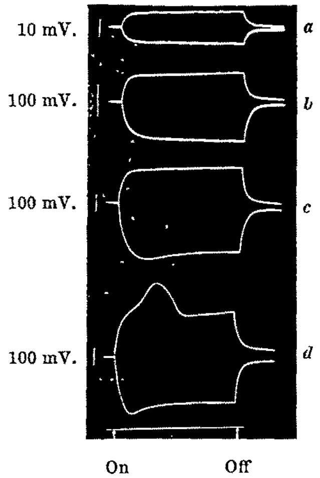

Fig. 1. The change in potential across isolated frog skin produced by 35-m.sec. square waves of current. Upward response is result of inward current; downward response is result of outward current. Currents are 20 μamp., 210 μamp., 500 μamp. and 550 μamp. for *a*, *b*, *c* and *d* respectively. Resting potential is 30 mV., inside positive. Gray–Ringer solution on both sides

Following an action potential, the skin becomes refractory for several seconds, not exhibiting an active response to the same stimulus that previously elicited it. If during this period the skin is stimulated at the rate of 10/sec. or faster, it will continue to remain refractory and show only an RC-type of response; stimulation at the rate of 1/sec. or less, on the other hand, has no appreciable effect on the duration of the refractory period.

In Fig. 2 is seen a striking example of the recovery of excitability following a full response. In this experiment a small short (2·5 m.sec.) pulse was superimposed on a 40 m.sec., just sub-threshold pulse. The interval between successive records was three seconds. Curves *a*, *b*, and *c* show a characteristic sub-threshold 'local response'; curve *d* is the full action potential. A pulse 3 sec. after this would give curve *a* again, etc.

I wish to point out several important features of these action potentials: (1) the response is large, in some skins being as great as 300 mV. (by the magnitude of the response I mean the difference between the peak height and the maximum sub-threshold level); (2) the long refractory period, which is of several seconds duration; (3) the sharp threshold, which is a general characteristic of more familiar excitable systems. Finally, I wish to contrast this response of frog skin to the changes of potential observed on stimulation of the nerves to the skin[1].

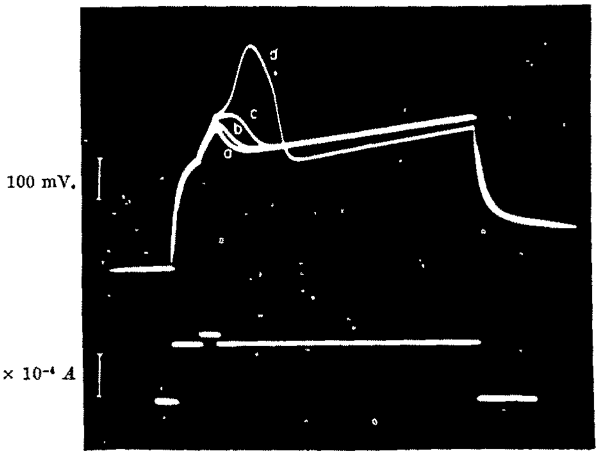

Fig. 2. The change in potential across isolated frog skin produced by a 40-m.sec. just sub-threshold inward square wave of current with a superimposed 2·5-m.sec. small inward square wave. Successive responses *a*, *b*, *c* and *d* are 3 sec. apart. Resting potential is 60 mV., inside positive. Gray–Ringer solution on both sides

I have repeated some of this earlier work and have confirmed that the response in this case is very slow, being of several seconds duration and quite different from the observations described. Other workers have attributed these slow changes to the skin glands.

With regard to the site in the skin of the electrical activity, it seems fairly clear that the magnitude of the effect and particularly the dependence of the direction of the response on the polarity of the stimulus precludes consideration of all unoriented structures, that is, smooth muscle and nerve twigs. This leaves us only with the epithelial cells and the glands. It is interesting that we have found that the toad bladder, the electrical and permeability properties of which are known to be in many ways quite similar to those of frog skin, exhibits essentially the same electrical excitability as described for the skin. In the bladder, the epithelial layer consists of a single sheet of cells with no glands. (About 5 per cent of these cells secrete mucus (Peachey, L. D., personal communication).) It seems, therefore, that the action potentials evoked in frog skin and toad bladder come from the germinal layer of epithelial cells. It is to these cells that is generally attributed the resting potential and 'transport properties' of these organs. A more detailed report on the phenomenon discussed here will appear elsewhere.

HÆMATOLOGY

Erythrocyte Glucose-6-Phosphate Dehydrogenase Deficiency in New Guinea and New Britain

COMPARATIVE investigations carried out on erythrocyte glucose-6-phosphate dehydrogenase deficiency in Negro and Caucasian subjects have revealed quantitative differences between these two groups[1]. It is suggested that different genetic mechanisms account for the deficiency of glucose-6-phosphate dehydrogenase in Negroes and Caucasians. This led to a search for other populations which might exhibit the trait, and which might therefore help to elucidate some of the questions concerning gene action in man.

Employing the rapid screening test described by Motulsky[2] a survey has been carried out on 155 subjects in the Gazelle Peninsula, New Britain, and 534 subjects in the Eastern Highlands, New Guinea. Any samples showing significant hæmolysis in the supernatant sera were discarded. Red cells from blood clots, both in field samples and in laboratory controls stored under conditions identical to those of transportation, have proved to be as satisfactory as those from similarly treated heparinized blood samples, provided the hæmoglobin value in all cases is adjusted to a constant standard value. Further controls were used in the form of repeated blood samples from a single normal European in New Guinea. The results are shown in Table 1.

Table 1

Area	Sex	No. examined	No. deficient
New Britain (Gazelle Peninsula)	Male	94	16
	Female	61	0
	Total	155	16
New Guinea (Eastern Highlands)	Male	383	3
	Female	151	0
	Total	534	3

Several females in the New Britain series had enzyme-levels in an intermediate range, possibly indicative of a heterozygous situation. For the first time the trait has been found to exist in New Guinea and New Britain, but with greatly differing incidence, 0·56 and 10·3 per cent, respectively, in these two areas. The Gazelle Peninsula in New Britain is highly malarious, while the several groups tested from the Eastern Highlands of New Guinea inhabit low- or non-malarial areas. These results thus add evidence supporting Motulsky's contention[2,3] that there may be a selective advantage in the development of this trait, in that enzyme-deficient persons may be more resistant to falciparum malaria. Populations previously reported to have a high incidence of glucose-6-phosphate dehydrogenase deficiency also exhibit the sickle-cell trait, but sickle-cell hæmoglobin has not been found in New Guinea[4] or New Britain[5]. In 13 of the 19 deficient cases reported here, there was no apparent segregation according to haptoglobin type, although the series is as yet too small for definite conclusions.

No cases of primaquine sensitivity have yet been reported in New Guinea (Schofield, F. D., personal communication). However, primaquine is given only to highland peoples when they return from the coast to their own malaria-free or comparatively non-malarious home areas. It is not used in treating native people in coastal regions, as the chances of re-infection with malaria are so high.

The finding of another distinct population with deficiency of erythrocyte glucose-6-phosphate dehydrogenase, as revealed by this preliminary survey, provides material for further evaluation of the gene-enzyme interaction concerned. Further investigations are in progress to determine more precisely the relation between malarial distribution and incidence of the trait, and to examine possible protection of the enzyme deficiency against malarial infection. A study is also being made of factors such as heat lability, pH optimum, and of the effect of storage on the enzyme in deficient subjects, for comparison with those of the enzyme in affected Negroes and Caucasians.

Acknowledgment is made of the co-operation of Dr. D. C. Gajdusek, of the National Institutes of Health, Bethesda, Maryland, and Mr. R. T. Simmons, of the Commonwealth Serum Laboratories, Melbourne, in obtaining blood samples, and of Dr. C. Curtain, of the Baker Institute, for the haptoglobin investigations.

Isolation of Haptoglobin by Chromatography on Diethylaminoethyl-Cellulose (DEAE)

HAPTOGLOBIN was isolated first by Jayle *et al.*[1] using a technique which combined precipitation by ammonium sulphate with preparative starch-gel electrophoresis. More recently we found that haptoglobin could be obtained as a by-product during the routine fractionation of human plasma[2,3]. This technique uses rivanol as a precipitating agent for the subfractionation of fraction IV, obtained at pH 5·8, and 35 per cent alcohol concentration, the final purification being achieved by chromatography on DEAE.

This technique gives pure haptoglobin suitable for metabolic research studies with and without addition of hæmoglobin[4]. However, geneticists interested in the variation of haptoglobin groups often have only small samples of plasma at their disposal and they only need minute amounts of the isolated protein as test substances for electrophoretic work.

In our routine technique, the final purification of haptoglobin is obtained by adsorption of haptoglobin at pH 5 on DEAE using 0·03 M acetate buffer, whereas siderophilin, the main contaminant, is not adsorbed. Haptoglobin can be adsorbed under the same conditions from whole plasma, but is then accompanied by other proteins: cæruloplasmin, a second α_2-glycoprotein, cholinesterase and some α_1-globulins. Smithies[5] already showed that the selective adsorption of haptoglobin needs a rather low pH. However, we noticed that haptoglobin at about 80 per cent purity can be obtained with a slightly modified elution technique.

Plasma is diluted to give a freezing point of −0·15°. The pH is then adjusted to 5 with acetic acid 0·03 M; DEAE-cellulose is equilibrated against acetate buffer 0·03 M, pH 5, a minimum of 25 gm. of dry cellulose being necessary for 1 l. of plasma. The adsorbent is poured into a column (the diameter being proportional to the volume handled) and the diluted plasma is passed by gravity flow. The column is then washed with acetate buffer, 0·03 M, until no more proteins appear in the effluent. Haptoglobin can then be eluted with 0·1 M acetate buffer, pH 5. The solution should contain 2–4 gm./l. of proteins; the total yield of haptoglobin based on the hæmoglobin-binding capacity is about 50–60 per cent.

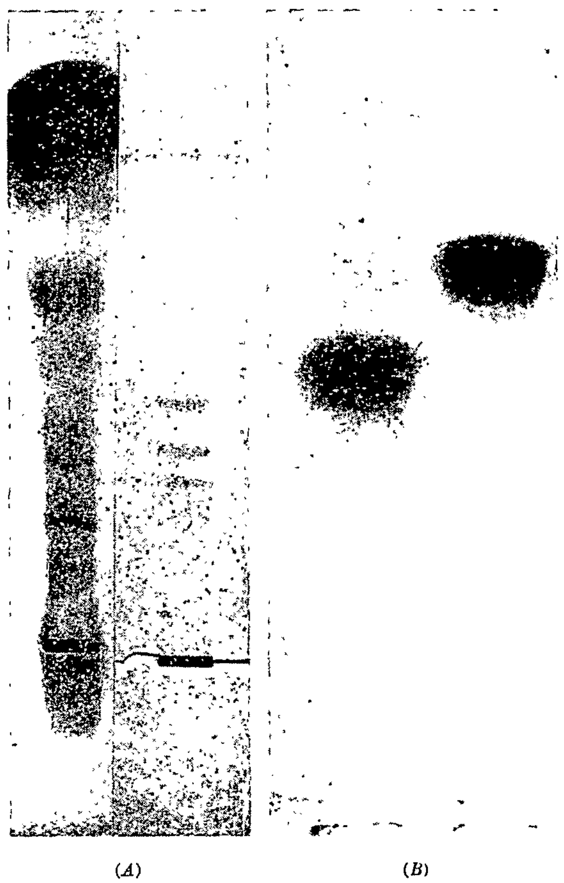

Fig. 1. *A*, Haptoglobin 2 : 1 separated by batch-adsorption from a small plasma sample. Eluate slightly concentrated. *B*, Haptoglobin 1 : 1 with and without added hæmoglobin. Sample obtained by column chromatography of 250 ml. of plasma

Cæruloplasmin together with some α_1-globulin can be eluted at 0·2 M acetate buffer concentration and at the same pH. A second, not yet identified, α_2-glycoprotein is eluted at 0·5 M acetate buffer.

Satisfying results have been obtained with small samples (2–4 ml.) as well as with volumes of 1 l. of plasma and more. Batch-adsorption can be used instead of the column adsorption. Since no dialysis is necessary, it is possible to achieve the isolation of haptoglobin a few hours after the collection of the blood sample.

The purity and the yield of the separated product seems to give data corresponding to those published by Smithies[5] for haptoglobin obtained by chromatography on 'Dowex 2 $X-10$', pH 4·2.

PATHOLOGY

Increased Sensitivity to Bacterial Endotoxin of F_1 Hybrid Mice undergoing Graft-versus-Host Reaction

THE development of graft-versus-host reaction in adult F_1 hybrid mice, following the injection of parental strain spleen cells, is accompanied by a considerable increase in the phagocytic activity of the reticulo-endothelial system[1]. Two weeks after injection of the spleen cells, the recipients were found to have phagocytic indices (calculated from the rate of clearance of colloidal carbon from the circulation) up to 10 times greater than normal. During investigations on the immunological reactivity of such animals to heterologous antigens[2], a few observations suggested that the mice were abnormally susceptible to the toxicity of relatively small doses of killed *Salmonella typhi*. Recent work has shown that stimulation of the reticulo-endothelial system in mice either by *Mycobacterium tuberculosis* (*BCG*) infection[3-5] or by repeated injections of the yeast cell-wall preparation 'Zymosan'[6] coincides with a profound lowering in resistance to the lethal effect of endotoxins from Gram-negative bacteria. In view of this association, F_1 hybrid mice undergoing graft-versus-host reaction were tested similarly for resistance to purified bacterial endotoxin, and an analogous effect has been demonstrated.

Male F_1 (*C57BL* × *CBA*) mice, weighing 20–26 gm., were injected intravenously with 75–85 million spleen cells prepared from adult male *C57BL* donors as described previously[1]. Various dosages of *Shigella dysenteriæ* type 1 endotoxin, freshly suspended in saline, were injected intravenously 14 days after the spleen cells. Previous work had shown that at this time interval stimulation of the reticulo-endothelial system was usually maximal in the strain combination used[1], although the mice appear well and indistinguishable from normal animals. The results given in Table 1 demonstrate that F_1 (*C57BL* × *CBA*) mice previously injected with *C57BL* spleen cells are 25 times more susceptible to the lethal effect of endotoxin than untreated control mice. The calculated LD_{50}'s are 11 μgm./20 gm. for treated mice and 272 μgm./20 gm. for control mice, with confidence limits at 5 per cent probability-level of 8–15 and 197–375 μgm./20 gm. respectively. All deaths occurred within 48 hr., while those mice previously injected with spleen cells which survived dosages of 2–20 μgm. endotoxin remained severely shocked for 24–48 hr. and then recovered. The subsequent onset and incidence of fatal graft-versus-host disease during the following six weeks did not seem to be influenced by the endotoxin injection at day 14.

Table 1. THE EFFECT OF GRAFT-VERSUS-HOST REACTION INDUCED BY INJECTION OF PARENTAL STRAIN SPLEEN CELLS ON THE SUSCEPTIBILITY OF F_1 (*C57BL* × *CBA*) MICE TO BACTERIAL ENDOTOXIN

Dose of endotoxin (μgm. per 20 gm.)	F_1 (*C57BL* × *CBA*) mice	
	Controls	Animals given *C57BL* spleen cells 14 days previously
500	8/8*	—
200	0/8	—
100	1/8	—
50	0/8	8/8
20	0/8	7/10
10	—	8/14
5	—	1/14
2	—	0/4

$* \frac{\text{No. of mice dying}}{\text{No. of mice injected}}$

The present experiment provides a further instance, in addition to *BCG* infection and the effect of 'Zymosan' injection, where stimulation of the phagocytic activity of the reticulo-endothelial system has been accompanied by greatly increased sensitivity to endotoxin. The role of the reticulo-endothelial system in this state of hypersusceptibility should, however, remain *sub judice*, for there is much evidence (see refs. quoted in 5–7) supporting also a direct relationship between acquired resistance to endotoxin and an increase in the level of reticulo-endothelial activity. This phenomenon is the opposite of the one at present under consideration, although in both cases the phagocytic activity of the reticulo-endothelial system is raised.

The immunological basis for the graft-versus-host reaction has been clearly established by work on 'runt disease' induced in the young animal and of 'secondary disease' in radiation chimæras. But the immediate causes of the wasting and death which frequently attend it are at present unknown. Decreased resistance to bacterial endotoxin absorbed from the gut may be a contributory factor towards its pathogenesis.

Immunological Differences of Deoxyribonucleoproteins from White Blood Cells of Normal and Leukæmic Human Beings

EXPERIMENTS were performed to determine: (*a*) whether deoxyribonucleoproteins from normal and leukæmic leucocytes react immunologically with their related control sera, or whether they cross-react with them; (*b*) whether they are capable of inducing formation of antibodies in rabbits; (*c*) whether normal deoxyribonucleoproteins cross-react with sera of rabbits immunized with leukæmic deoxyribonucleoproteins and vice versa.

Isolation of leucocytes was achieved by the method of Beck and Valentine[1]. Alternatively, after sedimentation of red blood cells, citrated human plasma was centrifuged at 1,000 r.p.m. for 4 min. to recover the leucocytes. Extraction of deoxyribonucleoproteins was performed with 0·01 *M* glycine overnight after washing leucocytes with 0·01 *M* sodium citrate and 0·01 *M* glycine solution. Purification of the extract was achieved by centrifugation at 24,000*g* for 25 min. Isolation and extractions were made at 4° C. Details of this new method and biophysical and biochemical work on deoxyribonucleoproteins will be presented elsewhere. Antibodies were prepared by injecting intravenously a total amount of 25–30 mgm. of deoxyribonucleoproteins into rabbits three times at weekly intervals. Rabbits were bled a week after the last injection. Titre of antibodies and optimal concentrations of deoxyribonucleoproteins were determined in test-tubes at room temperature. Human and rabbit sera prepared from venous blood were dialysed against 0·1 *M* glycine before use. In precipitin reactions a modified agar-gel diffusion technique of Outchterlony[2,3] was used. Agar (1 per cent), after washing with distilled water, was melted in 0·1 *M* glycine. For control purposes, it was melted in 0·01 *M* phosphate buffer and 0·1 *M* glycine at *p*H 6·8. Incubation of agar plates made at room temperature and at 4° C. yielded the same results. Each precipitin test was repeated 10–15 times.

The experiments used nine rabbits and the blood of seven normal and fourteen leukæmic persons.

Control tests of non-immunized rabbit sera with normal or leukæmic sera and deoxyribonucleoproteins of normal and leukæmic humans were always immunologically negative. No immune reaction was detected between control sera of normal and leukæmic individuals, between control sera of normal human beings and normal and leukæmic deoxyribonucleoproteins, between control sera of leukæmic humans and normal and leukæmic deoxyribonucleoproteins and between normal and leukæmic deoxyribonucleoproteins themselves. These results exclude the existence of a detectable naturally occurring immune limiting system which controls the growth of leucocytes in the blood both of normal and of leukæmic human beings.

Both normal and leukæmic deoxyribonucleoproteins were found to induce formation of high-titre antibodies in rabbits. They always gave a single precipitin line when fresh preparations were employed. Sera of rabbits immunized with normal deoxyribonucleoproteins did not cross-react with leukæmic deoxyribonucleoproteins, and vice versa (Table 1). These results show that the antibodies produced in rabbits are specific for the normal and leukæmic deoxyribonucleoproteins.

In a single instance a preparation of deoxyribonucleoproteins from a person with chronic lymphatic leukæmia gave a positive reaction with rabbit sera immunized with normal deoxyribonucleoproteins and a negative one with rabbit sera immunized with leukæmic deoxyribonucleoproteins. However, two other preparations from the same person, six months earlier, conformed to the general findings.

Table 1. CROSS-REACTIONS OF DEOXYRIBONUCLEOPROTEINS FROM NUCLEI OF LEUCOCYTES OF NORMAL (NDNP) AND LEUKÆMIC (LDNP) HUMAN BEINGS WITH THEIR RELATED ANTIBODIES (NAb, LAb) (NORMAL, LEUKÆMIC)

* Numbers indicate different individuals.

† Individuals considered normal on the basis of serological tests by Central Blood Bank of Pittsburgh.

‡ Insufficient quantity of $L_{12}DNP$.

The property of deoxyribonucleoproteins from nuclei of leucocytes of normal and leukæmic human beings of inducing formation of specific antibodies in rabbits is not restricted to these deoxyribonucleoproteins alone, but it is a property of deoxyribonucleoproteins from widely different sources (sea urchin, calf thymus, tumours). These results will be presented elsewhere.

The specificity of antibodies to normal and leukæmic deoxyribonucleoproteins indicates the existence of a structural difference between the deoxyribonucleoproteins. This specificity, at the same time, argues for the nativity of these preparations; and it implies a genetic differentiation of the nuclear deoxyribonucleoproteins in the growth of white blood cells.

It is hoped that these findings may stimulate the genetic approach to the study of leukæmia and cancer.

I wish to thank the Department of Biophysics for the use of its facilities and Dr. Frederick I. Tsuji for his help.

Correlation between Ulcerative Colitis and *Rh* Blood Groups

Winstone, Henderson and Brooke[1] did not find ulcerative colitis to be correlated with the *ABO* blood groups, secretor status, or the rhesus factor. Their *Rh* classification was, however, restricted to rhesus-positive and rhesus-negative, presumably based on the use of an anti-*D* serum only. When we recently examined 185 patients in whom ulcerative colitis had led to colectomy, we also did not find any particular relation to *D* status, but did find, considerably to our surprise, a definite correlation with the homozygous *CC* rhesus type. Using as controls Wiener's series of 1,071 New York Whites[2], we obtained the results shown in Table 1.

Table 1

	Rhesus type			Total
	CC	*Cc*	*cc*	
Patients with colectomy	51	97	37	185
Normals	209	502	360	1,071

From these figures a value of χ-square with two degrees of freedom of 15·214 was calculated; this value is very definitely significant (P about 5×10^{-4}). So far as we could judge, the group of patients we tested did not differ in ethnic composition in any notable way from our controls. There is, however, evidence of heterogeneity in our test material ($\chi^2_{(10)}$ = 19·115, $0·05 > P > 0·02$). No correlation was found with *ABO*, *MN*, or secretor status.

We plan to extend these investigations and publish a more complete account elsewhere.

We are very grateful to the members of QT, Inc. (The Ileostomy Association of Boston), and the Ileostomy Associations of New York and Chicago for their generous and invaluable co-operation.

BIOLOGY

Molecular Biology or Ultrastructural Biology?

IN a recent communication[1], Prof. C. H. Waddington protests against the increasing use of the name 'molecular biology' for a large and ever-growing field to which, he argues, it does not apply, and suggests confining it to more restricted topics for which in any event a better name would be 'ultrastructural biology'. Since, as I believe, I was responsible for first propagating the name 'molecular biology', and its widespread adoption seems to date particularly from my 1950 Harvey Lecture "Adventures in Molecular Biology"[2], it may be worth while stating again what I personally had in mind. In that lecture I said that molecular biology, as I envisaged it, "implies not so much a technique as an approach, an approach from the viewpoint of the so-called basic sciences with the leading idea of searching below the large-scale manifestations of classical biology for the corresponding molecular plan. It is concerned particularly with the *forms* of biological molecules, and with the evolution, exploitation and ramification of those forms in the ascent to higher and higher levels of organisation. Molecular biology is predominantly three-dimensional and structural—which does not mean, however, that it is merely a refinement of morphology. It must at the same time inquire into genesis and function".

I was inspired, obviously, by our early X-ray and accessory adventures at Leeds in demonstrating, for example, the folding and unfolding of protein chains and the nature of the long-range elasticity of mammalian hairs; the classification of the fibrous proteins into two principal configurational families—the *k-m-e-f* group and the collagen group; the similarity between the keratins of birds and reptiles which distinguishes them from the mammals; the apparent common configurational plan underlying the elastic and contractile properties of hair, epidermis, muscle and (more recently) bacterial flagella; the interpretation of protein denaturation and the relation between the fibrous proteins and the globular proteins (as we called them); the detailed exploration of the cellulose fabric of the cell wall of the alga *Valonia ventricosa*; first studies of the structure of the nucleic acids and nucleo-proteins, etc. Of later years, other examples of how we have continued along the same general line of thought are Rudall's work on the molecular structure of types of cuticles and of the various kinds of silks and other cocoon proteins[3], and Pautard's investigations into the problem of biological calcification, from ciliates to cetaceans, with his latest X-ray demonstration that the organic matrix of tooth enamel is not a collagen (as it is with dentine and bone) but is more like a member of the *k-m-e-f* group[4].

I trust that Prof. Waddington will not mind my recalling in this way our original concept of molecular biology, and will agree that we have kept fairly faithfully to it. It is impossible, though, to embark seriously on work of this kind without being interested in, and becoming more and more involved in, numerous associated studies, with the result that, as has happened, there soon comes a time when there seems to be no end to the business. Molecular biology has now inevitably spread to all aspects of biology looked at from fundamental molecular viewpoints—and thus includes 'molecular genetics', for example, if I may dare suggest it; and it is difficult to maintain that such an eventual extrapolation is unwarranted, for it is simply saying that that is the coming biology.

After all this it might well be asked, Why then is our laboratory at Leeds called the Department of Biomolecular Structure? The answer is that, when in 1945 I was appointed professor, the university committee considering me, and from which I was naturally excluded, preferred the name 'biomolecular structure' to 'molecular biology', which was what I myself wanted. Presumably, a majority of the members of that committee held opinions similar to those expressed by Prof. Waddington, and I offer this argument in his support; though I will confess that a probably more candid, and conceivably better justified, assessment that leaked out to me was that "he may know something about molecules but he knows precious little about biology". The answer to that one of course, in the tiresomely good old words, is that it all depends on what you mean by biology.

W. T. ASTBURY

Department of Biomolecular Structure,
University of Leeds.

OF all the recently developed types of analytical biology, the field of which Prof. Astbury was one of the main initiators has probably the best claim to the title 'molecular biology'. But even granting this, it is as well to remember that it was just because Astbury went on from the study of well-defined molecules to investigate entities such as hairs, which can at best by courtesy be called molecular, that he was able to open the doors through which so many people are now passing. If we want a title for the whole field of which Astbury's work forms a part, but which includes also the study of genes, microsomes, endoplasmic reticulum, antibodies and so on, by techniques only a few of which are definitely chemical, then I submit that we require a name which is more inclusive than 'molecular biology'.

Feather Lipids

The plumage of fourteen widely differing species of birds excepting that of a ratite, the emu (*Dromaeus novae-hollandiae*), contained approximately 2 per cent of lipids which were readily extractable with ether or chloroform. The primitive plumage of the flightless emu yielded only 0·4 per cent lipids.

These feather lipids were found to contain cholestanol, cholestanylstearate and other steroids. Cholestanol and its esters contaminated by cholesterol were found in all fourteen species examined in amounts of about 7–15 per cent of the total feather lipids expressed as cholestanol[1]. Non-steroid esters, the alcoholic components of which varied with species, were also present. For the duck these consisted mainly of octadecanol and eicosanol. However, the greater part of the feather lipids was made up of free optically inactive fatty acids, with a chain-length of 7–22 carbon atoms. The most prominent of these were palmitic and stearic acid.

The outstanding features of the chemical composition of the bird's feather lipids are their unexpectedly high cholestanol content and the large amount of free fatty acids. Usually, cholestanol is but a small fraction of the cholesterol present in vertebrate tissue and the bulk of the fatty acids is esterified.

Feather lipids are of dissimilar qualitative composition to preen or oil gland secretion, except for the octadecanol fraction of some birds. In these cases this fraction is still quantitatively different as, for example, in the duck, where octadecanol esters comprise about 90 per cent of the entire oil-gland secretion[2] and the total feather lipids only contain about 10 per cent.

The quantitative composition of feather lipids from any one bird varies according to the type of the feather and the part of the feather examined. For example, in the duck, small feathers have a relatively high octadecanol-eicosanol ester content (17 per cent) while the large tail and wing feathers contain only about 1 per cent of this fraction. The compact shafts of large feathers are characterized by a large amount of free cholestanol (16 per cent), while the barbs contain only about 4 per cent (Table 1).

Table 1. Composition of Feather Lipids (Duck)

	Cholestanol (per cent)	Cholestanyl esters (per cent)	Octadecanol fraction (per cent)	Fatty acids (per cent)
Small feathers	5	12	17	57
Large feathers	10	7	2	82
Barbs of large feathers	4	7	1	90
Shafts of large feathers	16	6	1	76

With no sebaceous glands in the bird's skin other than the preen gland, which may not be present (dove, emu, etc.[3]) the feather lipids found in the plumage are considered to be a by-product of the keratinization process apparently being formed with the feather as it develops. They are water-repellent enough to take the place of the secretion of the preen gland. Thus, water birds which had their oil gland removed surgically remained dry[4], because the feather lipids functioned as water-repellents. In the controversy about the water-repellent properties of bird-feathers the role of the feather lipids has apparently been overlooked.

α-Conarachin

It is generally considered that the major globulins of dicotyledons and the prolamins and glutelins of monocotyledons are reserve proteins, that is, they are digested enzymatically on germination, whereupon the amino-acids and peptides are made available for protein synthesis[1]. Actually, all the protein in the storage organ of the seed eventually disappears, as does the organ itself. But the label of reserve protein has been put on those proteins, small in number, which comprise a relatively large percentage of the total protein, which change early in germination, and which possess no obvious biological activity. Reserve proteins would be expected to have a characteristic pattern of metabolism on germination; ultracentrifuge patterns of protein extracts of pea-seeds at various stages of germination showed more rapid disappearance of the globulins[2], but this technique is not sufficiently discriminating to identify specific proteins with the pattern of change.

We have been able to achieve better identification of changes on germination with specific protein fractions of the peanut (*Arachis hypogaea*) by means of chromatography on DEAE cellulose. One fraction that changes its properties early on germination was isolated and named α-conarachin. It approaches monodispersity by standards of chromatography and ultracentrifugation.

The two major groups of globulins mentioned most often in the literature on peanut proteins are arachin, precipitated at 40 per cent saturation with ammonium sulphate from a salt extract of the peanut, and conarachin, precipitated by 85 per cent saturation of the supernatant after removal of arachin[3]. Both these fractions prepared from *NC*2 variety peanuts were dissolved in phosphate buffer, *p*H 7·9, $\mu = 0{\cdot}06$, and chromatographed on DEAE cellulose ('Selectacel', Brown Co.) by the procedures of Sober *et al.*[4]. Elution was with a linear gradient of 0–0·6 *M* sodium chloride; protein analysis was by the method of Lowry *et al.*[5].

Chromatography patterns of the two fractions are shown in Fig. 1*A*; a pattern of an extract of the globulins from peanut cotyledons in the same buffer is shown in Fig. 1*B*. We have grouped the proteins into four arbitrarily selected fractions: the first is that which is not adsorbed on the cellulose; the second is eluted by salt concentrations up to 0·14 *M*; the third is eluted in the range of 0·14 to 0·23 *M*; and the fourth by concentrations of salt above 0·23 *M*. Arachin is mostly of group IV; conarachin comprises groups I, II, and III.

With the same chromatographic techniques, observations were made of changes in the proteins of peanut cotyledons after three days germination at

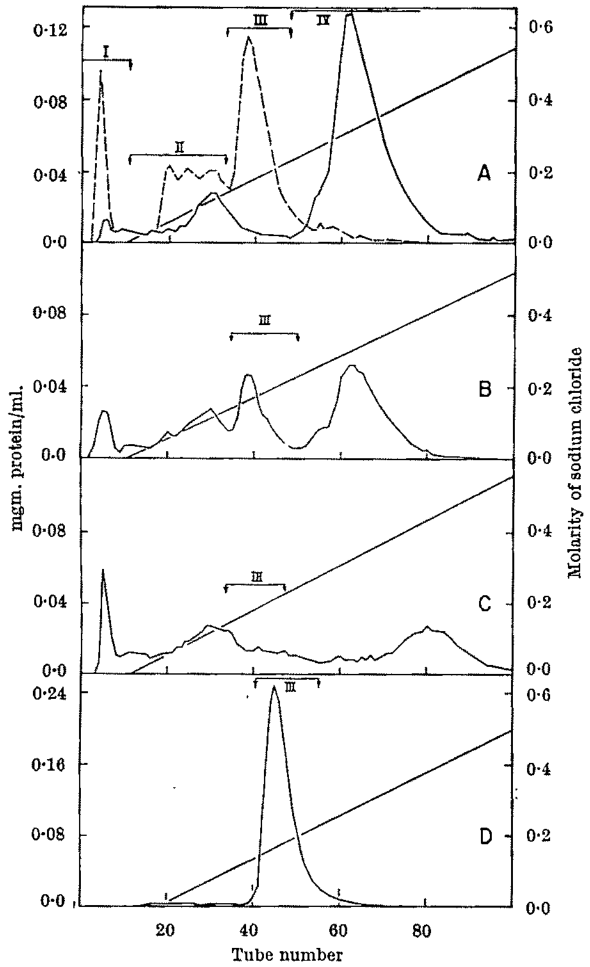

Fig. 1. Chromatography of peanut protein fractions on DEAE cellulose. 10 mgm. of each sample were put on 2 gm. of cellulose. The straight line indicates the sodium chloride gradient as measured on the eluate. *A*, Full line represents arachin fraction; broken line, conarachin fraction; *B*, extract of proteins from peanut cotyledons with buffer, *p*H 7·9, μ = 0·06; *C*, extract of proteins from cotyledons of germinated peanuts with same buffer; *D*, α-conarachin

25–28° C. Examination of the results given in Fig. 1*C* shows that the globulins of group III disappeared almost entirely from the chromatograph; there was an increase in the salt concentration at which the globulins of groups II and IV were eluted and a reduction in the relative amount of group IV; the proteins of the first group were mostly unchanged. We have no evidence yet of the nature of the changes that cause the disappearance of group III from the chromatogram; these may be selective hydrolysis of this protein or may arise from changes such as deamidation, which would result in an increase in negative charge at the *p*H of chromatography. Indeed, only 70 per cent of the proteins were recovered from the chromatogram when those of the germinated seed were examined as compared with 99–95 per cent from the resting seed. By using a higher concentration of salt and higher *p*H, other proteins were recovered from the column, but their relationship to the original protein has not been established.

The major protein of group III was purified by chromatography as follows: 250 mgm. of the conarachin fraction were dissolved in phosphate buffer at *p*H 7·9, ionic strength 0·06, dialysed for 24 hr. against the same buffer, adsorbed on a column (4 gm.) of DEAE cellulose, and chromatographed with 1,200 ml. of eluant under a linear gradient of 0–0·1 *M* added sodium chloride. This is a much gentler gradient than that used for the analytical chromatography. The eluate was discarded; a fresh gradient of 400 ml. of 0·1–0·2 *M* added sodium chloride served to elute the desired fraction. The middle portion of the eluate was saved, rechromatographed and concentrated; the yield was 30 per cent of the original conarachin fraction.

Chromatography of this fraction showed the presence of only one component (Fig. 1*D*); it contains 15·3 per cent nitrogen.

In buffer of ionic strength 0·5, *p*H 7·9, α-conarachin sediments as one component with an apparent sedimentation constant of 7·8; at $\mu = 0·06$, the sedimentation constant is 12·6; at intermediate ionic strengths, the pattern is a mixture of these two species. With the same constants as assumed for peanut protein by Johnson and Naismith[6], molecular weights of 142,000 and 295,000 were calculated for the two species. This confirms and extends the observations of Johnson and his associates that there are components of the peanut proteins which undergo association-dissociation.

Further work on the chemistry and on the metabolism of α-conarachin during germination might be expected to provide more information on the nature of reserve proteins. A full account of this and related work will be published at a later date.

We are grateful to W. K. Bailey for furnishing the sample of carefully selected peanuts.

Use of Agar Diffusion and Fluorescent Antibody

THE agar diffusion technique is very useful and has made a significant contribution in the analysis of antigenic materials. However, the difficulty encountered when trying to observe some of the precipitation zones is known to anyone who has used this method. Successful photography of the zones can be especially difficult to achieve.

By using fluorescent antibody in the agar diffusion procedure, the precipitation zones when viewed or photographed in the near ultra-violet range appear much clearer than with non-fluorescent antibody.

Fig. 1 shows the zone pattern of the plate on the right when photographed using fluorescent antibody and specific antigen. The plate on the left contains fluorescent antibody and non-specific antigen. Fig. 2 depicts the same materials when photographed without fluorescence.

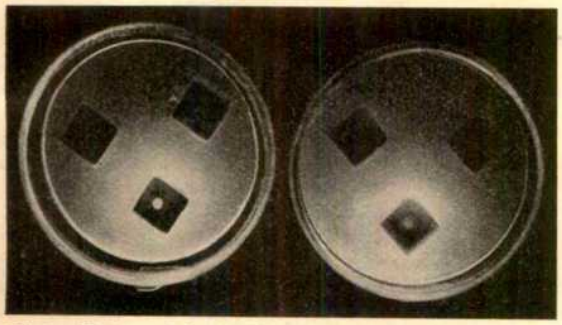

Fig. 1. Photographed using 'black light' and fluorescent antibody

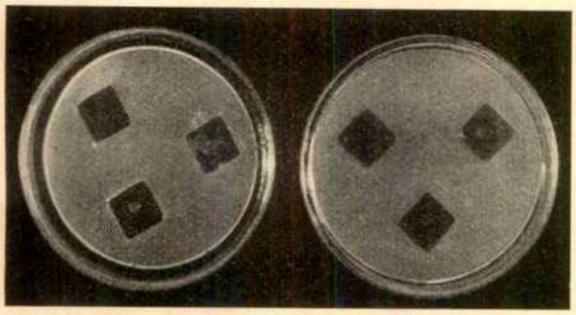

Fig. 2. Photographed using visible light without fluorescence

The method may be especially helpful if the concentrations of either of the reactants are limited.

An 'Apical Body' in the Galea Capitis of the Normal Bull Sperm

WORK on the ultrastructure of the bull sperm[1] has been continued on semen from normal, fertile bulls of the Red Danish Milk-breed. These earlier investigations were performed on bull semen kept on ice 24–48 hr. prior to osmium fixation.

More recently we have attempted to get the semen samples centrifuged as soon after the ejaculation as possible, and two specimens have been fixed (1 per cent osmium tetroxide) within 30 min. In such freshly prepared material the following new observations on the head of the bull sperm have been made.

Due to the characteristic tennis racket-like shape of the head (dimensions 8 × 4 × 0·5μ), complete coronal sections through the full flat area of the sperm head have only rarely been encountered.

For this reason more has been learned from the study of the sagittal sections such as those shown in Fig. 1*A*. An especially well-preserved median sagittal section of this type is marked with an arrow, and the schematic drawing (Fig. 1*B*) is based on this and similar photomicrographs.

The illustrations show that the sperm head contains a dense nucleus 0·2–0·3μ in thickness (*a*–*b*) with a somewhat thicker base (*a*) and a sharp-pointed apex (*b*) which forms a front edge. The basal half of the nucleus is covered by a rather thin but relatively electron-dense post-nuclear cap (*c*).

The apical half of the nucleus is covered by a somewhat thicker (about 0·1μ) and less electron-dense cap : the galea capitis (*d*). This structure has been described earlier[2] in the detached state in a light microscope study of the bull sperm.

Along the front edge of the sperm head the galea capitis forms a characteristic thickening, which we have chosen to name the apical body (Fig. 1*B*, *e*–*f*).

Our investigations indicate that the galea capitis with its apical body and the post-nuclear cap are completely enveloped by the cell membrane of the sperm, which thus covers the entire cell without interruption from the head to the tip of the tail. Further details of this morphological feature will be published elsewhere.

The apical body consists of a more or less closed fold (*f*) and a thickening in which a narrow cylindrical body or vacuole is situated (*e*). This presents a somewhat smaller density than the rest of the galea capitis, and seems to lie parallel with the fold along the front edge of the sperm head.

In the median section of Figs. 1*A* and *B*, the fold is seen as a hook-formed element and the vacuole as an oval less-dense area with a diameter of about 0·1μ.

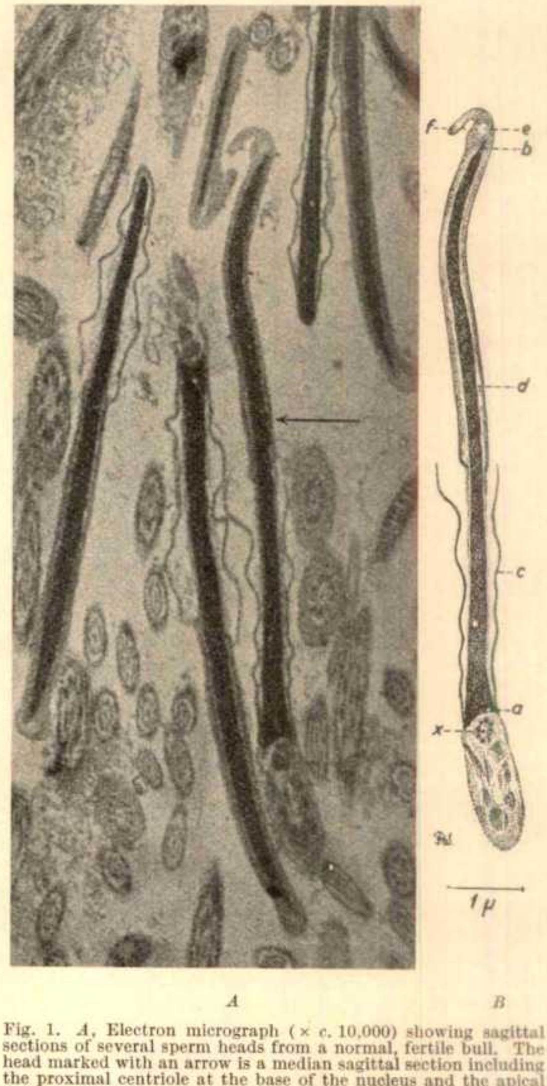

Fig. 1. *A*, Electron micrograph (× *c*. 10,000) showing sagittal sections of several sperm heads from a normal, fertile bull. The head marked with an arrow is a median sagittal section including the proximal centriole at the base of the nucleus and the apical body at the front edge of the head. In four of the other sagittal sections the apical vacuole is visible. *B*, Schematic drawing of a median sagittal section of the sperm head: *a*, base of the nucleus; *b*, apex of the nucleus; *c*, post-nuclear cap; *d*, galea capitis; *e*, apical body with the apical vacuole; *f*, fold of the apical body; *x*, proximal centriole. (Drawn by Poul H. Winther)

Often the fold is more acutely bent towards the sperm head proper than shown in Figs. 1*A* and *B*, and frequently the space between the fold and the rest of the galea has been almost closed.

At higher magnification the morphology of the apical body just described has been verified in sections of 12 individual sperm heads from 3 different bulls.

A similar structure has also been demonstrated in the galea capitis of rabbit sperm.

Most likely the apical body of the galea capitis in the bull sperm is a very delicate structure, so delicate that it can only be preserved and thus demonstrated in sperm fixed in the living state. Examination of the electron micrographs of unsectioned bull sperm published by Hancock[3] seems to present some support for this interpretation. The front edge of the head of a cell fixed in the living state (shown in plate 19*a* of Hancock's paper) contains a structure which could very well be identified as the apical body described in this communication, whereas the head of a sperm which was dead prior to preparation for electron microscopy and which is illustrated in plate 19*b* of the paper shows no evidence of this structure.

Structural Asymmetry in Cilia and Flagella

IT has become possible recently to describe the fine structure of cilia and flagella in more detail than was feasible before, and a characteristic structural asymmetry has been noted in the flagellum of certain flagellates[1]. This communication reports a similar asymmetry in cilia and flagella of a wide range of organisms.

The material investigated includes the ciliate *Paramecium multimicronucleatum*, and ciliated epithelia from mussel (*Anodonta cataracta*), frog (*Rana pipiens*) and the rat. Further observations are reported on the flagellates *Holomastigotoides*, *Pseudotrichonympha*, and *Trichonympha*. For convenience, the term 'cilium' will be used here to include the flagellum of these flagellates.

The cilia are cylindrical structures containing a complex array of fibres oriented longitudinally. Their asymmetry results from the arrangement of the nine outer fibres (Figs. 1, 3). In transverse sections of the cilium each outer fibre appears as a doublet with a figure-of-eight cross-section and bears two projections, or 'arms', that extend towards one adjacent outer fibre. These arms point in the same direction on all the fibres in a given cilium. This configuration could exist, theoretically, in two enantiomorphic forms; the clockwise form may be defined as that in which, to an observer looking outwards along the cilium from base to tip, the arms all point in a clockwise direction. In the basal body, at the cytoplasmic end of the cilium, the arrangement of the outer fibres is different, but again asymmetrical. Here the fibres are triplets; they do not bear arms, but each fibre is tilted inwards at about 40° to the overall tangent to the basal body. The relationship between basal body and cilium is such that in the clockwise form (as defined here), the configuration shown in Figs. 2 and 4 is seen by an observer looking outwards from the end of the basal body that lies deepest in the cytoplasm[1]. All these structural features are essentially the same in cilia of all the organisms examined.

In order to determine whether a cilium has the clockwise or counter-clockwise form it is necessary to examine in the electron microscope an accurate cross-section of known absolute orientation. With *Paramecium*, random sections were cut and the orientation determined in the microscope from the known asymmetry of the kinetodesmal fibrils[2]. With the other organisms it was necessary to know the orientation in which a section was cut from the specimen, and to keep track of it through later manipulations.

The asymmetry has been observed in six individuals of *Trichonympha*, one *Pseudotrichonympha*, one *Holomastigotoides*, and six *Paramecium*; gill epithelium from four mussels; pharyngeal epithelium from one frog; tracheal epithelium from six rats. The following results were obtained:

(1) So far as could be determined, all the cilia in any one specimen had the same enantiomorphic form (an average of about fifty cilia were examined in each specimen).

Fig. 2. Electron micrograph showing a cross-section of a basal body in *Holomastigotoides*
Fig. 3. Diagrammatic reconstruction based on Fig. 1
Fig. 4. Diagrammatic reconstruction based on Fig. 2

(2) All specimens had cilia of the clockwise form. This apparent uniformity in such widely separate groups of animals suggests that all cilia, whatever their source, have the same clockwise form. However, the occasional occurrence of the counter-clockwise form cannot be excluded.

Essentially the same arrangement of doublet fibres bearing arms occurs also in many sperm-tails, for example, from the sea-urchin[3], butterfly[4], and rat (Gibbons, I. R., unpublished observations). (The frequent presence of extra components not found in cilia is irrelevant to the present consideration.) It seems probable that sperm-tails will show the same uniformity of asymmetry as cilia, but the difficulty of determining the absolute orientation of cross-sections has so far prevented examination of this point.

For a number of years it has been known that the movement of spermatozoa from many animals is asymmetrical[5,6]. The most obvious, though not the most fundamental, expression of this is seen when freely swimming sperm come into contact with an obstructing surface: they usually move around on it in counter-clockwise circles (as seen on looking towards the surface). More recently, Parducz[7] has described a characteristic counter-clockwise motion of the cilia of *Paramecium*. Such asymmetry of movement might perhaps be related to the structural asymmetry that has been described here.

Genetically Mixed Perithecia in *Neurospora*

SANSOME[1] has produced evidence that the asci in a single perithecium of *Neurospora crassa* may originate from more than one pair of gamete nuclei. Despite Sansome's evidence, it has been accepted generally that there is only one egg and one sperm nucleus[2].

Sansome used a heterocaryon as one of the parents in her experiment, so that the genetically different sperm nuclei in each perithecium could have originated from a single multinucleate cell. If one accepts Sansome's results, the question still remains whether or not the sperm nuclei in the ascogenous hyphæ of a single perithecium can originate from two or more different conidia. An answer to this question is presented here by using an ascospore colour mutant *ts* (tan-spore)[3].

A mixed suspension was made of approximately equal numbers of conidia from a *ts* culture and from a wild-type culture, both of mating type *A*. This suspension was used to fertilize protoperithecia, which had developed from a wild-type culture of mating type *a* on Westergaard and Mitchell's minimal agar medium[4]. More than seventy-five conidia were applied per protoperithecium. Fertilization was carried out within 5 min. after the mixed suspension was prepared to prevent formation of heterocaryons by the germinating conidia. The average number of nuclei in these two kinds of conidia was determined by Huebschman's method[5] to be 2·6 and 2·7 respectively. After the perithecia had matured, 2,778 perithecia were dissected and examined under the microscope. All the perithecia examined were observed to have a single ostiole. Those with two or more ostioles were discarded.

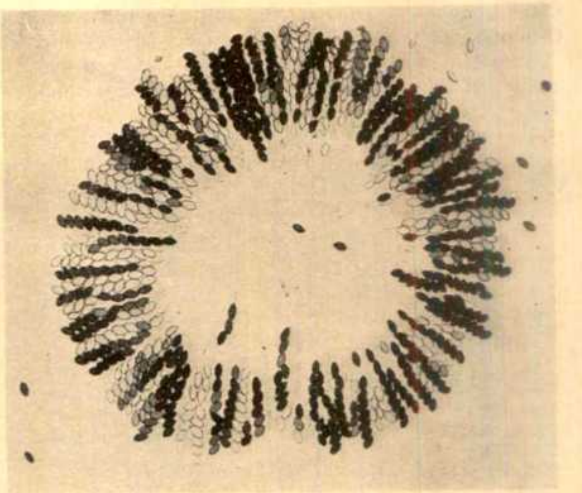

Fig. 1. Ascus cluster from a mixed-type perithecium, showing wild-type and segregating asci (the asci containing eight colourless ascospores are immature).

The great majority of these perithecia were homogeneous types, that is, they consisted entirely of asci segregating for *ts* and wild-type, or entirely of asci in which all the ascospores were wild-type. There were 1,231 perithecia homogeneous for the segregating asci, and 1,487 homogeneous for the non-segregating asci. Sixty perithecia, however, were found to be heterogeneous, containing both segregating and non-segregating asci (Fig. 1). The mixed perithecia indicate that two or more sperm nuclei from two or more conidia can be involved in the formation of a single perithecium. The frequency of heterogeneous perithecia (2 per cent) would indicate that at least 4 per cent of perithecia result from protoperithecia that have been fertilized by two or more conidia. This frequency is considerably lower than that reported by Sansome, who found four heterogeneous perithecia in a total of eight perithecia examined.

A count of the mature asci in 51 of the heterogeneous perithecia gave 933 of the non-segregating type and 692 of the segregating type. This differs significantly from a 1 : 1 ratio ($\chi^2 = 35 \cdot 7$, $P < 0 \cdot 001$), showing an advantage of the former during the time of ascus formation. The ratio of the two types of homogeneous perithecia also deviates significantly from a 1 : 1 ratio ($\chi^2 = 24 \cdot 1$. $P < 0 \cdot 001$), indicating a selective advantage of the wild-type nuclei over the *ts* nuclei for their entrance into the protoperithecium. Further analysis, at present being carried on by one of us (T. E.), shows that the ratio is affected in various ways by the stocks utilized in the crosses, indicating that a number of factors are involved in this phenomenon.

When this manuscript was in preparation, our attention was directed by Dr. D. D. Perkins to the unpublished work of Grant[6]. Grant obtained results very similar to those reported here. She obtained 2 heterogeneous perithecia from a total of 106 examined. One of these two, however, had two ostioles and was double the normal size, indicating that it was the result of the fusion of two separate trichogyne systems.

The supervision of Prof. T. Haga is greatly appreciated. Criticisms and corrections to the manuscript were supplied by Drs. D. D. Perkins and C. S. Gowans.

Flower Initiation in *Trifolium repens* L. : a Short-Long-Day Plant

PAST investigations into the photoperiodic control of flowering have led to the conclusion that *T. repens* is a long-day plant with a critical day-length of approximately 13·5 hr.[1]. It is also known that the response to photoperiod varies with temperature[2,3], the critical day-length being much shorter at low than at high temperatures. Investigations reported here now show that *T. repens* reacts as a typical short-long-day plant.

In a series of preliminary experiments, seedlings of New Zealand Government Stock white clover, grown at average temperatures of 20° C. at night and 25° during the day, failed to flower in long days unless they had previously received short days for at least 4 wk. Thus the response of *T. repens* to day-length is similar to that of *Campanula medium*[4] in which short days are necessary for the attainment of ripeness-to-flower before long days lead to the initiation of inflorescence primordia. Within the strain of clover used, however, 5–10 per cent of the individual plants fail to respond to day-length in any way.

A series of more detailed investigations was made into the nature of this short-long-day reaction system in clonal material from the same source. Ramets of two selected clones of white clover, *A* and *C*, were grown in glass-houses in which the temperature varied between minima of 15° and 21° C. at night and maxima of 21° and 32° C. during the day. Four day-length treatments were imposed: SDs (8-hr. photoperiods; plants darkened from 4 p.m.–8 a.m.); NDs (unsupplemented natural daylight providing photoperiods which decreased from 13 to 11 hr. during the experimental period); LDs (16-hr. photoperiods consisting of natural daylight supplemented from 4 a.m. to 8 a.m. and from 4 p.m. to 8 p.m. by artificial light); and CL (continuous light consisting of natural daylight supplemented by artificial light from 4 p.m. to 8 a.m.). Supplementary illumination was provided by 200-W. 'Sieray' mercury vapour lamps ballasted with a tungsten filament which gave an intensity of approximately 500 ft.-candles at the leaf surfaces.

In the first experiment, plants were exposed to either NDs or LDs for a preliminary period of two months and then transferred into either LDs or NDs. There were thus four groups of plants, each consisting of three ramets of each clone, which received NDs followed by LDs, NDs followed by NDs, LDs followed by NDs or LDs followed by LDs. Flowering was recorded on twenty vigorous runners from each ramet. Plants transferred from NDs to LDs produced an average of 0·82 flower head per runner in clone *A* and 0·91 in clone *C* as an immediate response to such treatment. No initiation of inflorescence occurred on the plants of any other group; 9 months after their period of preliminary treatment these were still entirely vegetative.

The first morphological sign of the transition of a vegetative apex to the reproductive state in white clover is the precocious development of a bud in the axil of the youngest leaf primordium. Such a bud appears in the axil of the first leaf primordium to be initiated at the apex of a ripe-to-flower runner after its transfer from short to long photoperiods. Following its initiation, this bud develops rapidly into a lateral inflorescence and the main stem apex reverts to the vegetative condition. This pattern of development is identical to that occurring in other *Trifolium* species[5,6].

The minimum requirement for both short days and long days has been determined by more recent investigations. The response to short days was tested by growing twenty plants of clone *A* for 2 months in LDs, exposing them to 0, 3, 6 or 14 SDs, and then returning them to LDs. The results (Table 1) show that in some circumstances initiation of inflorescence can occur in LDs after a preliminary exposure to as few as three SDs.

Table 1. THE EFFECT OF TREATMENT WITH SHORT DAYS ON INFLORESCENCE INITIATION AFTERWARDS IN LONG DAYS

No. of short days	0	3	6	14
Average number of inflorescences per runner Standard error	0·000 ± 0·000	0·105 ± 0·052	0·812 ± 0·098	1·595 ± 0·085

The sensitivity to long days is even greater than to short days. The combined results of two experiments to determine the minimum number of long days necessary to bring about inflorescence initiation are shown in Table 2. In both experiments plants of clone *A* which had been grown in NDs for 3 months immediately before treatment were exposed to a period of CL and then returned to NDs. Under these conditions a single day of CL was sufficient to induce the initiation of inflorescence primordia.

Table 2. THE EFFECT OF THE DURATION OF EXPOSURE TO CONTINUOUS LIGHT ON SUBSEQUENT INFLORESCENCE INITIATION IN SHORT DAYS

No. of days continuous light	0	1	2	4	6
Total number of runners	54	100	18	18	18
Percentage of runners bearing inflorescences	0	94	100	100	100

Some individuals within a population of New Zealand Government Stock white clover are thus very sensitive short-long-day plants at the temperatures used during the present investigation. Ripeness-to-flower will only occur in short days and, once this condition is attained, a single long day is sufficient to bring about inflorescence initiation. A comparable sensitivity to long days has so far been reported to occur in only one long-day plant: *Lolium temulentum*[7].

Further investigations into the nature of the short-long-day reaction system are in progress and will be reported in detail elsewhere.

Early Flower Initiation in the Banana

THE commercial banana is typically seedless and must be propagated vegetatively by lateral buds which appear on the true stem at the base of a large plant. Depending on climate and season, a flower bud appears when the pseudostem is 12–20 ft. tall (variety Gros Michel) and only after a succession of more than 40 leaves. Recently, however, on farms of the United Fruit Co. in Guatemala and Honduras, shoots have flowered when only 2–3 ft. tall, while still attached to the base of a 'mother' plant, and following the production of seven or fewer leaves.

These fruited suckers were noted in the field in conjunction with the application of a rapid method of banana multiplication[1], which is based on the forcing of immature lateral buds while harvesting the more matured buds as vegetative 'seed'. By this means up to 24 propagules have been obtained from a single planted bit within a year. The majority of these forced suckers have been normal and have flowered after the appropriate vegetative period. However, in at least 21 instances lateral buds have produced fruits after an abbreviated vegetative period and while still attached to the parent.

The circumstances surrounding this early flowering were investigated in Guatemala. Invariably the fruited suckers appeared as lateral shoots from the base of plants that were themselves in flower. Invariably the suckers developed from the latest formed viable buds—those appearing close to the terminal apex and passing through their early development at the time of the conversion of the apical parental bud to the flowering state. No more than one flowering sucker has ever been observed to be attached to any single parent plant and all have been noted on the variety, Cocos, a dwarfed sport of the Gros Michel.

The fruited small suckers generally were of normal appearance but dwarfed in size, as in Fig. 1. There were a number of variants; some produced a series of bladeless leaves enclosing anomalous structures that resembled lateral inflorescences yet showed no flowers; a few flowered directly without any leaves. Most significantly, however, all produced the terminal and clearly recognizable flower bud very early.

In three respects the plants involved were treated differently from similar plants grown in similar areas. All were wounded heavily and continuously in connexion with the multiplication technique. All were provided with an extremely high level of nitrogen, as urea, applied as a side dressing. Immature buds proximal to the parental apex were forced at the time of the conversion of the parental bud to the flowering state.

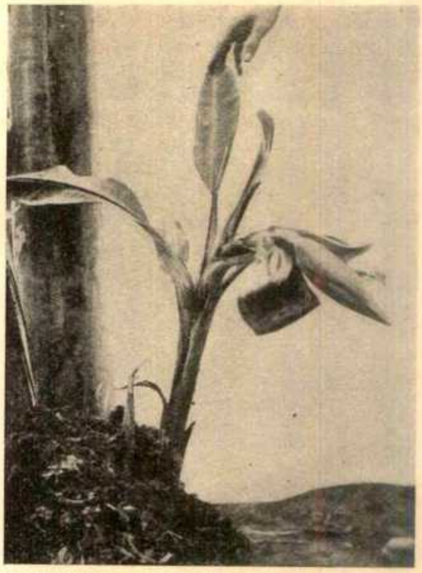

Fig. 1. Small, fruited sucker. The form is normal, however, the number of vegetative leaves preceding the inflorescence has been reduced to 7 and the number of flowers sharply decreased. Note the size relative to the hand and the parent pseudostem

It is not likely that the luxury supply of nitrogen would be concerned since classically this would favour vegetative development and suppress reproductive tendencies. The heavy wounding must not entirely be discounted since the stimulatory effect of wounding on plant and cell activity is well documented[2–4]. In addition, it has been noted that field banana fruiting abnormalities are almost invariably associated with wind damage, insect injury, machete cuts, or disease incidence. However, the rarity of such abnormalities would suggest that the response could only be elicited when the apex was in a susceptible stage.

The third possibility relates the conversion to flowering of the parental terminal bud to a simultaneous, but often less-efficient, induction by the same stimulus of a proximally located forced lateral bud. In untreated plants (not undergoing multiplication) such buds would be rudimentary and would never develop to form a shoot. In treated plants, and even so in rare instances, buds sufficiently advanced to be influenced by an overflow of the parental conversion factor are located sufficiently near to respond. These may then be imperfectly or wholly converted to the flowering status by the parental stimulus. Hence in the subsequent development of the lateral shoot, where this is permitted, the newly acquired character is manifest as either a perfect or anomalous inflorescence, with the number of preceding leaves dictated by the status of the bud at the time of its conversion.

Pertinent to this is a body of literature concerning lateral inflorescences in the banana[5]. Invariably these have appeared in conjunction with the flowering of the main axis and have involved buds very close to the terminal bud. The rarity of such occurrences in the field undoubtedly relates to the observation of Skutch[6] that buds do not form along the elongated true stem of the fruiting banana. Should buds occupy sites along the elongated axis, and should their later development occur, then the lateral inflorescences of Ghosh[5] could be explained by the overflow mechanism outlined above.

The occurrence of these early flowers is important from the point of view of the theory of flowering. For some years attempts have been made at influencing the onset of flowering in the banana, as has been done in the pineapple[7,8], but without success. The conversion of these young buds at such an early stage indicates that there is a good probability that the meristem of older plants also can be influenced if treated appropriately. The benefits of such control over the fruiting habits of a commercial crop need not be discussed.

ENTOMOLOGY

Control of the Responsiveness of the Blowfly to Water

'Hunger' in the blowfly (*Phormia regina*, Meig.) has been the subject of several studies. The present experiments were undertaken to examine the related problem of 'thirst' or the control of water intake. Bolwig[2] showed that blood osmotic pressure was correlated with responsiveness to water applied to the tarsi of a fly. Wolbarsht[3] suggested that the response of the contact chemoreceptors to water was increased in desiccated flies. Since ingestion is primarily controlled by the taste receptors[1], such a relationship would provide for a direct and specific regulation of water ingestion.

Flies, if dehydrated enough, reflexively extend their proboscis on contact of the tarsal or labellar chemoreceptors with water. Normally, taste thresholds are expressed as the effective concentration of the test substance in solvent. In the present case, the number of flies that responded to water was the measure used. Only those flies were included that were either uniformly negative or positive on each of three tests before treatment. Dehydration was accomplished by confinement of the flies over calcium chloride in a sealed vessel. Water-negative controls were members of the same population that had been kept in the normal room atmosphere or that had been given water after desiccation. Injections were given as described by Evans and Dethier[4]. Unless stated otherwise, tests were performed within 5 min. after the injection (Table 1).

Water-positive flies were rendered negative by injections of distilled water into the hæmocœl (exp. 1–3). The effect was immediate (exp. 1–3) and persistent (exp. 4) and depended on the volume injected (exp. 3, repeated injections). Injection of small (exp. 5 and 7) or large (exp. 6) volumes of hyper-osmotic solutions into the water-negatives did not render them positive. On the other hand, these same injections did, like distilled water, make positive flies negative (exp. 8–11). Some of the treatments produced a high mortality, but the effects on the water response appeared specific since the flies would respond normally to dilute sugar solutions after the most severe treatment (exp. 3, 5, 6).

Table 1. Effect of Injections on Responses of the Blowfly to Water

Experiment No.	No. of flies	Response before treatment	Injected †	No. negative after treatment
1	35	+	2·5 μl. water	6
2	52	+	8 μl. water	44
3	27	+	2 μl. water	2
			2 μl. water	6
			2 μl. water	18*
4	26	+	3 μl. water	
			immediately	15
			at 10 min.	15
			at 60 min.	14
5	120	−	3 μl. 2 *M* glucose	98*
6	116	−	7 μl. 2 *M* glucose	111*
7	29	−	2·4 μl. 4 × saline	29
8	53	+	3 μl. 4 × saline	29
9	69	+	3 μl. 2 *M* glucose	38
10	28	+	3 μl. 2 *M* glucose in saline	14
11	25	+	6 μl. 2 *M* glucose in saline	21

* Responded afterwards to 0·1 *M* sucrose.
† Water indicates distilled water; the saline was Bodenstein's (ref. 9); 4 × indicates saline four times more concentrated.

Since, however, all the foregoing procedures that were effective blocked a response and none elicited one, it was crucial to reduce blood volume and thereby elicit responses to water. The only effective method of bleeding *Phormia* is to cut off the forelegs near the base and compress the thorax on all sides[4]. In this way up to half the blood can be expressed with little damage to structures other than the forelegs. In the present experiments all the blood was removed that could be with gentle pressure. Although the forelegs are important bearers of contact chemoreceptors, the other two pairs of legs, when stimulated, can produce proboscis extension[5]. If a uniform population of flies was desiccated until some became responsive to water, most of the remainder were made positive by bleeding (45 out of 53). The result was dramatic: as quickly as the fly could be tested after bleeding (a few seconds), a vigorous response was obtained when before there was none. Even when the bleeding was deliberately traumatic, a feeble response could be obtained as the animal died. In flies that were originally water-positive, bleeding did not alter the response (12 out of 12). The amount of blood obtainable seemed markedly less in the positive than in the negative flies; and it seemed that the few flies that did not respond after bleeding were those from which the greatest volume could be obtained. Apparently, if blood volume was above a certain level, bleeding could not reduce it sufficiently below some threshold value. Similarly, when members of a population were bled that had been given water to repletion, few were made water positive (4 out of 13).

These results do not conflict with Bolwig's[2], since blood osmotic pressure may well be a function of body water and blood volume. The results, however, demonstrate that neither osmotic concentration nor the concentration of any blood constituent determines sensitivity to water. Moreover, they do strongly suggest that blood volume via a rapid acting (neural) pathway sets the sensitivity of some element involved in the feeding response. Since some aspect of blood volume is the effective agent, the detector is most likely a mechanoreceptor. Although dehydration of the chemoreceptors as the mechanism cannot account for the present results, Wolbarsht's[3] suggestion that chemoreceptor sensitivity is the regulated factor is tenable. This might operate in two ways: either the chemoreceptors (one or both) are also affected by mechanical stimuli and some aspect of blood volume is an effective mechanical stimulus, or mechanoreceptors elsewhere influence chemoreceptor discharge. Neither of these possibilities is unprecedented: Hodgson and Barton Browne[6] have evidence that bending of a chemosensory hair does alter (not very predictably) the response of the chemosensory cells to chemicals; and there are many demonstrations of the control of sense organ discharge by afferent neurones of the central nervous system[7]. However, histological[5] and electron microscopic (Dethier, V. G., personal communication) studies have not revealed nerve terminals on the chemosensory cells. The equally likely possibility remains that the mechanoreceptor discharge sets the sensitivity of some element further along the path of the feeding response. This latter mechanism has been shown to be the case for the regulation of taste thresholds to sugars[1]: sugar solutions in the foregut via an unknown connexion (neural or hormonal) with the central nervous system determine the behavioural sensitivity of the fly to sugars. Since all evidence indicates that the ingestion of both water and sugars is evoked by discharge of the same chemosensory cell[5], only a specific regulation of sensitivity to water at the level of the sensory cell would appear at first sight to provide for an independent regulation of water and sugar ingestion; but as will be shown elsewhere, this is not necessarily so[8]. There is evidence that the two are independently controlled (Dethier, V. G., personal communication). Additional details of the present experiments and other data relevant to the regulation of water ingestion will be reported elsewhere[8].

VIROLOGY

Multiplication *in vitro* of a Nuclear Polyhedrosis Virus in Insect Amœbocytes

Culture, *in vitro*, of nuclear polyhedrosis virus has been achieved, so far, in cells derived from what appears to be the outer epithelial sheath of the larval ovariole of Lepidoptera[1,2]. Grace[3] reported virus induction *in vitro* in cells from explants of the same organ.

A method for the preparation of primary monolayers, using the usually abundant supply of larval hæmocytes of one easily mass-reared species of Lepidoptera, *Peridroma saucia* (Hübner), is being described elsewhere[4]. Our interest in this type of cells for virological work was stimulated by the encouraging results obtained with similar cultures from vertebrate leukocytes[5]. Furthermore, it is not improbable, according to Wigglesworth[6], that the cells migrating from the explants of the larval ovariole maintained *in vitro* are hæmocytes formerly adherent to the tissues.

Glaser[7] attempted infection, *in vitro*, of hæmocytes from larvæ of *Malacosoma americanum* (Fabricius), with nuclear polyhedrosis virus. The results were negative. Formation of the typical intranuclear inclusions was observed by Glaser only when infection of the hæmocytes occurred *in vivo*, and the cells transplanted *in vitro*, 10–12 days following infection of the animal. The lack of success in Glaser's infection experiment could have been derived from a lack of virus adsorption, or more likely from inactivation of the labile Berkefeld filtrate or from its preparation at a time when filterable elements were extremely rare in the larvæ used. Glaser's hypothesis that "... the early stages of the virus require some particular organ or tissue or some particular condition" is not supported, in part at least, by our investigations, as we have achieved direct infection of amœbocytes *in vitro*, in the particular microenvironment of our cell cultures.

The hæmocytes of sixth-instar larvæ of *P. saucia* are cultured on Corning 22 × 22 mm. No. 1 cover glasses, in 60-mm. Petri dishes, with 4 ml. of medium[4] containing 15 per cent homologous insect blood plasma and 15 per cent fœtal bovine serum. After 20–24 hr. incubation at 25° C. in a gas mixture of 1 per cent oxygen, 3 per cent carbon dioxide and 96 per cent nitrogen, a continuous monolayer of single cells and polynucleated syncytia is formed (Fig. 1). The culture medium is discarded and the cells are rinsed with 3·5–4 ml. of a balanced salt solution[4]. The virus suspension is prepared as follows: Larvæ of *P. saucia* showing the definite syndrome of nuclear polyhedrosis are anæsthetized at the seventh day after peroral infection; their integument is cut laterally, along a longitudinal line, and the intestinal tract, with the Malpighian tubules, is excised and discarded. The remaining parts of the larvæ are placed immediately

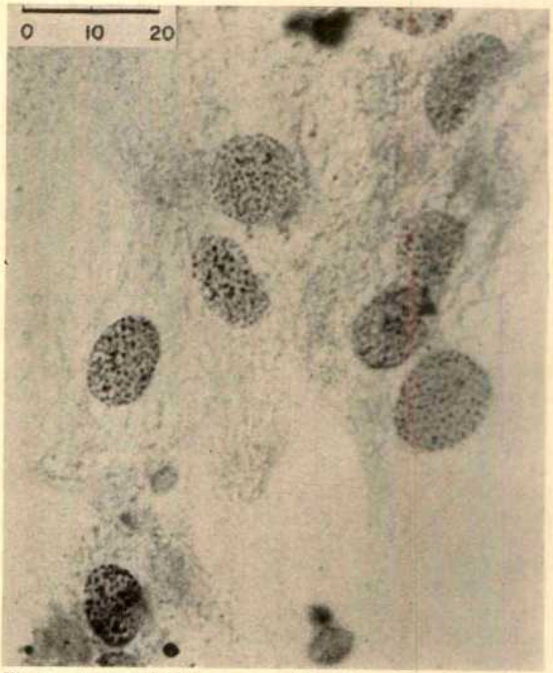

Fig. 1. Average field from a non-infected control culture of the same cell pool as in Fig. 2. Note the basophile granulations in the nuclei, which are typical for normal larval amœbocytes of *Peridroma saucia* (Hübner) *in vitro*. Culture, 6 days old. Duboscq–Brasil. Giemsa. Scale, microns

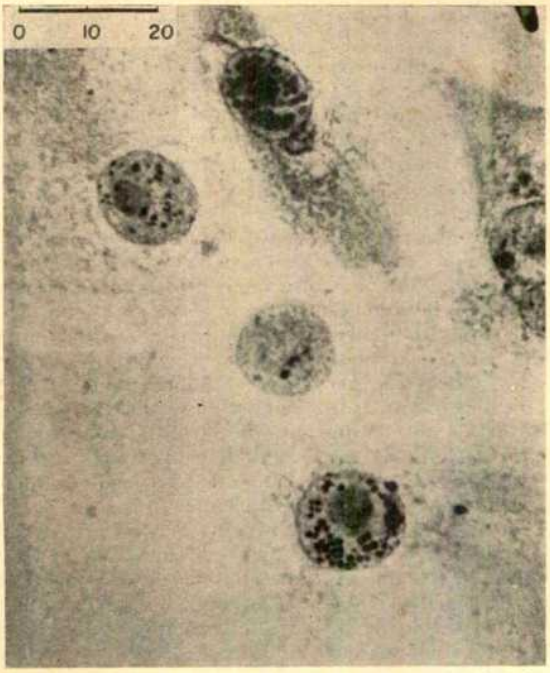

Fig. 2. A group of infected amœbocytes with nuclear polyhedra in an advanced stage of development. The central chromatin mass is still visible in two nuclei. Same cell pool as in Fig. 1. Culture, 6 days old. Infection, 5 days old. Duboscq–Brasil. Giemsa. Scale, microns. (Photography, V. G. Duran)

in a Ten Broek tissue grinder, with 2·5–5 ml. of culture medium[4] per larva. After homogenization, the fluid is centrifuged for 5 min. at maximum speed (3,200 r.p.m.) in the horizontal swinging tube head of an International clinical centrifuge, in order to eliminate the larger tissue particles and the polyhedral inclusion bodies. The supernatant is transferred to cellulose nitrate tubes and centrifuged for 10 min. at 10,000 r.p.m. in the angle rotor of a Servall *SS* 1 Superspeed centrifuge. The final supernatant is passed through a 'Millipore' microfibre glass prefilter disk and a 'Millipore' *HA* filter (pore size 450 mμ). The cultures are incubated with the virus suspension (0·5–2·0 ml.) for 3–4 hr., at 25° C. in the gas mixture described here. After this period the cultures are rinsed with balanced salt solution and supplied with 3·5–4 ml. of fresh culture medium, to which 30 per cent fœtal bovine serum has been added. On the third day after infection the medium is changed and at the fourth to sixth day after infection the cultures are fixed. The cover glasses are rinsed with balanced salt solution in a small Coplin staining dish, for about 5 min.; the balanced salt solution is replaced with Duboscq–Brasil's fluid (12 hr.), the slides are rinsed in repeated changes of 70 per cent ethanol and stained overnight in a 1 per cent solution of Giemsa's stain in *M*/112 phosphate buffer, at *p*H 7·17. Differentiation is performed in 80 per cent ethanol containing 0·5 per cent glacial acetic acid. The preparations are dehydrated in acetone–xylene mixtures and mounted in 'Caedax' Bayer.

Infection with nuclear polyhedrosis virus *in vitro* produced the typical sequence of cytological changes observed *in vivo*[8]. The cytopathogenic effect is particularly evident in the large, flattened nuclei of the amœbocytes (plasmatocytes), with a loss of basophilia, central condensation of the chromatin mass, formation of the 'anneau miroitant', and formation of the polyhedral inclusion bodies within the nucleus. In our preparations, most polyhedra were fixed and stained during their forming phase, when residues of the central chromatin mass were still visible: at this stage (Fig. 2) the inclusions are strongly eosinophile, and the infected cells can be spotted easily in the monolayer cultures by the bright red colour of the inclusion bodies, even at low magnification. These infected cells sometimes appear in groups, suggesting a possible use of these primary monolayers for virus titration *in vitro* by the plaque technique. Quantitative work on viral multiplication in our cell cultures is in progress.

This investigation was supported in part by research grant *E*–2307 from the National Institute of Allergy and Infectious Diseases, U.S. Public Health Service.

GENETICS

Effects of Maternal Age on the Incidence of Congenital Abnormalities in Mouse and Man

The value of data from laboratory animals for the interpretation of the incidence of congenital abnormalities in human beings was first pointed out some time ago by Wright[1]. Results I have obtained from a balanced two-point backcross linkage experiment in the mouse have shown an effect of maternal age both on viability and recombination. The purpose of this communication is to present these results and discuss their implications for similar phenomena in human beings.

The factors used in the linkage experiment were *pallid* and *fidget*; they are both recessives and known to be in linkage group V. Both factors are generally associated with fairly severe reductions in viability and fertility. The results were obtained from female coupling and repulsion heterozygotes using *pallid fidget* males. A summary of the results, analysed according to the age of the maternal parent, is given in Table 1. Following Fisher[2], the regression of the proportions of *fidgets*, *pallids* and recombinants with maternal age was analysed after applying the angular transformation. A more detailed analysis of these data will be published elsewhere.

The linear regression in the proportion of *fidgets* with maternal age is highly significant and the quadratic regression is significant at the 5 per cent level. The proportion of *pallids*, on the other hand, shows no significant linear regression but a highly significant quadratic component. It seems worth noting that the deterioration in *fidget* viability apparently starts before the major decrease in litter size.

The linear regression of recombination fraction with increasing maternal age is significant at the 5 per cent level and there is no evidence for any significant departure from linearity. A significant downward

trend of recombination with maternal age in mice was also reported by Fisher[2]. The phenomenon is well known in *Drosophila*[3].

Mongolism in man is now known to be caused by aneuploidy for one of the smaller somatic chromosomes[4]. This is most probably the result of meiotic non-disjunction for the relevant chromosome. Mongolism is also well known to increase in incidence with maternal age[5]. Early work with *Drosophila* showed that an increase of non-disjunction was generally associated with a decrease in crossing-over[6]. Thus the increase in the incidence of mongolism in man, reflecting an increase in non-disjunction, and the decrease in the frequency of recombination in mice may well have a common origin in the effect of maternal age on the efficiency of chromosome pairing at meiosis. In rye, Rees and Naylor[7] have shown that developmental variations within an anther cause significant differences in chiasma frequency. Chiasma formation and chromosome pairing may clearly be considerably affected by developmental differences such as probably occur in the ovum of the ageing mother. In fact Polani *et al.*[8] have suggested a specific mechanism for the way in which this might happen.

The effects of maternal age and order of birth on a number of developmental abnormalities in humans have been extensively studied (see, for example, Penrose[9]). The incidence of congenital deformities of the nervous system, in particular anencephaly, spina bifida and hydrocephaly, shows, in general, a marked increase with increasing maternal age. These are abnormalities which cannot be explained by any simple genetic hypothesis and which are considerably subject to environmental influences, as is well illustrated by Edwards's remarkable results[10]. An increase in the frequency of white spotting in guinea-pigs was also found by Wright[1]. It is in marked contrast to the decrease in the number of *fidgets*, and later *pallids*, with increasing maternal age in mice. In general it seems unlikely that any congenital abnormality associated with a single gene difference should show an increase in incidence with maternal age. Such a factor is likely to be associated with fairly severe viability disturbances, although perhaps not so severe as in mice because of the lack of intra-uterine competition. However, a decrease in incidence with maternal age certainly does not necessarily imply a simple genetic basis. Thus it has been shown in guinea pigs[1] and in mice[11] that the incidence of polydactyly decreases with maternal age. In both cases the variation was probably basically non-genetical developmental variation. It is, perhaps, surprising that it did not follow the same course as the developmental congenital abnormalities in humans.

Just as studies in mice may help in interpreting human phenomena, results from work on human beings may also be of relevance to the interpretation of mouse data. For example, Karn and Penrose[12] showed that birth-weight increases with parity and that birth-weights somewhat less than the maximum were most favourable to survival. Probability of survival, therefore, showed parabolic variation with parity. It is interesting that *pallid* viability, and probably also *fidget* viability, show similar parabolic variation with maternal age. No attempt has been made to separate the effects of maternal age and parity in these results; but the two are clearly highly correlated. Certainly *fidget*, and to a lesser extent *pallid*, reduce birth weight so that an initial increase in birth weight may well account for their initial increase in viability.

An initial decrease in the incidence of spina bifida and hydrocephalus with increasing maternal age in human beings was found by Edwards[10]. This may well reflect a similar phenomenon to the initial increase in *pallid* and *fidget* viabilities in the mice.

The parallelism between effects on the incidence of congenital abnormalities in mouse and man, which is illustrated by the above data, serves to emphasize the mutual benefits to be derived from workers on either organism studying each other's results.

I am grateful to Prof. K. Mather for directing my attention to the relationship between non-disjunction and crossing-over.

Variation in the Behaviour of Different Genotypes of *Drosophila* towards Odoriferous Vegetable Oils

Drosophila are repelled by certain odours; the repulsion from medium containing peppermint oil shown by adult flies can be converted into an attraction towards such food by exposing the individuals as larvæ or adults to the odour[1]. It might therefore be expected in a population exposed to two or more odours, for example, food plants, that part of the population could become specifically adapted to one and part to the alternative odour. Disruptive selection of this type could well give rise to polymorphism[2] or even biological races, and the work reported here was part of an attempt[3] to produce divergence within populations by such means, though Thoday[4] and others have already demonstrated experimentally the production of polymorphism as an outcome of artificial disruptive selection.

About forty etherized *D. melanogaster* were placed in a tube connecting two half-pint milk bottles. In

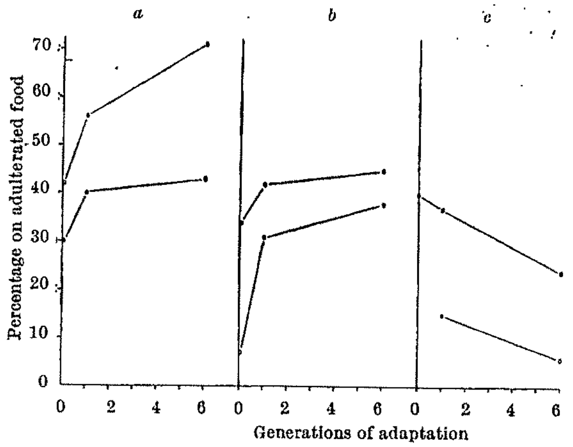

Fig. 1

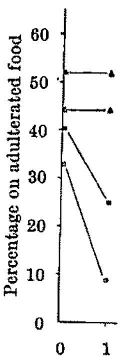

Fig. 2

Fig. 1. Response of Dronfield flies given a choice of normal food and food containing (*a*) 2 per cent peppermint oil; (*b*) 7 per cent juniper oil; (*c*) 3·5 per cent lavender oil. Solid symbols, flies; open symbols, eggs laid. Each point based on at least eight replicates

Fig. 2. Response of two mutant stocks when given a choice of normal food and food containing 3·5 per cent lavender oil. Solid symbols, flies; open symbols, eggs laid; squares, *th st cp*; triangles, *se cp e*. Each point based on at least ten replicates

one bottle was a spoon with food containing an adulterant, in the other was a spoon with normal food. The number of flies in each bottle was recorded after 1 hr. and after 24 hr., at which time the numbers of eggs laid were also scored. Flies were adapted by mass culture in bottles with adulterated food. Where more than one generation of adaptation took place, flies were transferred to new cultures at intervals of twenty days.

Fig. 1 shows the response of unadapted flies, one-generation adapted flies and six-generation adapted flies of a wild-type stock (Dronfield) presented with a choice of normal and adulterated food, for three adulterants. The black points represent the mean number of flies in the bottle with adulterated food (mean of two counts) as a percentage of the total. The circles represent the mean number of eggs laid on the adulterated food as a percentage of the total.

The response to food containing 2 per cent peppermint essence (Fig. 1*a*) is clearly one of increasing attraction with increasing adaptation. After six generations of adaptation to peppermint food, flies choose to lay eggs on this, rather than on normal, food; though as individuals they do not show so marked a preference for remaining on the adulterated food. Fig. 1*b* shows comparable data for food containing 7 per cent juniper oil, and clearly the pattern of response, both of flies and egg laying, is similar to that found with peppermint food. By contrast, flies reared on food containing 3·5 per cent lavender oil are more repelled by such food than are flies reared normally (Fig. 1*c*). The proportion of eggs laid on adulterated food by six-generation adapted flies is less than the proportion laid by one-generation adapted flies. Comparable egg-laying data for unadapted flies are unfortunately not available because of culture failures.

Two mutant genotypes $\frac{th\ st\ cp}{th\ st\ cp}$ and $\frac{se\ cp\ e}{se\ cp\ e}$ tested as unadapted and one-generation adapted flies with food containing lavender oil produced results shown in Fig. 2. The *th st cp* stock resembles the Dronfield stock in that adaptation increases the repulsion of the adulterated food for the flies. The behaviour of the *se cp e* flies is unaffected by rearing on food containing lavender.

In two strains adaptation to food containing lavender oil produces increasing repulsion from such food, and we do not know whether these behavioural changes are the result of physiological conditioning[5], natural selection, or both processes. It seems highly unlikely that only the conditioning process is involved, for considerable mortality was observed in the adapting cultures, and the stocks of *Drosophila* used are known to be genetically heterogeneous. The adaptation (*sensu* biological efficiency) of the populations to lavender food after six generations of exposure to such food must be greater than the initial level of adaptation and therefore adaptation to, and preference towards, lavender food are negatively correlated. Lavender oil essence is toxic, and a behavioural tendency to avoid it, when a choice of food with and without it is presented, probably confers selective advantage in such an environment.

It is unlikely that the distribution of lavender oil in the culture bottles was heterogeneous, for the oil in solution was mixed into the food whereas the latter was liquid. Thus the increased repulsion with adaptation demands that relative ability to survive on lavender food and relative distaste for this food are effects either of pleiotropy or of rather closely linked genes. Whatever the mechanism controlling the behaviour, it is clear that genetic variation for it exists within the species.

The only other example of a similar situation which we have been able to find is that described for *Leptinotarsa* (Colorado beetle) fed on various species of *Solanum*[6]. After feeding on potato, larvæ and male adults preferred horsenettle to this plant. After feeding on horsenettle all individuals preferred potato to this, and after feeds on bitter nightshade this was rejected for horsenettle. Clearly only a conditioning process and not natural selection is involved here.

In any biological population in which this phenomenon of adaptation producing relative distaste occurred, the chances of evolutionary advance to the formation of a biological race via disruptive selection would be minimal, but the population might retain a greater range of exploitable habitat and hence greater versatility. Nevertheless since, as our results show, genetic variance for this character is available in the species, it is possible that some populations could produce polymorphic systems based on behavioural differences.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, June 19

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 3 p.m.—Annual General Meeting.

Monday, June 19—Tuesday, June 20

Plastics Institute (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 9.30 a.m. daily—Conference on "Education and Training in the Plastics Industry".

Monday, June 19—Thursday, June 22

Laboratory Apparatus and Materials Exhibition (at the Royal Horticultural Society's New Hall, Westminster, London, S.W.1).

Tuesday, June 20

Oliver Bird Trust, and the Society for the Study of Fertility (in the Large Lecture Theatre, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5 p.m.—Dr. A. S. Parkes, F.R.S.: "The Biological Control of Conception" (Fifth Oliver Bird Lecture).

Wednesday, June 21

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. D. Tyrrell: "Some Recent Experiments on the Common Cold Problem".*

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Scientific Papers.

Society for Analytical Chemistry, Microchemistry Group (at "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—Discussion Meeting on "Quantitative Paper Chromatography" introduced by Mr. E. C. Hunt and Dr. D. Gross.

Thursday, June 22

Birkbeck College (in the Large Physics Theatre, Malet Street, London, W.C.1), at 4.15 p.m.—Prof. H. Zocher (Ministry of Agriculture, Rio de Janeiro): "Spontaneous Orientation in Suspensions of Macromolecules and Phase Particles".*

Friday, June 23

University of London (in the Chemistry Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Riccardo Passerini (University of Catania): "Refining Processes and Petrochemical Raw Material Sources".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (with special qualifications in pure mathematics) in Mathematics (Grade I or II)—The Registrar (Room 22, O.R.B.), The University, Reading (June 21).

Lecturer or Assistant Lecturer in the Department of Physiology—The Registrar, The University, Liverpool (June 23).

Assistant Lecturer, Grade B (with a good honours degree in chemistry or an equivalent high qualification, and preferably a higher degree) in the Department of Chemistry and Biology, to assist with teaching in Higher National Certificate and Graduate R.I.C. courses with special reference to inorganic and analytical chemistry—The Registrar, Welsh College of Advanced Technology, Cathays Park, Cardiff (June 24).

Scientific Officer or Senior Scientific Officer (graduate, experienced in agricultural research), to assist the Head of the Field Experiments Section—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (June 24).

Assistant Lecturer or Lecturer (with special qualifications in geometry) in Mathematics—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (June 26).

Chair of Bacteriology—The Registrar, The University, Manchester 13 (June 30).

Demonstrator in Geography—The Registrar, University College of North Staffordshire, Keele, Staffs (June 30).

Research Assistant (honours graduate (or prospective graduate this summer) in botany or agricultural botany) in Agricultural Botany in the Department of Agricultural Sciences, School of Agriculture, Sutton Bonington, to carry out ecological and genetic studies on natural hybrids between ryegrass and meadow fescue—The Registrar, The University, Nottingham (June 30).

Research Fellow (with research experience in biochemistry or chemistry and interest in physico-chemical aspects of biochemistry) in Physical Biochemistry at the John Curtin School of Medical Research, Australian National University—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, June 30).

Scientific Officer or Senior Scientific Officer (with research experience in enzymology and/or protein chemistry, and some knowledge of, and interest in, fundamental genetic problems), to work on biochemical aspects of genetics—The Secretary, John Innes Institute, Bayfordbury, Hertford, Herts (June 30).

Assistant Lecturer, and a Lecturer in the Department of Physics—The Registrar, University College, Singleton Park, Swansea (July 1).

Lecturer or Assistant Lecturer in Physics—The Registrar, The University, Sheffield (July 1).

Lecturer (preferably with a Ph.D. or equivalent experience in metallurgy, or in pure science if interest and experience are related to metals) in Metallurgy—The Registrar, The University, Sheffield (July 1).

Chair of Chemical Pathology in the University College, Ibadan, Nigeria—The Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1 (July 3).

Lecturer or Assistant Lecturer (botanist, with special experience in the taxonomy, morphology or genetics of horticultural plants) in the Department of Agricultural Botany—The Registrar (Room 22, O.R.B.), The University, Reading (July 3).

Lecturer in Zoology—The Secretary, The University, Aberdeen (July 6).

Lecturer (preferably qualified to teach ancient philosophy or the philosophy of science) in Logic—The Secretary of University Court, The University, Glasgow (July 8).

Research Student (with a good honours degree including chemistry) in Chemistry, to read for a higher degree working on problems related to cationic polymerization under Dr. P. H. Plesch—The Registrar, University College of North Staffordshire, Keele, Staffs (July 8).

Senior Lecturer or Lecturer in Hæmatology in the Department of Pathology, University College of the West Indies—The Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1 (July 8).

Professor of Philosophy at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, July 15).

Research Student (with an honours degree or equivalent qualification) in Electrodialysis—Prof. G. M. Burnett, Department of Chemistry, The University, Aberdeen (July 15).

Lecturer in the Department of Physiology—The Secretary, The University, Aberdeen (July 18).

Lecturer in Psychology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, July 28).

Chair of Chemistry in the University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, July 30).

Senior Lecturer in Physiology at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, July 30).

Lecturer (preferably with experience in teaching, research and the design and construction of hydraulics works and apparatus) in Civil Engineering (Hydraulics) at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 4).

Assistant Experimental Officer (with experience in analytical chemistry), to work on protein and carbohydrate metabolism—The Secretary, Rowett Research Institute, Bucksburn, Aberdeen.

Assistant, Grade B (male), to teach Chemistry, Physics and some Mathematics to Ordinary level G.C.E. standard—The Principal, North-West Kent College of Technology, Miskin Road, Dartford, Kent.

Assistant Lecturer (preferably with an interest in fuel technology) in the Department of Chemical Technology—The Secretary, The Royal College of Science and Technology, George Street, Glasgow.

Laboratory Technician (preferably with biochemical experience, and A.I.M.L.T. or equivalent), for the Neonatal Unit at the Hammersmith Hospital, Ducane Road, London, W.12—The Secretary, Institute of Child Health, The Hospital for Sick Children, Great Ormond Street, London, W.C.1.

Lecturer (preferably with a higher degree and research experience in an industrial environment) in Metallurgy in the Department of Materials, to lecture at postgraduate level on the fundamental metallurgical aspects of technological processes—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks.

Master to teach Physics—The Headmaster, Plymouth College, Plymouth, Devon.

Reader (with a higher degree in electrical engineering and adequate research experience) in Electrical Engineering; and a Principal Lecturer (with a good honours degree in electrical engineering and practical experience in the electrical industry) in Electronics—The Secretary, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

Research Assistant (preferably with a medical qualification) in the Clinical Bacteriology Laboratory—The Administrator and Secretary, University College Hospital, Gower Street, London, W.C.1.

Research Assistant (science graduate, with an interest in either biology or chemistry), for duties concerned with the investigation of immunological problems—The Regional Director, Blood Transfusion Service, Law Hospital, Carluke, Lanarkshire.

Scientific Officer or Senior Scientific Officer (suitably qualified honours graduate) in the Bacteriology Department, for work concerned with microbiology of the rumen—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 61/17.

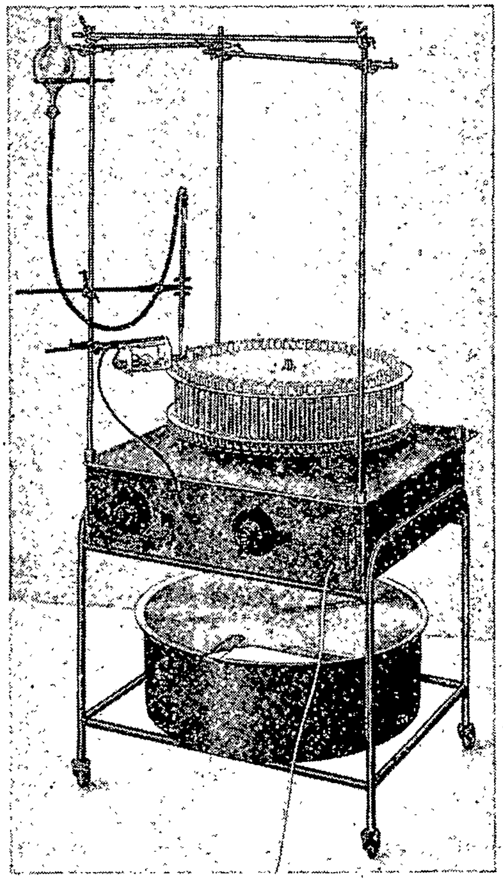
Direct feed system complete reliability — saves you time!

LOCARTE FRACTION COLLECTOR



Now even double-row test tubes are fed directly from the column, giving clearer separations than any other Fraction Collector in the world. Select from any of 16 versatile models; operate up to 220 standard test tubes (conductivity or photo-electric, drop counting or time interval), which allows for unattended operation over weekends.

All models are supplied with unique Fraction Counter, indicating at a glance the number of test tubes already filled.

Especially suitable for Moore & Stein analysis, it is used today by Universities, Govt. Departments, and Laboratories throughout the world.

Also made in our London factory: Ultra-Violet Hand Lamps, Desalters, High Voltage Electrophoresis Equipment, Amino Acid Analyser, Recording Densitometers, Fluorimeters, Column Scanners and Pipette Washers.

SCIENTIFIC AND TECHNICAL DEVELOPMENT IN PAKISTAN

IN January 1960 the Government of Pakistan appointed a Scientific Commission, under the chairmanship of A. K. Khan, to consider how best scientific research in the country, at present disjointed and scattered, could be promoted and integrated; ways and means for providing adequate facilities to the research organizations of the country and of ensuring the utilization of the results of their researches for the overall development of the country; and ways and means of making scientific careers attractive and comparable in prospects, emoluments and status to other services of equal national importance. The Commission was assisted in its deliberations by Prof. A. V. Hill and Dr. L. A. Jordan, Dr. F. T. Rosser, of the National Research Council, Canada, Mr. F. E. Nicholls, of the Australian Commonwealth Scientific and Industrial Research Organization, and Dr. S. Komagata, formerly chairman of the Japanese Atomic Energy Institute. Apart from an introductory chapter reviewing the importance of science to under-developed countries and Islamic contributions to science, which gives a timely reminder of the outstanding contributions Muslims have made to science, the Commission's report* follows the pattern of numerous other reports in this field in other countries. Reviews of the development of scientific organizations and of the tasks and problems for science in Pakistan are followed by chapters on a National Science Council, the establishment of which is recommended, on the organization of defence research, the careers and status of scientists, utilization of the results of research, and on facilities and resources for research.

Generally speaking, the recommendations of the Commission are in line with the policies that have been adopted in Great Britain and in the United States, and with the recommendations of the recent report, *Strengthening Western Science*. It is recognized, for example, that in view of the rapid industrialization of Pakistan and the programme of general economic development envisaged in the Second Five-Year Plan, it is necessary to accelerate scientific research in certain fields that have lagged behind. Emphasis is placed on strengthening scientific effort in the universities and the assumption of greater financial responsibility by the Government. It is also recommended that more attention should be given to research ability and the needs of research in recruiting staff; Western experience would suggest that the Commission goes too far in recommending that the promotion of lecturers, readers and professors in the Science Department should depend on the quality of their research. It is now widely recognized that one weakness in British universities is due to the failure to pay sufficient attention to teaching and organizing ability, and to the practice of giving undue weight to the amount of published work in appointments to university posts.

The Commission recommends that universities should be primarily concerned with fundamental research, leaving applied research to the Government-sponsored research councils. It suggests, however, a mutual exchange of personnel between universities and research councils; such mobility of research workers, as well as of academic staff generally, might with advantage be more encouraged in Britain. The subjects noted as comparatively neglected in Pakistan's universities at present and requiring greater attention include the biological sciences, biophysics and biochemistry, geology, mining, astronomy, metallurgy and chemical engineering.

Of the administrative structure of Government departments, the Commission is highly critical. Apart from recommending considerable decentralization and study of the possibility of creating a separate Scientific Service, the Commission found considerable duplication of activities of the provincial and central Government departments, and that the administrative and executive heads of scientific departments were exercising control over teaching and research institutions which was detrimental to efficiency. Such teaching and research institutions should either be autonomous or linked up with universities. In particular, reconstitution of the Agricultural Research Council and the Medical Research Council is recommended; the Council of Scientific and Industrial Research should reorganize its laboratories and research division so as to conserve the limited scientific man-power available and should devote greater attention to major problems of consequence to the national economy, as well as initiate a co-ordinated programme for training research workers. The Atomic Energy Council, besides intensifying its own training programme, should establish an Institute of Nuclear Sciences and Technology. The Commission also advocates the formation by industries of co-operative research associations which should be subsidized by the Government.

The research organization visualized by the Commission, outside the universities and Government departments, comprises the five councils already mentioned, together with the Council for Works and Irrigation Research and a National Science Council with purely advisory and co-ordinating functions located in the President's Secretariat, and responsible either to the President or to a Minister designated by him. The Research Councils, which should be autonomous bodies, attached to the respective Ministries of the central Government, should establish research institutes and laboratories in different parts of the country, while defence research should be entrusted to an independent organization under the Ministry of Defence, headed by a scientific adviser, and with a Defence Science Liaison Committee with the chairman of the National Science Council as chairman to maintain close liaison with the National Science Council. The Defence Science Organization should be entitled to place contracts with any of the Research Councils for the solution of specific problems.

---

* Government of Pakistan: Ministry of Industries. Report of the Scientific Commission of Pakistan. Pp. iv+102. (Karachi: Ministry of Industries, 1960.)

As regards the programme for science in Pakistan, priority is given to the food problem; but this is not conceived simply in terms of extending and intensifying agriculture. It embraces also research on the utilization of plant material and on improving the nutritional value of food crops. In the field of irrigation, problems concerned with waterlogging, subsoil structure, soil mechanics, rate of water-flow, de-silting, dredging and bed-lining of canals call for intensive research, and there are the special problems of de-salting sea-water and conservation of subsoil water resources involved in irrigating the arid zones of West Pakistan. Cheap electric power, however, is a pre-requisite for the development of agriculture and irrigation, as of industry and communications, and the Commission recommends raising the consumption per head of electricity within the next thirty years from 30 to 400 units, a figure which is still only about half the present consumption in Japan. The upgrading of mineral ores, the various aspects of fibre technology and the utilization of indigenous raw materials all offer great opportunities for scientific and technological research to contribute to the development of Pakistan. Attention is also directed to the serious problems in the field of public health, including the eradication of epidemics and control of preventable diseases, the investigation of diseases peculiar to Pakistan, to family planning and birth control, and to nutrition. These may require tackling in special institutions, and finally the Commission recommends the establishment, attached to a university, of an institution where modern statistical methods of sampling can be investigated.

The Commission recognizes that utilization of the results of research requires special attention, and in agriculture it makes a number of specific suggestions for establishing co-operation between research workers and those engaged in extension services and securing the co-operation of farmers. As regards industrial development, it recommends that processes developed by the Council of Scientific and Industrial Research which call for heavy investment should be handled by the Pakistan Industrial Development Corporation, and that where exploitation is undertaken by private industrialists, foreign exchange should be released for import of the machinery and raw material required. It also recommends the organization by the Council of Scientific and Industrial Research of an Industrial Extension Service with the view of publishing and disseminating information on the latest techniques and processes.

It is interesting to read these specific recommendations for Pakistan in the light of the papers on science and the new States which occupy the greater part of the February 1961 issue of the *Bulletin of the Atomic Scientists*, more especially those by Principal W. A. Lewis and Prof. E. Shils. Principal Lewis points out that the primary need of the new States is not the development themselves of new knowledge but the application of existing knowledge to their problems, and especially the devising of new technologies which will make man-power much more efficient without much capital—a point on which both Lord Fleck and Prof. P. M. S. Blackett have already laid some stress. Principal Lewis devotes most of his paper to this question of man-power, stressing the critical importance of secondary education and the need for political leaders to give priority to economic development and the factors which promote it. Although he writes rather pessimistically about this point in general, the fact that the Pakistan Government has already indicated its intention of implementing the recommendations of the Science Commission's report shows that in that country at least there is the will to seek new ways of progress.

On the financial aspect Principal Lewis has little to add, but stresses once more the importance of political stability, in order to attract technical assistance and to use it wisely and productively. Prof. Shils, discussing scientific development in the new States, is concerned more particularly with the conditions required to foster research and training in science and technology, and likewise stresses the importance of secondary education, as well as the major dependence of technological and scientific research in such States on Government policy and support. Of specific fields of research he only mentions the importance of the prospecting and appraisal of resources, and of work directed to the adaptation to new circumstances of industrial or agricultural processes already used in other countries. He notes, however, the impracticability of planning fundamental research, or even technological research, from a central position, and his paper largely discusses the policy and organization required to create the appropriate conditions of scientific work in laboratories and universities. So far as organization is concerned, his suggestions fully support the recommendations in the report from the Scientific Commission of Pakistan, and that is also largely true of the recommendations relating to the careers and status of scientists and those facilities and resources for research contained in the fourth and eighth chapters of the Commission's report. One comment might here be made in respect of both Principal Lewis's and Prof. Shils's observations about fundamental research: while undoubtedly it would be unwise for the new States to devote more than a minor effort to such research, some such research has its place both in attracting creative workers to a scientific career and in providing the stimulus of participating in scientific advance generally. Such factors are sometimes more important than remuneration, on which the Commission reasonably enough lays a good deal of stress. Conditions in Pakistan are, in fact, so poor that the Commission makes detailed recommendations for the creation of a Pakistan Science Service, and specific salary scales are recommended for scientists and technicians employed by the Research Councils. There are recommendations regarding the ratio of scientific to supporting staff which, while intended to increase the proportion of scientific staff, do not seem to take account of the number of supporting technicians required to make effective use of the scientists and technologists. Some attention is given to the question of status, and Government support of scientific societies is recommended; but generally the report is a good way behind the recommendations of the Barlow Report on scientific staff in Britain published in 1945.

To overcome the existing shortage of scientific and technical man-power, the Commission advocates a massive training programme to be entrusted to the National Science Council, which will be responsible for co-ordinating the requirements of the various Research Councils. The programme contemplates sending abroad at least a hundred talented science graduates each year for intensive training during the next five years, the establishment of two big training centres, one in East Pakistan and one in West Pakistan, for training technicians in glass-blowing, precision tool-making, high-vacuum maintenance and the like, while import duties on scientific instruments and apparatus, laboratory chemicals and furnishings should be waived until manufacturing capacity is developed within the country. Similarly, to facilitate the import of scientific books and technical periodicals and the equipment required to maintain scientific laboratories, the universities, selected scientific departments of Government and the Research Councils should be granted an 'individual general licence' which they could operate freely. Establishment of branches at Lahore and Dacca of the Pakistan National Scientific and Technical Documentation Centre is recommended, while the Commission also recognizes the importance of training librarians and offering them an attractive career.

The Commission has clearly taken a most comprehensive view of Pakistan's needs, and stresses some factors to which little attention has yet been given in Government quarters in Britain. It visualizes the allocation to this scientific effort of at least 2·5 per cent of the national budget. Principal Lewis estimates that most under-developed countries need to provide about 25 per cent of the national output to promote economic growth at the rate of about 4 per cent per annum, of which about half is required for capital formation and half to supply an adequate framework of public services—3 per cent for education, 2 per cent for public health, 3 per cent for communications, agriculture and geology, and about 4 per cent for general administration and welfare. Actually, in most such countries only 15 per cent of the national income is available for the public services and capital formation together; but Principal Lewis takes an optimistic view of the prospect of providing the necessary saving from taxation.

However that may be, the report of the Scientific Commission of Pakistan shows as clearly as the papers in the *Atomic Scientists Bulletin* how large a contribution science can make to the development of new States, and the opportunities for the scientist or technologist to assist the process. These papers add little to our knowledge of the conditions in which technical assistance can be most effective; but in emphasizing the conditions in which scientific work can flourish, they point to the value of the interest and support of the scientific community. When Prof. Blackett writes of the need for a greatly increased international effort and the co-operation of such organizations as the World Health Organization and the Food and Agriculture Organization, or of the primary need to understand the problems and difficulties of the emergent countries and appeals for more men and money from the more affluent countries, he is unlikely to be overlooking the way in which the scientists and technologists of Britain and other advanced countries can help to create the conditions in which such assistance is effectively used. The association with the Scientific Commission of Pakistan of Prof. A. V. Hill and Dr. L. A. Jordan from Britain, of Dr. F. T. Rosser from Canada and Mr. F. E. Nicholls from Australia, illustrates one way in which help is given. It can be given all the time, however, not only in response to such specific requests, but also in the continuing contacts between scientists and technologists in Britain with those of the under-developed countries at present in British universities and colleges of technology—now perhaps some 50,000—in the interchange of visits in many different ways, in the Overseas Scientific Service and the expanding programmes of the Commonwealth Education Conferences. These opportunities were emphasized by several speakers in a debate in the House of Lords on February 22. Only perhaps as such opportunities are used to the full can the vital task of educating the Governments of these countries to the full understanding of the conditions in which science and technology flourish be fully discharged. The report of such a Commission as the Scientific Commission of Pakistan is only a beginning. Its implementation requires public understanding as well as the co-operation of scientist, technologist and administrator in countries where such collaboration has scarcely begun; and the declaration, unanimously accepted by the Rehovoth Conference last summer, which Abba Eban describes in his article "Science and the New States" in the *Bulletin of the Atomic Scientists*, fittingly urges the scientists of advanced countries to become more pre-occupied with the problems facing newly developing communities, and to advise the Governments of new States to include the establishment of a scientific tradition and practice among their early targets.

ATOMS AND ELECTRONS

Quantum Theory of Atomic Structure

By Prof. John C. Slater. (International Series in Pure and Applied Physics.) Vol. 1. Pp. xii+502. 85*s*. 6*d*. Vol. 2. Pp. ix+439. 101*s*. (New York: McGraw-Hill Book Company, Inc.; London: McGraw-Hill Publishing Company, Ltd., 1960.)

IN 1933, only seven years after the introduction of wave mechanics, Slater and Frank published their *Introduction to Atomic Physics*. They allotted 200 pages to atomic structure. But in 1951, when wave mechanics was just 25 years old, this material had grown to a complete book, *Quantum Theory of Matter*, with 500 pages. To-day, in 1961, Prof. Slater takes the first half of this second book, and expands it into two full volumes totalling nearly 1,000 pages. This is a striking indication of the almost catastrophic way in which our knowledge of this field has developed.

But the field itself has spread. Atomic theory is no longer the province of the spectroscopist measuring line frequencies and line widths. It plays a fundamental part in the totally new field of molecular structure, and its ideas have taken root in much of nuclear structure and the most exciting of all modern branches of theoretical physics—the solid state.

The subject is ripe for a major exposition. It seems likely that most of the main results and theories are now known. The advent of electronic computers has already influenced techniques. Much remains to be studied, but the methods of doing this are now fairly clear. It is entirely appropriate that Prof. Slater should write this monumental work. For during the past fifteen years his group at the Massachusetts Institute of Technology has studied atoms, molecules and solids with great success. We are now promised further books on these other topics. If they match the present ones in excellence they will be very welcome indeed.

Here is effectively everything that matters in the theory of atomic structure. It is set out in Slater's lively style (sometimes almost too colloquial), and with very great assurance. Reading these volumes is like watching a first-class chess player march irresistibly to his object. There is complete mastery of the material, much of which is his own, and a complete certainty about its ordering.

The first volume starts with 160 pages recapitulating elementary wave mechanics. Despite the author's claim, I do not feel that this is suitable for a beginner: it is inevitably compressed. But it is excellent for a student who already has some knowledge. Then follow accounts of the hydrogen atom, self-consistent-field, angular momentum, multiplet structure, with application in the iron group, and a series of some twenty appendixes elaborating points inadequately covered before. This material is enough to understand the main lines of thought, but not sufficient to start research.

Volume 2 starts with Hartree–Fock theory, and then goes on to group theory, angular momentum operators, Racah's method for complex spectra, the Dirac theory, magnetic properties of complex atoms, transition probabilities and hyperfine structure. It contains a wonderful set of tables, and carries the subject right up to the present day. Both volumes are enriched with a series of bibliographies that greatly enhance their value.

Comparison is inevitable with Condon and Shortley's *Theory of Atomic Spectra*. In Slater there is much less direct comparison with experimental data, and more 'drive' towards the basic theory: there is almost nothing about *jj*-coupling (this is a pity) and isotope effects, or about polarizability and Stark effects. But there is the first full-scale development of Racah's work, the use of projection operators, the Fermi hole, nuclear quadruple effects, none of which is found in Condon and Shortley's book. Numerical techniques are also more advanced, and the whole outlook is more modern.

No one can expect to be entirely satisfied. But I found only one minor mistake. I could have wished for more reference to the Thomas–Fermi statistical method, and a better account of Hund's rules (Hund does not get quite his share of credit). I also wish that the Rydberg unit of energy had been replaced by the atomic unit, so that a self-consistent set of units could be used. But these are relatively trivial. Here—without any doubt at all—is a definitive account of atomic structure. It is a magnificent work, which no one but Slater could have written: and it is beautifully published.

C. A. COULSON

PROBLEMS OF ECONOMIC AND SOCIAL DEVELOPMENT

Jamaica, 1830–1930

A Study in Economic Growth. By Gisela Eisner. Pp. xxiii+399. (Manchester: The University Press, 1961.) 50*s*. net.

THE publication of this work can be welcomed without reservation by all who are interested in the problem of economic and social development. The investigations on which it is based were initiated and guided by Dr. Arthur Lewis, when professor of economics in the University of Manchester, and it thus provides evidence of the growing sense of responsibility of the new West Indian middle classes for the welfare of their communities. The project is as ably conceived as it is brilliantly executed.

Our knowledge of economic growth and social change has hitherto been severely restricted by the scarcity of accurate studies of the history of the societies which have been subject to the most rapid development over the past century. Here is one more, and a very good one, to add to our small collection. The author has extended her work over a wide field; she has thus been able to show how economic growth and organization have been interrelated with the social structure and social history of Jamaica. The result is to give the book a much wider interest than a more restricted study of economic statistics and economic trends would possess.

It would have been even more helpful if the period covered could have been extended to 1943, a year in which an elaborate census provided much material which could have been used for purposes of general comparison with the situation which prevails to-day. Even though the data were somewhat affected at that time by the impact of the Second World War, this was not so important as might be supposed; the influence on economic and social life of the post-war period of planned economic development has been made more profound. It is probable, therefore, that 1943 will in the future be regarded as the end of the old era of colonial policy, rather than the start of the new period of democratic self-government. One thus hopes that Mrs. Eisner's work will be used as the basis for further studies by Jamaican economists. It will serve this purpose admirably.

T. S. Simey

ORGANOMETALLIC CHEMISTRY

Organometallic Chemistry

Edited by H. Zeiss. (American Chemical Society Monograph Series, No. 147.) Pp. xiv+549. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1950.) 140*s*. net.

THE enormous output of work within the broad definition of organometallic chemistry fully justifies the production of this monograph.

The ten chapters, occupying 528 pages, consist of "a series of research subjects which are under active investigation—at the present time—by their respective authors". The book is intended primarily for graduates and the more advanced chemist. The subjects and authors of the chapters are: carbon-metal bonding, James W. Richardson; benzyne chemistry, Rolf Huisgen; vinyl-metallics, H. D. Kaesz and F. G. A. Stone; organoboranes, Herbert C. Brown; organo-aluminium compounds, Karl Ziegler; organo-silylmetallic chemistry, Henry Gilman and Hans J. S. Winkler; cyclopentadienyl metal compounds, P. L. Pauson; arene complexes of the transition metals, H. Zeiss; transition metal alkyls and aryls, G. E. Coates and F. Glockling; metal carbonyls and related compounds, J. Chatt, P. L. Pauson and L. M. Venanzi.

In Chapter 1 a modern qualitative treatment by molecular orbitals of the carbon–metal bond is given. An introductory molecular orbital description of the HeH^+ molecule is extended rather rapidly to some specific metal cyanide, carbonyl and cyclopentadienyl complexes. This specialization is intended to "demonstrate and catalogue the variety of interactions present in metal–carbon bonds in detail" rather than review a broad range of compounds. A final discussion of the stability of alkyl and aryl transition metal complexes is complementary to the theoretical discussion in Chapter 9. The thorough review of the very recent benzyne chemistry is decidedly more 'organo' than 'metallic' and its inclusion in this monograph emphasizes the wide scope of organometallic chemistry. A competent systematic coverage of vinyl metallic chemistry complementary to recent reviews is given. The infra-red spectra of a number of vinyl substituted compounds are reproduced and the group characteristic patterns clearly shown.

The chemistry of organoboranes has also been reviewed recently and therefore the emphasis in this work is laid on the most up-to-date advances, and on new synthetic procedures. The hydroboration reaction is discussed in considerable detail and the great familiarity of the author with this field is evident.

Nearly 400 references including a large number to patent literature demonstrate the importance and extent of organo-aluminium compounds. As would be expected, there is an authoritative coverage of the synthesis and classification of these complexes by K. Ziegler. This is followed by a discussion of their molecular structure and properties. The necessarily limited size of one chapter has resulted in rather a compromise between useful detail and generalizations.

Organosilylmetallic chemistry is a field which surely must expand rapidly in the next few years, particularly where transition metal chemistry is concerned. The few organosilyl transition metal complexes which have already been reported are, however, not mentioned in this review. Detailed preparations of the alkali-metal derivatives are given and their reactions are described. This chapter does not make very exciting reading. The division of the so closely interrelated fields of aromatic, carbonyl, and alkyl and aryl transition metal complexes into four chapters, under different authorship, has resulted in a good deal of confusion as to who should write what about which. In the attempt to avoid duplication with recent reviews and with subsequent chapters, the topic of cyclopentadienyls is given a fragmentary treatment. The aromatic ring substitution reactions are, however, summarized and some useful reaction schemes are given.

A historical approach to arene complexes is developed into a concise survey of the known examples which are given in a seven-page table. Non-benzenoid arene metal complexes are briefly considered. The acetylenic synthesis by cyclic condensation of arene compounds is discussed, as is also the mechanism of the Job–Cassels reaction.

Chapter 9 on transition metal alkyls and aryls is largely culled from the book on *Organometallic Chemistry* which is written by one of the authors of this review. Insufficient progress has been made in this field in the few months separating the appearance of these two books to warrant this duplication. The topic is well and more extensively covered in the original book.

Finally, Chapter 10 consists of a rather limited review of metal carbonyl and related compounds. The most recent and important developments are, however, considered and more than 300 references are given.

The book has an author- and subject-index and is excellently produced. On the whole a useful book but unfortunately rather expensive.

M. L. H. Green

THEORIES OF CARCINOGENESIS

Carcinogenesis

By I. Hieger. Pp. xi+138. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1961.) 35*s*.

DR. HIEGER'S principal theme is "the putting into perspective of the theories which have been advanced to interpret the process whereby normal cells and tissues are transformed into cancer". Except for one chapter in which the main types of cancer-producing agents are described, and their effects on various tissues illustrated by experimental records, the book is devoted to the consideration of the most important theories which have been advanced to explain the carcinogenic process in general. It is in the bringing together in one place of critical accounts of these various theories that the main value of the book lies.

Hieger analyses them with refreshing candour and no undue respect for persons. His criticisms merit serious attention. The evidence on which cancer theorists rely is often equivocal and always incomplete, but it must be remembered that criticism necessarily rests on a re-interpretation of the same data. For example, Hieger uses the "multicentric view" of carcinogenesis to support his attack on the somatic mutation theory. He argues that the observed multicentric genesis of tumours in a region of tissue undergoing carcinogenic stimulation requires that all or almost all the cells in the region should mutate, and that this is numerically impossible given the known mutagenic capacity of effective doses of carcinogens. But it is pre-cancerous changes which are regional, that is, appear to affect all cells in a treated region (as Hieger points out in one place, but ignores in his argument); tumours arise at relatively few points within the region. The number of cells in which the definitive neoplastic change (whatever that is) occurs may be only a minute fraction of those at risk.

One might pick out other instances of this kind, but they would not invalidate Hieger's main theme—the unsatisfactory state of cancer theory to-day. That is undeniable, and, indeed, to survey the divergence and mutual incompatibility of rival theories of carcinogenesis is a chastening experience. But I doubt if it is reasonable or wise to demand, at this stage, that they should be consistent and generally applicable. Most fruitful hypotheses have started with a strictly limited application; inconsistencies were disregarded for a time and eventually explained, and in the meantime experiment and speculation were stimulated.

A frequent complaint of Hieger's is that theories of carcinogenesis are "tautologous". For example, he quotes the following passage of Burnet's: "In many ways it (carcinogenesis) resembles the evolutionary process among free-living organisms. Change in Nature results from the appearance of mutations, from their phenotypic expression in various combinations, and from the selective action of environmental factors in ensuring the survival of the fittest. In the body the cancer cell has an undoubted short-term survival advantage over normal cells and in a sense we can look at it as representing a clone, which, by processes formally equivalent to mutation, has developed a gross advantage in proliferation within the existent internal environment of the body". Hieger's comment is: ". . . Sir Macfarlane has only said: 'An advantageous mutation confers an advantage'—a tautology which does not assist us in understanding carcinogenesis". I do not think this type of criticism is well directed. Opinions differ as to whether Burnet has drawn a valid comparison; but it must be remembered that what he and some other theorists are trying to do is to show the formal equivalence of carcinogenesis to other processes in Nature which are better understood, or for which there are, at any rate, generally accepted explanations covering wide fields of fact. They attempt this by making assumptions, in line with other evidence, from which the known facts of carcinogenesis can be deduced. The steps of such arguments are certainly tautologous, but only in the sense that all mathematics is tautology (as some in fact maintain).

There is much more to be learned from these theories than appears from a catalogue of their inadequacies, real or apparent, and I hope that the readers of this book will not be prevented by the author's scepticism from studying them.

When reading or listening to a severe critic of the theories of others it is natural to look forward to the moment when he will introduce a theory of his own, in order that we may give him a taste of his own medicine. Dr. Hieger does not fall into the trap. Since he believes that all present theories of carcinogenesis are inadequate he is surely wise in not adding to their number. He indicates, however, what he regards as the most hopeful directions for future work, some of which have received less attention than they deserve. In his last paragraph he states his opinion that "the most hopeful approaches to the solution have not been from a theoretical direction but by a more modest and empirical route". His own important contributions to the study of carcinogenesis have been made chiefly by the latter method, and many experimental pathologists, whether or not they endorse his strictures, will agree with his conclusion.

M. H. Salaman

THE PROBLEMS OF AGEING

Man against Aging

By Dr. Robert S. de Ropp. Pp. v+310. (London: Victor Gollancz, Ltd., 1961.) 21*s.* net.

One of the results of medical advances in the past hundred years has been an increasing proportion of elderly people in the population, and the public is becoming increasingly aware of and interested in the new medical and social problems which these changes are creating. *Man against Aging* is intended to provide them with the sort of information about old age which they have grown accustomed to receiving in other branches of medicine.

To get the basic information and attitude over to lay readers requires special techniques and unusual gifts from an author and perhaps modified standards of criticism from a reviewer. The start of this book is not at all encouraging, for it contains a collection of the various fanciful notions that have accumulated over the centuries, interspersed with vaguely salacious remarks and unwarranted, and irrelevant, side-cracks at the standards of biological science in communist countries. One assumes that this is intended to persuade someone who picks up the book to go on reading, and having got it all off his chest the author settles down to a very reasonably accurate assessment of the present state of our knowledge about the ageing process, our difficulties in defining it, how it affects different forms of animal life and different parts of the body, and how we are trying to analyse the process and decide whether there is a specific cause of ageing or not. After dealing with these gerontological problems the author goes on to the geriatric aspects and describes the common serious diseases of the latter part of life. Once again his reading of the specialist literature seems to have been wide and his assessment not at all extravagant. The last part of the book is entitled "The Art of Aging". This part, which boils down to a recommendation to old people to keep on working, is less successful perhaps because the social science side of gerontology is less well developed than the biological side.

Once one has discounted the jargon and lavish use of adjectives that it is apparently necessary to introduce into any popularized account—the incredibly complex, the ceaseless stream, the wealth of vital chemicals and so on—one can recognize in much of this book a successful attempt to make the reader aware of the problem and our present position of ignorance in ways which can only be helpful.

P. L. Krohn

CARL NÄGELI AND THE FINE STRUCTURE OF LIVING MATTER*

By Dr. J. S. WILKIE
Department of the History and Philosophy of Science, University College, London

THE status of Nägeli as the founder of a new branch of biological science has been very generally recognized. Among his contemporaries, we find Sachs, Hofmeister and Pfeffer speaking in terms of the highest admiration of his work in this field; and among workers in the present century Seifriz, Meyer and Mark, Preston and particularly Frey-Wyssling, seem to be in no doubt that he was the first to obtain results of value in the study of fine structure.

Prof. A. F. Huxley, in his inaugural lecture delivered at University College, London, has pointed out that the work of Brücke on the fine structure of muscle has been confirmed in important respects by recent studies. Brücke was a contemporary of Nägeli, who refers to his work on muscle, and if the title of 'founder' were to be awarded simply for brilliance or originality it would be difficult to decide to which of the two it should properly be given. By this criterion there might, indeed, be others entitled to claim the title. However, just as we rightly award to Darwin the honours due to the founder of evolutionary studies, because of the extent of his labours and the cogency of his arguments, so do we, I think, appropriately assign to Nägeli the status of founder and originator of studies in fine structure.

I have for some time been engaged in studies intended to supply answers for the following two questions: (1) What exactly was the nature of the original contribution to biology made by Nägeli ? (2) By what processes of observation, experiment and ratiocination did he produce the most original part of his work ? To such historical questions it is scarcely possible to offer final and complete answers, and certainly the answers which I shall suggest here are not intended to be more than tentative.

It seems reasonably certain that Nägeli's work in this field was original in the three following respects:

(1) He appears to have been the first to appreciate the great and universal importance of what are now called high polymers—their importance, that is, in the fine structure of living things. Pfeffer[1] goes so far as to assert that Nägeli employed the concept of higher-order molecules, that is, of polymers, at a time when it was 'unknown to chemistry' ("zu einer Zeit . . . als die Chemie meines Wissens Molecülverbindungen als nähere Körperbestandtheile noch nicht kannte"); this is not strictly correct, for the possible existence of higher-order molecules formed by the union of many similar or identical unit-molecules was suggested by Berzelius in 1827 [2]. It seems, however, only reasonable to accept the testimony of Pfeffer that the notion was not widely known or widely accepted among chemists at the time when it was successfully applied by Nägeli. It is in any event certain that Nägeli owed nothing to Graham in this respect, for Graham's suggestion that "colloid molecules may be constituted by the grouping together of a number of smaller crystalloid molecules" appeared in a paper of 1862 [3], whereas Nägeli had formulated his hypothesis fully in his monograph on starch-grains, published in 1858 [4]. It seems to me probable that the idea of polymerization was in the air, as a mere notion without much empirical substance, during the 'fifties; but, if so, it is certain that Nägeli was among the first to make use of it and to give it the empirical substance which it lacked.

(2) Nägeli seems to have been the first to appreciate the presence and importance of a variety of cohesive forces in the structure of living matter at the molecular level. That this idea was in itself very original I cannot assert, though I believe it was; but the empirical observations by which Nägeli sought to establish it, and the arguments drawn from these observations are, I think, among the most original, as well as the most lasting, of his contributions. I describe this as a 'lasting contribution' because it seems to be a vague perception of what is more precisely formulated in, for example, the theory of *Haftpunkte*[5].

(3) A final original and lasting contribution is his discovery (for here we may use this dangerous word) of microcrystals or submicroscopic regions of lattice order in starch-grains and in the walls of plant-cells, together with the extensive development of his theory of the universal presence of such structures in plant-cell walls.

For the sake of completeness it will be as well to quote here Nägeli's formulation of his set of hypotheses concerning the structure of 'organized materials', by which he meant the structured parts of organisms, as contrasted with, for example, blood-plasma or cell-sap. In this passage[6], which belongs to the middle period of his activity, he is still using an old terminology, in which it was usual to call molecules 'atoms', so that he is able to use the term 'molecule' to designate his polymer-particles. This usage will be more readily grasped if it is remembered that the 'atoms' mentioned in this passage are 'atoms of starch', or 'atoms of cellulose', or even 'atoms of albuminous material'.

"Organized materials consist of crystalline, birefringent molecules (themselves consisting of very many atoms), which lie freely, but with a definite regular arrangement, alongside one another. As a consequence of preponderating attraction, each is surrounded in the moist state by an envelope of water; in the dry state they touch one another. Hence there are in organized materials two kinds of cohesive force: one unites the atoms to form molecules, in the same manner as they unite in general to form crystals; the other unites the molecules."

In his later writings, Nägeli calls his crystalline particles *Micelle*, or *Micellen* (for, *in unkonsequenter Weise*, as Prof. Frey-Wyssling says, he used both forms of the plural), a word which has passed into English as (still considering the plural) micelles or micellæ.

Fig. 1 shows, above, one of the two figures given by Nägeli to illustrate his concept of micellar structure; and, below, a diagram published in 1929 by the late Prof. Seifriz (the illustration is made from the diagrams as reproduced in Prof. Frey-Wyssling's

---

* Substance of a lecture in a series, "Case Histories in Biological Discovery", delivered during Trinity Term in the University of Oxford, and arranged by Dr. A. C. Crombie and H. B. Havré.

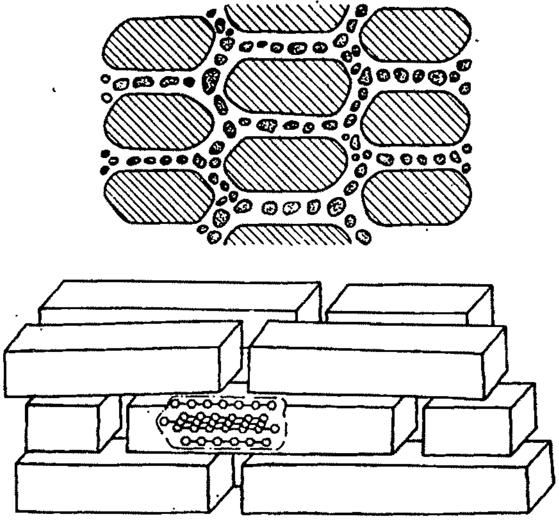

Fig. 1. Former conception of the micellar structure. Above, from Nägeli and Schwendener (1877); below, from Seifriz (1929) and K. H. Meyer (1930). (Above, reproduced by permission of Elsevier Publishing Co. from Frey-Wyssling, *Submicroscopic Morphology of Protoplasm*, Fig. 59; and below, by permission of *The American Naturalist*)

book, *Submicroscopic Morphology of Protoplasm*, of 1953, by kind permission of the author and of the Elsevier Publishing Co., of Amsterdam).

There is some superficial resemblance in the diagrams, but in fact the concepts represented are much nearer one another than are the diagrams: indeed, the concepts are virtually identical.

In the first place, Nägeli did not give a figure to illustrate his general notion, so we have to be content with one representing a particular case. Between the larger blocks, representing the micellæ, where in the general case there is simply water or some dilute aqueous solution, we see smaller blocks representing some incrusting material, such as lignin. To obtain a representation of the general case, we have to think these away ; we then have only micellæ and water, as in Seifriz's diagram. Then, Seifriz has represented the constituent molecules of the micella, which should be shown in Nägeli's figure, but are not.

Seifriz's diagram[7] was drawn as an interpretation of results obtained in X-ray analysis by K. H. Meyer and H. Mark[8], and the diagram was accepted by Meyer as a correct interpretation[9]. Thus we find micellar order conceived in exactly the same way by Nägeli and by Seifriz and Meyer. Nägeli's figure was published in 1877; but the concept it illustrates was virtually perfected in 1858, and completely formed in 1863. This is sufficiently remarkable, even though more recent work has shown that the Seifriz diagram is a most inadequate representation of what seems to be the actual structure of cellulose. But this is not the end of the matter.

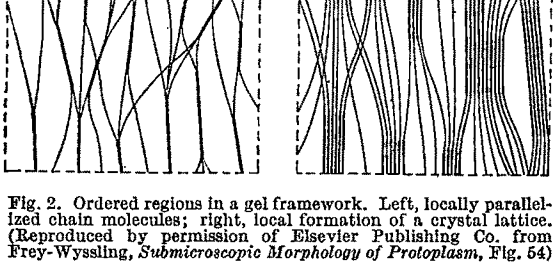

Fig. 2. Ordered regions in a gel framework. Left, locally parallelized chain molecules; right, local formation of a crystal lattice. (Reproduced by permission of Elsevier Publishing Co. from Frey-Wyssling, *Submicroscopic Morphology of Protoplasm*, Fig. 54)

Nägeli's concept is, of course, intended to have a much wider generality than Seifriz's model, which was suggested only for the fine structure of natural cellulose; but Nägeli was, of course, as a botanist, particularly interested in the structure of cellulose, and his idea of micellar order was undoubtedly intended to explain, also, the structure of this substance as it occurs in plant cell-walls; so let us consider the further development of ideas on this structure.

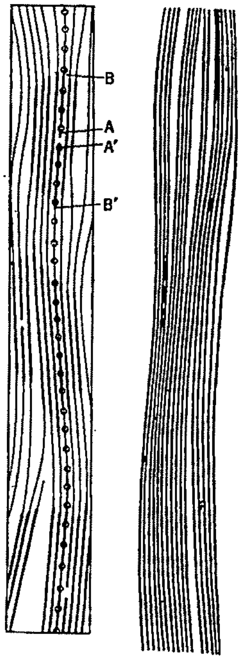

Fig. 3. Diagrammatic representation of the micellar structure of cellulose. Right, as suggested by K. H. Meyer. Left, micellar structure from primary valency chains (Kratky and Frey-Wyssling). The successive molecules, marked by circles, behave as a single molecule traversing the whole structure, since the ends, *A* and *A'*, lie within a crystalline region (thick lines). (Reproduced by permission of Interscience Publishers, Inc., of New York, from K. H. Meyer, *Natural and Synthetic High Polymers*, Figs. 87*a* and 87*b*)

Seifriz, in making his diagram, had neglected an argument already propounded by Sponsler and Dore in 1926 [10]. Sponsler supposes that the polymer chains in plant-fibres must be of very great length, for one of the most striking features of plant-fibres is their very great tensile strength. This argument from tensile strength to continuity of polymer chain soon became widely known and generally accepted as valid. Thus later workers modified the Nägeli–Seifriz diagram (at least in its application to the fine structure of fibres) in various ways, to make it more consistent with the known facts of tensile strength of plant-fibres ; though there were other reasons for modifying the original 'bricks in a wall' model, for it seemed that the length of the micellæ must be about 600 Å., the minimal length given by X-ray analysis, whereas Staudinger obtained values for the molecular weight of natural cellulose which would suggest a chain-length of 10,000 Å. It was suggested that one chain might belong to many micellæ. The model thus arrived at is illustrated in Fig. 2, also derived from a figure in Prof. Frey-Wyssling's book.

Although these drawings were prepared specially for the book published in 1953, they represent suggestions made earlier. On the left is a figure showing the fine structure proposed by Herrmann, Gerngross and Abitz[11] for gelatine, and on the right the new model for cellulose suggested by Prof. Frey-Wyssling[12].

It will be seen that this model satisfies both the requirement of micellæ (localized regions of crystal-order) and that of very long polymer chains. The chains lie parallel in some regions and are elsewhere arranged loosely. Where they are parallel they give a lattice with the optical properties of a crystal.

This notion of the fine structure of fibres was found unacceptable by K. H. Meyer[13], who suggested that the regions of lattice order were themselves continuous. "It seems more correct," he writes, "to represent the micellar structure as in Fig. 87*b* [on the right of Fig. 3 of this article], where no limit is set to the crystalline regions in the direction parallel to the fibre-axis."

The figure on the left shows a slight modification of the Frey-Wyssling model, a modification suggested by Kratky in 1938[14]. Fig. 4 shows Meyer's 'micellar ropes' in cross-section. The diagonal strokes represent the position of the 'glucose rings' (in the cellulose molecule), the regular arrangement of which gives the crystal lattice. This notion of micellar ropes is accepted by Prof. R. D. Preston, in his elegant monograph, *The Molecular Architecture of the Plant Cell Wall*, of 1952. Fig. 5 shows an electron-micrograph of a layer of the cell-wall of the alga *Cladophora rupestris* showing just such ropes as Meyer had postulated. Prof. Preston has kindly supplied me with this micrograph.

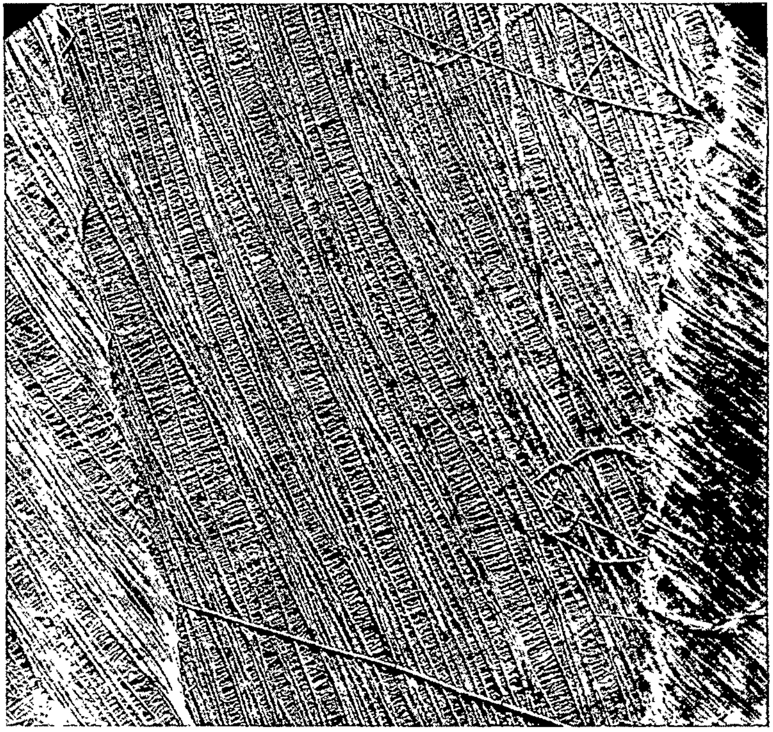

Fig. 5. Electron micrograph of inner-wall lamellæ of *Cladophora rupestris* viewed from outside. Palladium-gold shadowed. Top to bottom is direction of cell axis. (× 24,000.) (From V. Frei and R. D. Preston, *Proc. Roy. Soc.*, *B*, **154**, 70; 1961)

We seem to have come a long way from Nägeli's model. In fact, however, this development of ideas took place in Nägeli's mind between 1877 and 1879, for in 1879[15] he himself suggested that the tensile strength of plant-fibres requires a modification of the model of 1877, and pointed out that what is required is that the micellæ should "grow together" end to end, so as to form continuous strands.

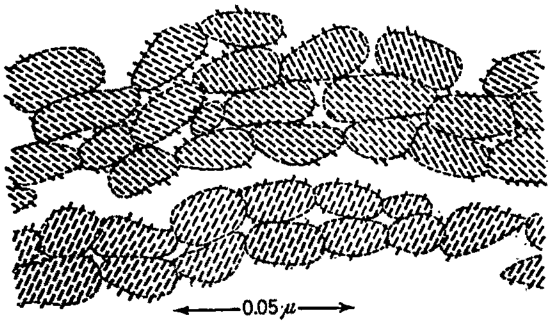

Fig. 4. Part of a schematic cross-section of two successive lamellæ of the cell-wall of a cellulose fibre. The strokes indicate the position of the glucose rings; the scale refers to the micellar ropes (the glucose rings are about four times too large). The micelles should therefore contain more glucose units. The spaces contain water, air or cementing materials. (Reproduced by permission of Interscience Publishers, Inc., of New York, from K. H. Meyer, *Natural and Synthetic High Polymers*, Fig. 90)

This must serve as an illustration of what I may call the 'predictive force' of Nägeli's ideas. It is clear that he must have obtained a true insight into the structure of the objects he was examining; for his predictions, if we may so call them, are too elaborate to be the results of mere luck. What then was his method? How did he arrive at these results?

It is often supposed that Nägeli's principal tool was the polarizing microscope; and if this had been the case it might perhaps be argued that the model of discrete crystallites surrounded by envelopes of water would be the simplest and most obvious for the observed phenomena. A starch-grain between crossed nicols shows the spherulite cross characteristic of a spherical body composed of radially arranged crystallites. Dry starch absorbs water, and in certain reagents starch-grains swell very greatly without losing their shape. Thus a system of radially placed crystallites with interspaces containing water seems, perhaps, an almost inescapable proximate hypothesis for the structure of the starch-grain. When it is added that cell-walls are also optically anisotropic and liable to swelling, the initial stage of generalization is also given.

The truth is, however, that Nägeli had completed his model for the fine structure of starch-grains before he made any extensive use of the polariscope. The model suggested in the monograph of 1858 is exactly that represented by the figure in my Fig. 1 (even the encrusting substance is here appropriate; for Nägeli knew that there are two substances in a starch-grain, though he incorrectly identified the less soluble as cellulose). Indeed, the figure (Fig. 1, here) is particularly apt to illustrate the concept of 1858, for it shows no internal order in the micellæ of starch; and in 1858 he had not yet decided that the micellæ were micro-crystals[4]. He says explicitly that the forces holding the individual molecules (then called 'atoms') together within the micellæ are "analogous to the forces of crystallization", but are not identically the same as these forces; for starch is formed in the plant from aqueous solution, but is not itself soluble in water, which it would be (he argues) if composed of crystals.

This statement is of the first importance. In the first place it shows, I think conclusively, that Nägeli was not then using the polarizing microscope. Then, it seems to me that, had he from the first believed that the compound molecules, later called micellæ, were in fact crystallites, he might have had more difficulty in conceiving that idea which is, if not identical with the notion of polymerization, at the least a close precursor. For the molecules, or 'atoms of starch' as he then called them, would simply have been united by what seemed to be the familiar forces of crystallization, and no new and unexplained forces need be postulated.

I will now attempt to give some idea of the process by which Nägeli arrived at his most important hypotheses. As I have pointed out, most of these hypotheses are already formulated in the monograph on starch-grains, of 1858. This monograph is a huge work of more than 600 quarto pages, of which probably 550 are in a type usually reserved for footnotes. Though I have read it, it cannot be expected that I should do more here than give a summary account of what seem to me to be the most significant observations and the most important arguments.

The notion of a system composed of solid particles each surrounded by an envelope of water, a system which, however, is itself solid and rigid, was partly suggested by the phenomena of imbibition and of swelling, particularly swelling without loss of shape, but also, I think, by his belief that starch-grains grow by intussusception. From a review article by N. P. Badenhuizen[16], I gather that there is little doubt that starch-grains grow by deposition on the outer surface, and not by intussusception, so that this looks like an erroneous belief leading to a truth. But I think it likely that Nägeli had first formed the much more probable hypothesis[17] that cell-walls must grow at least partly by intussusception, and that this inclined him to believe that the same could be asserted of starch-grains. He does refer in his monograph to the immense growth in length of some cylindrical cells, and argues cogently that this can scarcely be accounted for by passive stretching of an already formed wall[4]. Naturally the space allotted to the consideration of cell-walls cannot be very great in a monograph on starch-grains, and it is possible that they were of greater importance in Nägeli's theorizing than the space assigned to them would suggest.

The hypothesis of supermolecules (polymers) is of great interest, and I am far from certain that all the influences leading to it are made explicit in the monograph. I suspect that this idea was latent in the earlier work on osmotic phenomena, which was certainly well known to Nägeli, as it was to Graham (the first volume of the *Pflanzenphysiologische Untersuchungen*, dated 1855 and published with the second volume, *Die Stärkekörner*, dated 1858, is concerned exclusively with osmotic phenomena); but this is a subject which I have not yet been able to investigate.

The explicit argument seems to be:

(1) Starch-grains are composed of alternating layers of dense and loose material, the loose material being much richer in water than the dense.

(2) The whole grain is, however, certainly all starch (or at least, the cellulose which he thought to be present is evenly diffused throughout the grain, and does not account for the difference between the layers).

(3) The only explanation of the difference in water-content in the alternate layers is that the particles of starch are larger in the dense than in the loose layers; but, since both large and small particles are chemically starch, the larger must be compounded from the smaller, which, of course, cannot be less than one molecule each.

(4) Nägeli also asserts that the larger particles cannot be isodiametric, but must be elongated in the direction of the radii of the starch-grain. This is, of course, a subsidiary proposition, and the hypothesis of compound molecules does not depend on it; but it is of considerable importance in the development of the theory of fine structure.

All these conclusions, which together give an outline of the main argument, seem rather poorly supported when examined individually. Nägeli could not be very certain that the layers differed only physically, not chemically, from one another; though he gives evidence for his belief that the difference could not be due to the second substance which he thought to be cellulose: if the starch is digested out with ptyalin, a complete ghost of 'cellulose' remains.

The conclusion that the difference is physical would receive powerful support from Nägeli's mathematically developed argument based on the supposition that growth is by intussusception; but the basic supposition is erroneous.

Nägeli's arguments[4] for the existence of larger compound molecules in the dense layers of the starch grain are extremely complicated, and it is not easy to decide the degree of interdependence between the parts of the whole logical complex.

Two main arguments seem to be involved:

First there is an elaborate dynamical argument, based on the supposition that organized materials have the kind of structure illustrated in Fig. 1—a sort of 'bricks in a wall' structure. The model is itself suggested by the belief that there are only two possible fine structures: the 'bricks in a wall' on one hand, and a network structure on the other. The network-model is then eliminated by the following argument. Starch can swell to 27 times its original volume; it then contains 90–98 per cent water, and between 10 and 2 per cent starch. Some cell-walls may probably contain as much as 200 or more parts of water to one of solid. If the solid parts formed a kind of scaffolding full of holes able to contain water, it would follow that starch and cellulose must possess a high degree of extensibility, a property entirely foreign to them. Further, it would necessarily be possible to express water by mechanical means but this is not possible with the cellulose-jelly. He notes that extremely aqueous cellulose walls may even be brittle.

To account for both rigidity and swelling of the system, he postulates two forces, one attracting starch to starch, and the other attracting starch to water. He supposes the starch–starch force to be inversely proportional to some power of distance, and the starch–water force to be inversely proportional to some higher power of distance.

Thus, $F_{ss} = \frac{A}{D^p}$ and $F_{sw} = \frac{B}{D^{p+q}}$

where p and q are positive, and A and B are parameters.

At some distance determined by the parameters, which of course are constants for any one system, the forces will be equal. At any lesser distance than the distance of equality, the starch attracts water preponderantly; at any greater distance, starch attracts, preponderantly, starch. This gives us the repetitive pattern of blocks of starch separated by layers of water and allows for forced drying and re-imbibition with water.

An extremely elaborate development of this fundamental dynamic idea enables him to show that, given the initial postulates, the width of the layer of water would be greater if the particles of starch were smaller. Thus, if his mathematics and dynamics are correct, the postulates deliver a hypothesis connecting particle size with quantity of water. So, accepting that all particles are chemically starch, the notion that the compound molecules in the dense layers are larger than those in the loose layers acquires a certain status. That status remains, however, rather tenuously hypothetical. That he really came to believe in compound particles in this way is improbable, and he gives at least two much more direct arguments.

"Now it is possible to conceive of the relation of the particles of solid starch to the enveloping water in two ways: either that each atom of starch (consisting of 12 atoms of carbon, 10 of hydrogen and 10 of oxygen) is surrounded by an envelope of water, or that several atoms of starch are united to form a molecule, lying in an atmosphere of water . . . the fact that the water-content of solid starch varies between widely separated limits cannot be reconciled with the supposition that each atom of starch is surrounded by an envelope of water; for then . . . they would have to have a variety of properties . . . in the solid state; they would have to attract water in various quantities. In a word, there would have to be as many modifications of insoluble starch as there are different amounts of contained water. We are therefore led to adopt the second supposition as the more probable"[4]—that is, the supposition that different numbers of starch-atoms can combine to form starch-molecules of different sizes. When, in the passage just quoted, Nägeli speaks of starch containing very different quantities of water, he is thinking of the swelling of starch-grains on treatment with heat or with reagents. He must therefore argue that treatment of starch with the reagents concerned does not alter the starch chemically, and he writes:

"It is not possible to explain this phenomenon merely by the supposition that starch possesses for acids, for alkalis and for water at higher temperatures a greater affinity than for water at lower temperatures. Were this the cause of swelling, it would follow that, on the neutralization of the acids or alkalis and on cooling, the fluid taken up in excess must be released[4]."

He also notes that in all these cases, the swelling is a threshold phenomenon; heating must reach a certain temperature, and acids and alkalis a certain concentration before there is any swelling at all. The degree of polymerization he postulates can be judged by his computing the possible number of starch-atoms in a molecule to be "up to 9,000".

We may now consider how he attempts to prove that the compound (or polymer) molecules must be elongated in general form.

He argues that the rigidity of the whole structure (starch-grain or cell-wall) requires that the solid particles exercise different attractions in different directions, and he considers that it is "simpler and more natural" to suppose that this is due to their being anisodiametric, rather than to postulate different forces exercised in different directions by isodiametric particles[4].

This argument, which was probably correct in 1858, prevents him, I believe, from completing a most ingenious and characteristic argument based on the phenomena of cracking of starch-grains in shrinking or in swelling. From the space given to these phenomena in the more empirical part of his monograph, and from their being explicitly referred to in the theoretical part, it seems that they impressed his mind strongly.

Starch-grains are commonly composed of concentric spherical or ovoid shells, but when they are dried they do not, he says, show fissures between the shells, but very often do show radial cracking. This he interprets as proving that the particles "must have a radial as well as a concentric ordering". I cannot find that he anywhere makes clear that a mere geometrical ordering of particles in rank and file scarcely explains the observed phenomena. Unless I am greatly mistaken, what is required is a difference of attraction between particles; the attraction being greater along the radius of the starch-grain than in the tangential direction. If this could be conceded, we at once arrive at rod-shaped compound molecules with their length along the radius of the grain. But this would, of course, not be consistent with the postulate that isodiametric particles, such as he supposed the starch-atoms to be, must not be required to exercise different attractions in different directions.

Yet, in this discussion of cracking, which occurs early in the monograph, he does seem to have made up his mind on the presence of rod-shaped compound molecules; for, noticing that cracks occur also in the radial direction when the grain swells under reagents, he adopts as an explanation that in this case water-particles are inserted preferentially along the radius, which increases the radial dimensions relatively, just as in drying the radial dimensions are relatively increased by the removal of water lying principally tangentially between particles. Neither of these explanations seems to be very lucid unless we do assume that different forces are operative between the starch particles in the two directions, radial and tangential respectively.

Compared with the mass of work under review, my account, long as it is, is inadequately brief. But if it is of any value at all, what conclusions does it seem to hint at ? Some conclusion I feel called on to offer; for a case-history without a diagnosis is necessarily disappointing.

It seems to me probable that the elaborate theorizing in which Nägeli indulged was to a minor extent responsible for his conclusions: that its chief function was to fortify his mind; to give him courage to make his way through an immensity of tedious detail (he weakened his sight seriously by the extreme assiduity of his microscopic studies), and courage to enunciate with conviction conclusions partly, if not wholly, arrived at by a process of independent judgment exercised immediately on his observations. It is not without significance that both Hofmeister and Pfeffer praise him for his *Scharfsinn*; which seems to be the same quality as that referred to by Aristotle under the name ἀγχίνοια, and called by Kant, *Mutterwitz*. This is something the lack of which, as Kant remarks, no schooling can make good. We cannot analyse it, but one of its characteristics appears to be the ability to judge the relative importance of a piece of evidence; this is illustrated, to give only one example, by Nägeli's willingness to alter his model, which seemed to fit a number of the facts, when he found it inadequate to account for the tensile strength of plant fibres. It does appear to be a faculty which many, but not all, great scientists have had in an unusual degree. Mendel must have had it supremely or he would have been as unable as were his contemporaries to digest the mass of facts offered by Gärtner. Claude Bernard, on the other hand, is perhaps an example of a scientist who lacked this power. His results seem largely the product of an excellent method, and when called on to guess he commonly guessed wrong. Perhaps Faraday and Clerk Maxwell present a similarly contrasting pair.

The art of investigation, it may be, has, like other arts, its rules, by following which more can be accomplished than by the rules of other arts; but it has also, like them, an element which cannot be taught because it cannot be analysed.

THE RADIO TELESCOPE INTERFEROMETER AT THE ROYAL RADAR ESTABLISHMENT

By Dr. J. S. HEY, M.B.E.

A NEW installation for radio astronomical and upper atmosphere research at the Royal Radar Establishment, Ministry of Aviation, has recently been constructed on the site of a former airfield at Defford, near Malvern. The equipment consists essentially of two steerable and mobile radio telescopes with parabolic reflectors 25 m. (82 ft.) in diameter, which can be used either separately or in conjunction as an interferometer (Fig. 1.) The radio telescopes can be operated over a wide range of wave-lengths down to a few centimetres, and their spacing can be varied up to about 1,000 m. in any orientation for interferometric observations of high angular resolution. It is planned to use the aerials both as radiometers for the reception of radio emissions and also with transmitters for radar astronomy. The aim was to devise a radio telescope system which would combine sensitivity, accuracy and versatility.

Before describing the equipment in more detail some of the guiding principles governing the choice of system will be outlined. A parabolic reflector is particularly suitable for a radio telescope which is to be steerable in any direction and capable of changing wave-length easily. The sensitivity of a radio telescope when receiving radio emissions is proportional to its collecting area A; the least angle that can be resolved is approximately λ/D where D is the diameter of the aperture; when used with a transmitter in radio reflexion experiments the echoed signals are proportional to A^2/λ^2. The shortest wave-length to be used determines the accuracy required in the surface contour of the reflector, and surface deviations should not exceed $\lambda/16$ in working conditions (about 6 mm. at $\lambda = 10$ cm.). While metre wave-lengths are appropriate for much radio astronomical work there is an important field of research at shorter wave-lengths; consequently, it was planned that the system should be able to operate at wave-lengths as short as 10 cm. Unfortunately, constructional problems and cost increase rapidly with size of reflector when high accuracy has to be maintained. A reflector diameter of 25 m. was therefore accepted, and it was decided to use two radio telescopes as an interferometer in order to increase angular resolution.

When two separated aerials are connected together as an interferometer the aerial pattern consists of interference lobes with maxima separated at intervals of approximately λ/L where L is the spacing between the two aerials. The half-power width of each lobe is approximately $\lambda/2L$, compared with λ/D for the half-power beam-width of a single aerial of diameter D. The angular resolution is thus greatly increased and is determined by the spacing; consequently, very accurate measurements of angular positions are possible on isolated sources. An interferometer with mobile aerials can be used for the determination of source diameters and the analysis of complex distributions of sources of radio emissions. This is achieved by the method of aperture synthesis in which observations obtained with the aerials at various spacings in different directions are combined. The resolution corresponds to that which would be achieved by exploring the sources with the very narrow beam produced by an aperture of dimensions comparable with the largest spacing.

The pointing errors of the radio telescopes must clearly be small compared with the beam-width. A 25-m. reflector gives a beam-width of about 20 minutes of arc at $\lambda = 10$ cm., so the pointing errors should not exceed 2–3 minutes of arc. The accuracy of the interferometer depends on the length and stability of the base-line. A variable spacing up to about 1,000 m. was chosen as appropriate for many purposes in the wave-length range of 10 cm.–1 m. To ensure an angular accuracy of a few seconds of arc it was specified that when operating at a given spacing the distance between the phase centres of two aerials should not vary more than 1 cm. and relative displacements at right angles to the line joining them be not more than a few mm.

The main contract for the equipment was placed with Werkspoor, which possessed unique qualifications in having previously constructed in Holland an accurate radio telescope of the required size as well as having special experience in the design and manufacture of traction equipment, bridges and large-scale structures. Several sub-contracts were arranged with British firms, and in particular the radio telescopes were erected at Defford by Carter-Horseley (Engineers), Ltd.

Several factors determined the choice of a site: it had to be nearly flat over distances of about 1 km. and with no screening of the field of view above a few degrees elevation, with freedom from sources of radio interference, and within a reasonable distance of the main Establishment at Malvern. The former Defford airfield fitted these requirements satisfactorily as well as providing runways suitable for the laying of tracks to support the mobile aerials, which are steel constructions each weighing about 240 tons. Two intersecting runways were required and the disposition of the tracks is shown in Figs. 1 and 2. The length of the tracks from the intersection is about 750 m. One aerial can run along the track in direction *AB* and the other along *CD*. It will be seen that any relative position can be achieved, the maximum spacing being 700–1,200 m. depending on direction. Along each runway are two parallel sets of standard double railway tracks 90 ft. apart. Each radio telescope is supported on a triangular carriage which can be electrically driven along the tracks. When they have been brought to the required positions for an experiment, the radio telescopes are levelled by means of hydraulic jacks. On each aerial, running, braking, levelling and locking are all controlled from one panel.

Although the radio telescope reflector is closely parabolic in contour, it is in fact polyhedral and consists of 1,464 triangular facets. These are in sets of 4, each set being separately adjusted to the correct position after mounting in the reflector framework. In this way a high accuracy of contour, within the specified limits for 10 cm. wave-length, can be attained. The reflector is constructed of wire mesh to minimize differential heating and consequent distortion, and also to reduce heat reflected to the focus during solar observations. The central region, of 20-m. mean diameter, is of fine mesh composed of wires 1·25 mm. in diameter with 7·25 mm spacing. The remaining outer part, to 25 m. diameter, is of slightly thicker wires with about twice the spacing. This concession in the

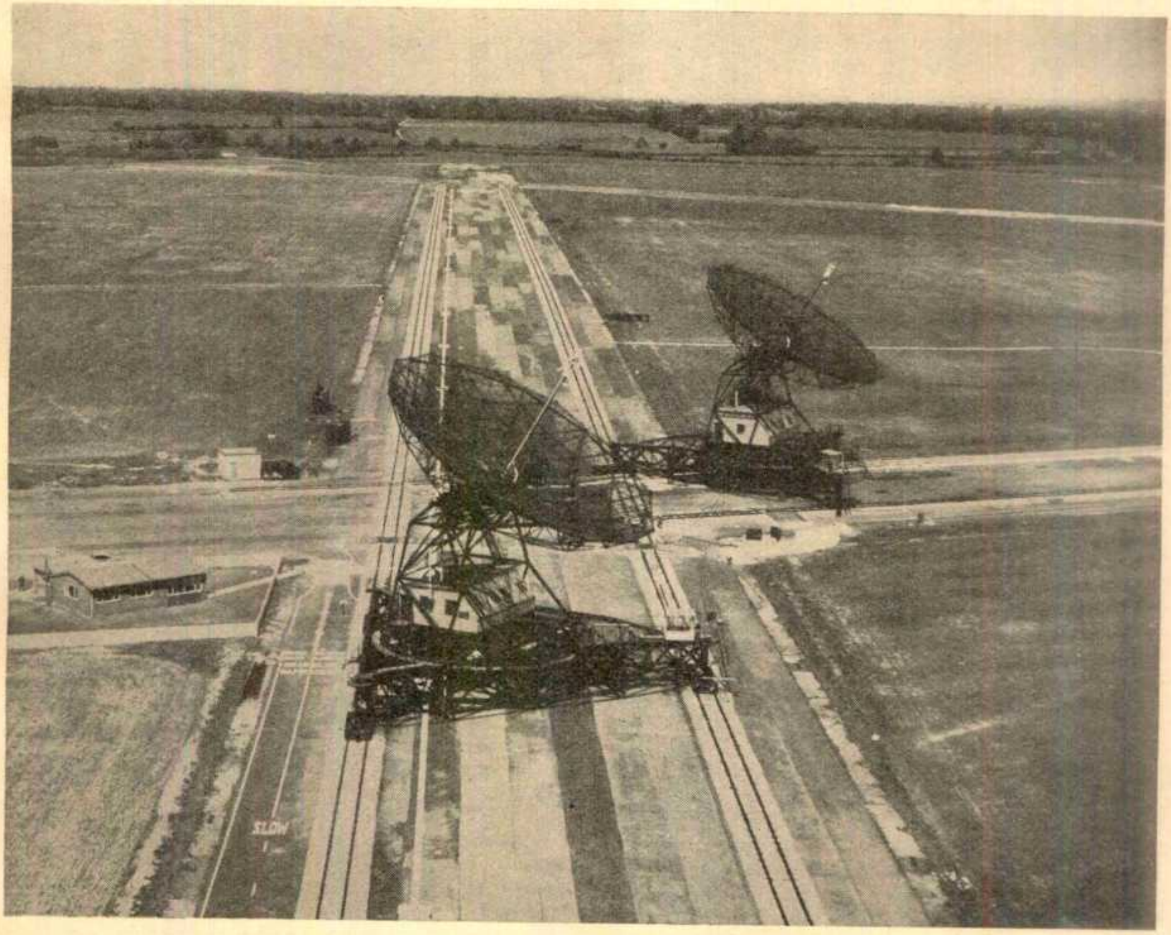

Fig. 1. The radiotelescope interferometer (Crown copyright)

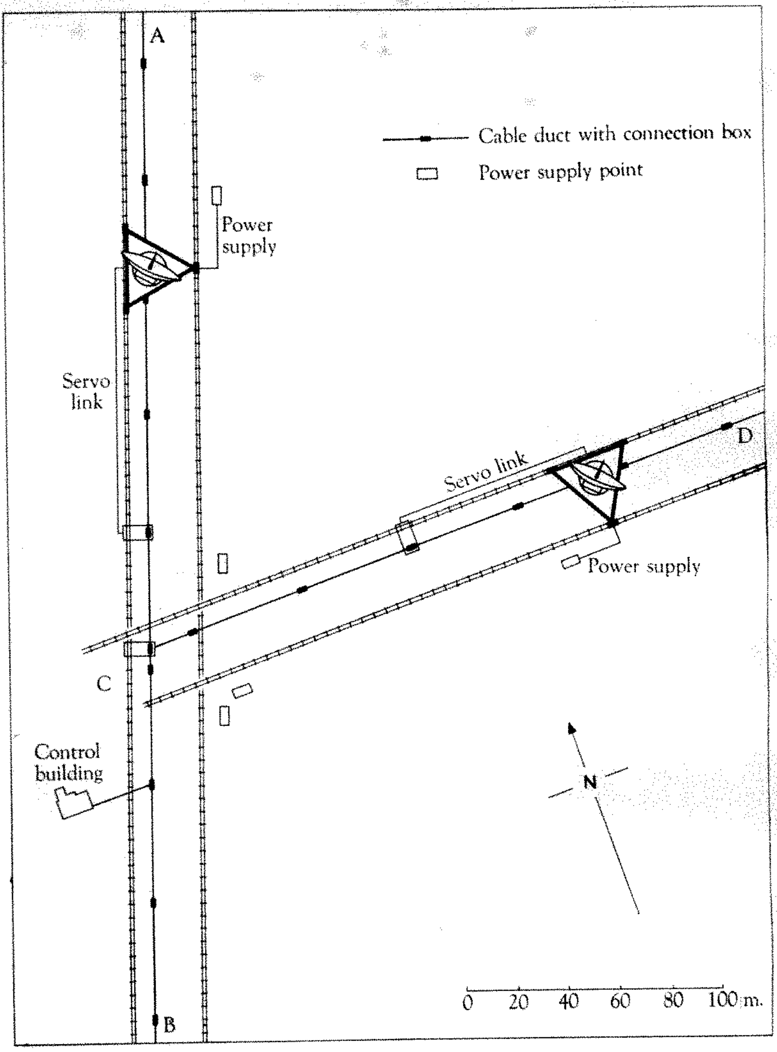

Fig. 2. Diagram of central part of the installation. The total length of the track in direction AB is 1,500 m. and that in direction CD is 750 m.

outer mesh eases mechanical construction without serious detriment to performance, since it entails only a small loss of reflexion efficiency at 10-cm. wave-length. In any event, when highly sensitive radiometers are operated at short wavelengths, it is sometimes advisable not to attempt to utilize the whole reflector since 'spill-over' tends to bring in unwanted radiation from the ground. The focal length of the reflector is approximately 12 m., and the position and polarization of the aerial feed at the focus are adjustable during operation by a mechanism behind the reflector.

The reflectors have alt-azimuth mounts, and are provided with servo-motor drives. The central pivot for azimuth rotation takes about half the load, the other half being shared by four wheels running on a horizontal circular rail of 16 m. diameter mounted on the mobile carriage. The system is designed to give a pointing accuracy of better than 3 min. of arc at azimuth and elevation-rates up to 18° and 12° per min. respectively in normal working conditions and wind speeds up to 20 m.p.h.

Each aerial is provided with a mechanical analogue converter or 'pilot' which automatically transforms celestial co-ordinates of declination and hour angle into azimuth and elevation. With this device a celestial object such as a radio star can be followed continuously. When the two radio telescopes are used together as an interferometer they must track simultaneously in the same direction, and they must be connected together to combine the radio signals they receive. The first requirement is met by providing a control room at the intersection of the runways where the directional data of the radio telescopes are displayed and from which both equipments can be controlled. In meeting the second requirement the interconnecting cables must satisfy certain stringent conditions: there must be little change of electrical length due to temperature fluctuations or moisture, and reflexions at connecting points and attenuation in the cables must be small. Coaxial cables are used of which the outer conductor is a solid aluminium tube filled with dry pressurized air, and the inner conductor is held by a helical membrane spacer. For thermal insulation and protection, the cables are surrounded by glass wool and bituminous felt and placed in concrete cable ducts. Connecting boxes are placed at intervals of about 50 m. along the cable run as indicated in Fig. 2. The connectors are specially designed to minimize discontinuities and consequent reflexions.

The cabins mounted behind the aerials are each large enough to accommodate two high-power radar transmitters as well as receiving and other apparatus. If desired, one aerial may be used for transmission and the other for reception to eliminate some of the difficulties which can arise in common transmitter-receiver systems with highly sensitive receiving devices. At present, a transmitter with 2½ MW. peak-power and 5 µs. pulse-length working at a frequency near 1,300 Mc./s. has been installed in one of the cabins, and in the other a transmitter with 100 kW. peak-power, 200 µs. pulse-length, with operating frequencies at 300 Mc./s and 500 Mc./s. At 3,000 Mc./s. it is planned to utilize the 2 MW., 5 µs. transmitter already available in the 45-ft. radio telescope at Malvern.

It will be appreciated from this description that the new installation is a major addition to British facilities for the radio exploration of space. It is a suitable instrument for observations of radio emissions originating from many different sources such as radio stars, the Sun, Moon and planets, Earth satellites and space probes. Within the solar system radar methods can also be applied. In the upper atmosphere, investigations can be made of meteors, auroræ, and ionospheric phenomena. The radio telescope system combines versatility and high angular accuracy for a wide variety of research in radio astronomy and the radio phenomena of the upper atmosphere.

NEWS and VIEWS

The Henry Dale Professorship of the Royal Society

THE Council of the Royal Society has accepted a generous gift of £100,000 from the Trustees of the late Sir Henry Wellcome to establish and endow a Royal Society professorship in medical research to be known as the Henry Dale professorship. The Wellcome Trustees have made this gift to commemorate the unique services of Sir Henry Dale to the Trust as its chairman for twenty-two years as well as his outstanding contributions to science and medicine in a wider context. In accepting the gift, the Society expresses its gratitude and great satisfaction in being associated with the Trustees in this act of honouring its distinguished Fellow, Sir Henry Dale, who has also rendered conspicuous service to the Society both as secretary (1925–35) and as president (1940–45). The Council of the Royal Society greatly values this outstanding benefaction, which will significantly increase the Society's capacity to promote medical research. The appointments to the new professorship will be especially, but not necessarily exclusively, in relation to research in physiology and pharmacology, which are the particular interests of Sir Henry Dale. This announcement of the establishment of the new professorship was made on Sir Henry Dale's eighty-sixth birthday, June 9.

The National Institute for Medical Research :

Sir Christopher Andrewes, F.R.S.

SIR CHRISTOPHER ANDREWES retired on June 6, after thirty-four years service as a member of the scientific staff of the Medical Research Council; he was head of the Division of Bacteriology and Virus Research at the National Institute for Medical Research, and had been deputy director of the Institute since 1953. Sir Christopher's scientific career coincides closely with the modern development of medical virology, and he is recognized internationally as an authority in this field. His name will always be associated with the outstanding work that led to the discovery of the influenza virus; in this he played a leading part, and the viruses of influenza and other respiratory diseases have remained his principal scientific interest. This is illustrated by the courageous decision that was taken by the Medical Research Council, on the personal initiative of Sir Christopher, to set up a research group under his direction in the Harvard Hospital at Salisbury for the long-term study of the elusive problem of the common cold. The combined laboratory and human volunteer organization that he established was universally recognized as being admirably designed for this type of work, and it is most gratifying that Sir Christopher's persistence in the face of repeated disappointments should have been rewarded by the discovery at Salisbury, a year before his retirement, of methods of isolating and cultivating common cold viruses. Sir Christopher has also contributed to the increasingly important subject of the nomenclature and classification of viruses. He has lectured on his subject in many countries and he has trained many pupils; the present flourishing state of medical virology owes much to his work and influence.

Dr. A. Isaacs

SIR CHRISTOPHER ANDREWES is succeeded as head of the Division of Bacteriology and Virus Research at the National Institute for Medical Research by Dr. Alick Isaacs. Dr. Isaacs qualified in medicine at the University of Glasgow in 1944. After house appointments and the tenure of a research scholarship in the Department of Bacteriology in Glasgow he spent a year in the Department of Medicine at Sheffield, and then worked for two years with Sir Macfarlane Burnet in Melbourne; this experience has had great influence on his subsequent career. Dr. Isaacs joined the scientific staff of the Medical Research Council in 1950 in order to work at the National Institute for Medical Research in the Division of which he is now taking charge, and during the past ten years he has established himself as a leading research worker in virology. His interests have lain chiefly in influenza and related viruses, and he has been responsible for the World Influenza Centre which was set up at Mill Hill, in co-operation with the World Health Organization, for the study of the epidemiological aspects of the disease, particularly in relation to the appearance of new strains of virus and their influence on the spread of epidemics from country to country. During the past few years Dr. Isaacs' work has attracted much attention through his discovery of interferon, a substance produced in cells as a result of viral infection, which has an inhibiting effect on viral growth. This is a discovery with widespread implications, and it has aroused interest and stimulated new research in laboratories throughout the world.

Mineral Technology at the Imperial College of Science and Technology: Prof. M. G. Fleming

DR. M. G. FLEMING, who has been appointed to the new chair in mineral technology in the Department of Mining at the Imperial College of Science and Technology, is a graduate of Queen's University, Kingston, Ontario. On leaving college he spent four years in the mining industry, finally holding the appointment of chief metallurgist at the Paymaster Gold Mine, Ontario. Following the outbreak of the Second World War, Fleming joined the Royal Canadian Air Force, and after various appointments in Training Command flew as flight lieutenant navigator with 435 Squadron from Down Ampney, Gloucestershire. On his return to civilian life in 1946, Fleming was appointed to the staff of the Royal School of Mines, which is one of the constituent colleges of the Imperial College, becoming senior lecturer in 1951 and reader in 1958. These years since the War have seen the establishment of the new degree course in mineral technology following the opening of the Mineral Dressing Laboratories in 1953. Fleming's main research interest has been connected with investigations into flotation phenomena, particularly the characteristics of secondary lead minerals, and he has also given much attention to the application of basic research to plant operation. He is well known for his work in both these fields and has been consulted frequently by industry and overseas Governments. As a consequence, he has travelled widely and has first-hand knowledge of mining conditions in many parts of the world, which, coupled with his research experience, will prove to be of particular value to the Royal School of Mines while building up the traditions of the new Department—a Department the work of which is devoted to one of those fascinating areas to be found lying between pure science on one hand and conventional engineering on the other, and which only now are beginning to be investigated systematically.

The National Institute of Agricultural Botany : Dr. P. S. Wellington, D.S.C.

DR. P. S. WELLINGTON has been appointed assistant director of the National Institute of Agricultural Botany as from July 1, 1961. The vacancy was caused by the death of Mr. G. W. G. Briggs (*Nature*, **190**, 861; 1961). Since 1952, Dr. Wellington has been the chief officer of the Official Seed Testing Station for England and Wales, which is one of the branches of the Institute. In this position he has been responsible for statutory tests under the Seeds Act and has initiated a programme of investigations into the problems arising from new methods of handling and conditioning the seed of farm and garden crops. Dr. Wellington is a graduate of the University of London, where he obtained first-class honours in botany at the Royal College of Science (Imperial College). During the War he served as an observer in the Fleet Air Arm and was awarded the D.S.C. in 1941.

International Meteorological Organization Prize for 1961 : Prof. K. R. Ramanathan

PROF. K. R. RAMANATHAN, of the Physical Research Laboratory, Ahmedabad, has been awarded the International Meteorological Organization Prize for outstanding work in meteorology and international collaboration. Prof. Ramanathan studied at Victoria College, Palghat, and Presidency College, Madras, and after obtaining a doctor's degree in science, he became a demonstrator in physics at Trivandrum College and later a research scholar at the University of Madras. In 1922 he joined Rangoon University College as a lecturer in physics. In 1925 he became a member of the Indian Meteorological Department. After having been director of the Kodaikanal and Bombay Observatories, he was appointed deputy director-general of observatories. In 1948 he was appointed director of the Physical Research Laboratory in Ahmedabad. Prof. Ramanathan has worked on problems of molecular scattering of light in fluids, atmospheric and solar radiation, study of the Indian monsoon, general circulation of the atmosphere, atmospheric ozone, physics of the ionosphere and aeronomy. For several years he was the president of the International Union of Geodesy and Geophysics, and was also president of the International Association of Meteorology of that Union. He has been, and still is, the president of the International Ozone Commission. The International Meteorological Organization Prize was established in 1955 by the World Meteorological Organization in honour of the former non-Governmental organization which had initiated international collaboration in meteorology in 1878, but which ceased in 1951 when the World Meteorological Organization took over. The Prize consists of a gold medal and 1,200 U.S. dollars.

Taxation of Scientific Bodies

ON the second reading of the Rating and Valuation Bill in the House of Lords on May 31 the position of the scientific societies was strongly represented by the Earl of Halsbury, the Earl of Cranbrook and Lord Douglas of Barloch, though Earl Jellicoe had not mentioned this question in moving the second reading. Lord Hailsham, in replying on the debate, said that there is a prospect of fairly general agreement between the Government and the learned societies about the way in which the problem should be tackled (see *Nature*, May 20, p. 657). He referred again to the deputation he had received on behalf of the societies, but repeated that he did not think it would be right to deal with the question within the scope of the present Bill beyond the 50 per cent mandatory relief. It would not be right to ask local authorities to undertake what was fundamentally a national burden. Lord Hailsham said that he recognized to the full what Lord Halsbury and Lord Cranbrook had said about the value of the work of these societies, that many of them are essential to the working of science, that they produce publications and maintain libraries of national importance, but his own opinion was that the difficulty could not be dealt with by rate relief at all, but that it must be dealt with by grants in some form. He thought we should consider using the Royal Society and the British Academy as vehicles for this kind of negotiation, and if they were prepared to act the Government would be glad to hear from them as and when the situation developed.

United Kingdom–Euratom Technical Collaboration

IN a written answer in the House of Commons on June 6, the Parliamentary Secretary for Science, Mr. D. Freeth, said that co-operation under the United Kingdom–Euratom Technical Collaboration Agreement had covered a wide range of subjects. These included basic reactor physics, reactor planning and programming, reactor economics and the costing of nuclear power, fast reactors and gas-cooled reactors, thermonuclear fusion, nuclear measurements, mass spectrometry, workshop organization, health and safety, corrosion, the construction of 'hot' laboratories, the industrial applications of radioisotopes, juridical problems arising from nuclear ship propulsion, radiation protection and third-party liability. Co-operation had proceeded by exchange of reports, visits of experts, conferences and symposia, and attachment of staff to specific projects and establishments. The United Kingdom also collaborated with Euratom and the United States Atomic Energy Commission in the translation pool "Transatom", which concentrated on translations from Russian and Japanese.

Funds for Cotton, Silk and Man-Made Fibres Research

THE Cotton Industry Development Council (Amendment No. 4) Order, 1961, which was approved by the House of Commons on May 8, enables the Cotton Board to collect a statutory levy from firms processing man-made fibres, to support the British Cotton, Silk and Man-Made Fibres Research Association, which is being formed by the merging of the British Cotton Industry Research Association and the British Rayon Research Association, as recommended last year in the report of the working-party appointed by the Councils of the two Associations (see *Nature*, 190, 589; 1961). Article 6 of the Amended Order enables the Cotton Board to collect from the man-made fibres section of the industry 11 per cent of the total being collected from the whole industry, which in 1959–60 and 1960–61 was £385,000. For 1961–62 the total proposed to be collected from the industry for all the Cotton Board's activities was £400,000, of which £45,000 would come from the man-made fibres section, and, with £200,000 from the cotton section, would go to the Research Association. The Order also enables the Cotton Board to assist scientific research on the man-made fibres side. In reply to a question, Mr. N. Macpherson, Parliamentary Secretary to the Board of Trade, who moved the approval of the Order, said that one object of the merger was to reduce expenditure; the income of the Shirley Institute was £462,000 in 1959–60 and was expected to be £531,000 in the first year of the next quinquennium: that of the Rayon Research Association had been £376,000.

The Devon Naturalists' Trust

THE Devon Naturalists' Trust was formally inaugurated on March 27. Its objects are to conserve the wild-life of the county against encroachment, to protect places of interest to naturalists, and to encourage the study of natural history. Lord Roborough is the first president. A public meeting to invite support was held in Exeter on May 16, and the speakers were Lord Roborough, Lord Hurcomb, Mr. H. G. Hurrell and Major J. Coleman-Cooke. Mr. Hurrell announced his gift to the Trust of Lady's Wood, its first reserve. This is an area of some 9 acres near South Brent which contains much of interest, including dormice and wood anemones. Apart from the reserve given by Mr. Hurrell, there is a strong possibility that the Trust will be offered another. It is also in contact with a farmer who has a large colony of *Lobelia urens* on his land, and it is hoped to do something to preserve this very rare plant. The Trust and the Devon Wild Fowlers Association are acting together to see if the management of the bird sanctuary on the River Exe can be improved. The prospects of introducing blackgame and *Zostera marina* in suitable places is being studied and may be put in hand if the initial inquiries indicate a good chance of success. The Trust is also making inquiries to discover if the commercial primrose picking reported in the Press last spring is likely to be damaging.

Conservation of Askham Bog

THE Nature Conservancy and the Yorkshire Naturalists' Trust have agreed to conserve Askham Bog. This area, near York, is a 100-acre remnant of a swamp which must at one time have covered much of the Vale of York. Now almost wholly covered by a thicket of birch, oak and alder, the Bog illustrates the later stages in the succession from open fen to woodland. The ground vegetation includes many bog and fen species uncommon in Yorkshire, among them the rare royal fern. Associated with this flora is a rich variety of insects, particularly beetles. The land is partly owned and partly leased by the Yorkshire Naturalists' Trust, which manages it as a nature reserve. At present it is managed successfully with due regard to the scientific interest and, accordingly, the Nature Conservancy does not feel it necessary to acquire a direct interest in the Bog or to declare it as a National Nature Reserve. By the agreement, Askham Bog is designated a Site of Special Scientific Interest (*A*). The Bog will continue to be managed by the Yorkshire Naturalists' Trust, advice from the Nature Conservancy being available when necessary. Permits to visit the site or undertake research there must be obtained from the chairman of the Management Committee, Mr. C. J. Smith, 7 Malton Way, Clifton, York.

Aerial Photographs in Geological Mapping

IN the construction of geological maps, increasing use has been made in recent years of photo-geology, and to-day even the most junior research student tends to regard aerial photographs as a pre-requisite to his field work. Notwithstanding an extensive periodical literature, however, comprehensive and up-to-date text-books on this subject have been generally unavailable, and geologists throughout the world will therefore be indebted to Dr. Richard G. Ray, of the United States Geological Survey, who has produced an excellent monograph, *Aerial Photographs in Geologic Interpretation and Mapping* (United States Department of the Interior: Geological Survey. Professional Paper No. 373. Pp. vi+230. Washington, D.C.: Government Printing Office, 1960. 2 dollars). This well-produced prestige publication, sold at a nominal price, lucidly describes the photo-geological techniques employed not only in routine geological work but also in the search for petroleum and ore deposits, in engineering geology, and in hydrological investigations; and it furnishes a readable account of the instrumentation utilized in these studies. The text is illustrated by 116 figures, principally stereoscopic-pair photographs chosen from the collections of Government departments in the United States.

The Australian Museum, Sydney

THE *Australian Museum Magazine* (13, No. 9; March 15, 1951. 3*s*.) includes an account of new aboriginal exhibits which have recently been placed on display in the Museum. One of the most successful of the exhibits illustrates how the aborigines make and use stone implements. Each technical process is demonstrated by using actual implements in cast hands and the impression is given of a native standing behind the exhibit and poking his arms through holes in the wall. The section on "Dress and Ornament" appeals to all visitors, and models of the various types of wind-breaks and huts, together with a painting of a camp scene, are equally arresting. The exhibits have been especially designed to be attractive and interesting to the casual visitor, instructive to those wishing to learn about the aborigine, and of service in the Schools Department. Other articles in this interesting *Magazine* deal with the gem-stones of Australia, fossil insects, freak fishes and the use of radioactivity in entomology and insect-pest control.

Site for Ulster Folk Museum

THE Trustees of the Ulster Folk Museum have announced the purchase of the Cultra Manor Estate in County Down for the purposes of a site for a permanent folk museum. It includes a manor house and 136 acres of delightfully situated land overlooking Belfast Lough and the Antrim coast. The estate is about six miles from the centre of Belfast and is in an area unlikely to suffer from suburban development. Initial work on the land will start in the summer, and as much material for the Museum has been gathered together since the Folk Museum was established by Act of Parliament some two years ago, it is hoped that developments will be well advanced in the foreseeable future.

University News :

Belfast

The following appointments have been announced: Dr. A. Dalgarno, to the chair of quantum mechanics in the Department of Applied Mathematics; Dr. E. A. Cheeseman, to the chair of medical statistics in the Department of Social and Preventive Medicine.

Bristol

Dr. R. G. Chambers has been elected reader in physics, also Dr. D. Bohm (until he takes up his appointment to the chair of theoretical physics at Birkbeck College). A. R. Paterson has been appointed lecturer in applied mathematics.

Hull

The following appointments to senior lectureships have been announced: Dr. G. C. Bond (chemistry); Dr. A. Cunliffe (physics); Dr. H. W. Parsons (mathematics).

London

The Wolfson Foundation has made a grant of £200,000 to University College, London. The money will be used to develop the Galton Laboratory and the Department of Eugenics, Genetics and Biometry in a building north of Euston Road which has been leased to the College by the University Grants Committee. The chair of biometry, vacant since Prof. J. B. S. Haldane left the University, will be re-established in the new premises.

Nottingham

Dr. James Crossland, lecturer in the Department of Physiology, University of St. Andrews, has been appointed reader in pharmacology in the Department of Pharmacy as from next session.

Sheffield

Dr. A. M. Murray has been appointed lecturer in physics.

The Night Sky in July

New moon occurs on July 12d. 19h. 12m. U.T. and full moon on July 27d. 19h. 51m. The following conjunctions with the Moon take place: July 8d. 20h., Venus 2° N.; July 9d. 11h., Aldebaran 0·4° S.; July 16d. 03h., Regulus 0·3° N.; July 17d. 02h., Mars 0·3° S.; July 27d. 07h., Saturn 3° S.; July 27d. 17h., Jupiter 3° S. In addition to these conjunctions with the Moon, Venus is in conjunction with Aldebaran on July 16d. 06h., Venus being 3° N., and Mercury with Pollux on July 31d. 19h., Mercury being 6° S. Mercury is a morning star, and is visible low in the east before sunrise during the later part of the month. Venus is a morning star, rising at 1h. 20m., 1h. 10m. and 1h. 05m. on July 1, 15 and 31, respectively. Its stellar magnitude on July 15 is − 3·7; the visible portion of the apparent disk increases from 0·555 to 0·683 during the month, and its distance from the Earth increases from 73 to 96 million miles. Mars is too close to the Sun for easy observation. Jupiter and Saturn are visible almost all night, rising at about sunset and setting at about sunrise. Jupiter has stellar magnitude − 2·3 and Saturn + 0·3 on July 15, and their distances from the Earth on that date are 380 and 840 million miles, respectively, when they are in Capricornus and Sagittarius. There is one occultation of a star brighter than magnitude 6 visible at Greenwich: July 9d. 11h. 13·0 m., α Tau. disappearance; July 9d. 12h. 24·4m., α Tau. reappearance. The Earth is at aphelion on July 5, its distance from the Sun being 94·6 million miles.

Announcements

Prof. C. W. Wardlaw, professor of botany and director of the Laboratories and Experimental Grounds in the University of Manchester, has been elected an honorary foreign associate of the Royal Academy of Belgium (Section of Natural Sciences).

Dr. G. D. H. Bell, director of the Plant Breeding Institute, Cambridge, has been elected a vice-president of the National Institute of Agricultural Botany and a vice-president member of the Council.

Dr. I. M. Lifschitz of the Academy of Sciences of the Ukrainian S.S.R., Kharkov, has been awarded the Simon Memorial Prize by the U.K. Committee of the Low Temperature Group of the Institute of Physics and the Physical Society, for his work on the structure of the Fermi surface in metals and his work on liquid helium. The Prize, a memorial to Sir Francis Simon, a pioneer for the Low Temperature School of the Clarendon Laboratory, Cambridge, consists of £250.

From July 3, the address of the Director of the Service and all branches of the headquarters administrative office of the Public Health Laboratory Service will be: 24 Park Crescent, London, W.1; Tel. No. Museum 2223.

The opening of the new Creep Laboratories of the Electrical Research Association, Cleeve Road, Leatherhead, Surrey, will take place on July 7. Further information can be obtained from Leslie Jervis, press officer, Electrical Research Association, Cleeve Road, Leatherhead, Surrey.

A conference on "Behavior Genetics" will be held at the Center for Advanced Study in the Behavioral Sciences during August 14–September 3. Further information can be obtained from Preston S. Cutler, Center for Advanced Study in the Behavioral Sciences, 202 Junipero Serra Boulevard, Stanford, California.

An international conference on "Heat Transfer", presenting new developments in theory and practice, will be held at the University of Colorado during August 28–September 1. Further information can be obtained from Alan Brown, director, Bureau of Continuation Education, University of Colorado, Boulder, Colorado.

A meeting of the Photobiology Group will be held at the University of Sheffield during July 7–8. The programme will include papers on metabolism in photosynthetic bacteria and some aspects of photochemistry. Further information can be obtained from the secretary of the Group, Dr. D. Vince, Horticultural Research Laboratories, Shinfield Grange, Shinfield, Berks.

The United Nations conference on "New Sources of Energy" will be held in Italy during August 21–31. The programme has been divided into a number of sessions, including (*a*) geothermal energy; (*b*) wind power; (*c*) solar energy. Further information can be obtained from the United Nations Information Centre, 14–15 Stratford Place, London, W.1, or the Executive Secretary, United Nations Conference on New Sources of Energy, United Nations, New York.

RECENT SCIENTIFIC INQUIRIES IN PARLIAMENT

AT question time in the House of Commons on May 16, the Parliamentary Secretary for Science, Mr. D. Freeth, was faced with no fewer than 39 questions relating to scientific matters, ranging from the performance of the reactors at Calder Hall and Chapel Cross, progress with production of nuclear reactors for research and teaching purposes, to arterial disease and fire hazards of domestic equipment.

In the course of his replies, Mr. Freeth said that rather more than three-quarters of Great Britain has been covered by the Geological Survey in the primary 6-in. survey. At the present rate of progress the primary 6-in. solid and drift survey would be completed in about 55 years; it is hoped to reduce this to 35–40 years. Nearly as much secondary survey as primary survey is being carried out, and work is now being done on the more difficult mountainous regions. The Survey has also prepared the tectonic map of the United Kingdom as part of a co-operative scheme for a tectonic map of Europe.

On research into coal utilization, Mr. Freeth said that besides the British Coal Utilization Research Association, the British Coke Research Association and the Coal Tar Research Association are primarily concerned with the utilization of coal. All three research associations are doing very valuable work and there is a great deal of co-operation between them and between the National Coal Board, the Central Electricity Generating Authority, the Gas Council and the appliance and equipment makers. The total income last year of the Coal Utilization Research Association was £450,000, of the Coke Research Association more than £150,000 and of the Coal Tar Research Association less than £113,000. There was the fullest possible co-ordination on the matter between the Minister for Science and the Minister of Power.

Mr. Freeth was also asked what research was being conducted into the better use of the mineral resources of Britain; he referred to the basic information supplied by the Geological Survey and Museum in its maps and memoirs. The Warren Spring Laboratory and the National Chemical Laboratory undertake research on processing ores and extracting metals, and various research associations, industrial firms and universities undertake research into the better use of minerals.

Asked as to the action taken to apply scientific development to the machine tool industry, Mr. Freeth said that besides the scientific development work of the Machine Tool Industry Research Association and the Production Engineering Research Association, research of direct value to such scientific development was carried out at the National Engineering Laboratory and the National Physical Laboratory. In addition, 12 grants totalling more than £170,000 have been made for research and development work in this field in the past two years to six universities and two colleges of technology in England and Wales. The Machine Tool Advisory Council is reviewing progress made in implementing the recommendations of the Mitchell Sub-Committee. Mr. Freeth also referred to a ten-fold increase in the accuracy of large modern gears over the past twenty years, to which research and development work at the National Physical Laboratory and the National Engineering Laboratory had contributed. Gears up to 16 ft. in diameter can now be made with an error of one-quarter of a thousandth of an inch from the true form and spacing of the teeth and the automatic error-correcting system developed recently by the National Engineering Laboratory have been applied to a gear-cutting machine.

While the Department of Scientific and Industrial Research has not sponsored any research into the use and operation of multi-purpose pipe-lines for the transport of both liquids and solids, it is itself carrying out research into the subject, and the Department is always willing to discuss with industry the part it could play in assisting research and developing techniques in every field.

In response to a specific request which had been made for a breakdown of the figure of £42·9 million for Government expenditure on civil research and development in 1958–59 given in the report of the Advisory Council on Scientific Policy, Mr. Freeth gave the following figures for the source of the funds concerned: defence departments, £2·9 million; civil departments, £34·7 million; private industry, £4·5 million; other organizations, £0·8 million.

MAWSON INSTITUTE OF ANTARCTIC RESEARCH

ON April 15 the Prime Minister of Australia (the Rt. Hon. R. G. Menzies) inaugurated, within the University of Adelaide, the Mawson Institute of Antarctic Research. In his inaugural address Mr. Menzies referred to the great achievements of Sir Douglas Mawson in science and exploration, and affirmed that Mawson had accomplished so much because he possessed, in the highest degree, the qualities of imagination, courage and endurance.

The University of Adelaide has established the Institute, believing that it would provide the best means to commemorate one of its most distinguished members. Mawson joined the University staff in 1905 as lecturer in mineralogy and petrology. In 1921, he was appointed professor of geology and mineralogy, and he retired in 1952. He remained a member of the University Council until his death in 1958.

The main purpose of the Institute will be to foster polar studies and research. In order to do this it will maintain and develop reference collections of geological and biological materials from the Antarctic.

PHYSICS DEPARTMENTAL LIBRARY

It will maintain and develop a library of papers and maps as well as books on Antarctica. It will provide accommodation for workers engaged in antarctic research. It will promote public interest in polar matters by means of lectures and a museum devoted to antarctic materials and equipment.

The University plans to accommodate the Institute in a major annex to the geology school. This would contain a library in which the map collection would be included, a museum which would serve as a meeting-room, generous storage space and a number of small research rooms.

The basis of the reference collections will naturally be the materials collected by Mawson and members of the expeditions which he led, although valuable collections from other parts of Antarctica have been obtained by exchange with the British Museum and other institutions. At present these are largely housed in the Geology Department of the University. Many periodicals and other books have been segregated in a 'polar' room in the University library, and their number will soon be greatly increased as Lady Mawson has announced that she will present to the Institute the extraordinarily fine library collected by Sir Douglas.

To mark the inauguration of the Institute a small 'Antarctic Room' has been partitioned from the geological museum. This is mainly occupied by rocks arranged on a regional basis and well documented with maps and geological sections. It also serves to illustrate the achievements of the expeditions of which Mawson was a member or which he led.

The interest created by the inauguration of the Institute has been very wide. Representatives of the Royal Society and the Academy of Science of the U.S.S.R. were present and the Australian Academy of Science was represented by its president. Other institutions which were represented included the Royal Geographical Society, the American Geographical Society, the Argentina Institute of Antarctic Affairs and the Scott Polar Research Institute. Messages of goodwill and congratulations were read. In addition, the Governments of the United Kingdom and New Zealand sent representatives and, from the South Australian Government, two Ministers of the Crown attended. Many men with personal experience of antarctic exploration and research were present. The occasion revealed wide approval of the University's move and paid high tribute to a very great Australian. A. R. ALDERMAN

TRAINING IN OCCUPATIONAL HYGIENE

THE twelfth Conference of the British Occupational Hygiene Society was held in London on April 11. The morning session, with Dr. J. C. Gilson in the chair, dealt with the need for training, and the afternoon, with Dr. L. G. Norman as chairman, covered present and future facilities in universities.

Dr. Gilson opened the proceedings by contrasting the considerable effort now being put into radiation monitoring with the meagre resources available for checking dust and fumes, which he estimated to be a risk to some 150 times as many people as were exposed to nuclear hazards. The disparity of effort on the job was reflected in training resources, and no university course in occupational hygiene existed.

The interest of management in working conditions was emphasized by Mr. H. F. Spencer, managing director of Richard Thomas and Baldwins, Ltd., who criticized the term 'occupational hygienist'. Dr. J. M. Rogan, of the National Coal Board, who directs one of the largest epidemiological investigations at present being made in the world, considered that the existing employment of industrial medical officers in large concerns, with specialist laboratory help when required, might be more satisfactory than the appointment of broadly trained occupational hygienists.

Dr. K. P. Whitehead of Imperial Chemical Industries, Ltd., and Dr. P. G. Swann of Esso gave accounts of the ranges of activity of the personnel whose health, as industrial medical officers, they had to safeguard. The former emphasized the diversity of the chemicals handled. In his firm an industrial hygiene research laboratory studied toxicity and advised on works policy and plant design. He could see little need for the employment of industrial hygienists at factory-level in large, well-organized industries although they might be of considerable benefit to smaller firms.

Dr. Capel's firm employed an industrial hygienist, a graduate in chemistry, who had been trained in the United States. His reports were countersigned by one of the medical staff. It was advantageous for the candidate for such a post to have a degree related to the activities of the firm, or possibly a degree in general science, in which case a six months' course in the principles and practice of industrial hygiene would be sufficient. The parent American company maintained a medical research division which served affiliates all over the world and provided toxicological data on all materials handled.

Mr. H. Collinson, chairman of the Trades Union Congress Social Insurance and Industrial Welfare Committee, concentrated on the problem of the small employer with a back-street factory where conditions were often appalling, although work in the highest tradition of craftsmanship might emanate from it. To some extent this was a matter of educating the employer who was unaware and unco-operative towards suggestions for improving working conditions, but it was unlikely that voluntary action was going to be sufficient. The responsibility for making occupational hygiene available to the whole range of industry rested on the Government. The T.U.C. attached great importance to the pioneer work being done by group health services, such as that at Slough. The Nuffield Foundation had recently placed a quarter of a million pounds at the disposal of the Ministry of Labour for the encouragement of such schemes.

It was important that training should include practical experience in factories, which could only be achieved by the persuasive powers of those planning courses.

Ten years experience in providing an occupational hygiene service for the 200 member firms of the Slough Industrial Health Service was described by Dr. D. Hickish. The firms ranged in size from 2 to 2,000 employees and the backing of the group medical ice was available. Recently, consultant work utside the group has been undertaken. The function of the occupational hygienist was : (*a*) to recognize environmental stress affecting health ; (*b*) to evaluate the stress ; (*c*) to prescribe control measures.

The occupational hygienist needed to have studied elementary physiology, industrial medicine and toxicology. Training in sampling and analysis, including dust, radiation and noise, detailed knowledge of heating, ventilating, air-conditioning and lighting, and a familiarity with statistical methods were desirable. Courses at a technical level, in addition to those for graduates, would be advantageous.

The deputy chief inspector of factories, Miss K. Crundwell, described a recent attempt to catalogue the facilities which at present exist for testing factory air. It was going to be difficult to convince industry of the need for testing to such an extent that they were willing to pay for it. Some employers were anxious to improve their working conditions but others might not take kindly to the suggestion that they should pay, as they might see it, for the evidence on which to hang themselves.

The last speaker in the morning session was Dr. S. G. Fortuin, director of the Philips Medical Services, Eindhoven, Holland. He explained that in every plant they tried to have a full-time medical man, whose services might also be shared by smaller firms in the same town. The checking of environmental conditions was the task of the medical department and there was no place for a more or less independent industrial hygiene department. The physician alone should be responsible for the evaluation of health hazards.

The industrial hygiene laboratory was part of the Medical Service ; chemists and engineers were employed in this work and no university programme existed in the Netherlands for training them in the specific theoretical and practical problems of industrial hygiene ; postgraduate courses should be organized for this purpose.

In the discussion which followed the first session it was generally agreed that a need for testing facilities existed, and this involved the training of occupational hygienists to carry out environmental measurements. The cost and method of paying for such services was debated and it seemed unlikely that small firms would be willing, or even able, to carry this individually, although trade associations might offer a way round the difficulty. Another problem was the cost of remedial measures, involving re-design of plant or exhaust equipment, which might be crippling to a small undertaking.

The afternoon session was opened by Dr. L. G. Norman. In a survey of courses related to occupational hygiene which are at present available, Dr. C. H. Wood said that very little was offered in Britain. British employers of occupational hygienists, when questioned, were unanimous in stating that the only training provided was in-service, augmented, occasionally, by short courses given, as a rule, by senior members of the staff.

It was difficult to find out what British teaching institutions gave in the way of special courses, as distinct from the comprehensive type in the United States, since no general list was published; nevertheless quite a number of subjects could be investigated in this way, lectures on radiation hazards being liberally provided.

Mr. S. A. Roach gave an account of a nine-month course in industrial hygiene engineering which was being planned at the London School of Hygiene and Tropical Medicine and which was to open in October 1961.

Prof. R. E. Lane, who is responsible for the teaching of occupational hygiene in the University of Manchester, stated that the current course for industrial medical officers lasted two years but required attendance for only a day and a half a week. The department also appointed research fellows who were postgraduate science candidates for M.Sc. or Ph.D. degrees.

Prof. R. C. Browne, who occupies the Nuffield chair of industrial health at the University of Durham, felt that the chemistry graduate was usually the best equipped for the work, followed, in order, by physicist, engineer and doctor, though special risks, such as radiation, clearly affected this. Such graduates were in short supply at present.

During the discussion on the afternoon papers the question of payment for training was raised. Several speakers thought that industry, while willing to send employees on short courses lasting a week or two, might not be prepared to lose their services for a year. The suggestion that Government bursaries might be paid drew the reply that all the students taking a somewhat analogous course in public health engineering had been from overseas for several years past, supported by the World Health Organization or their own Governments ; no Treasury support was available for Britons. Other speakers considered it likely that bursaries would become available from industry.

The conference proceedings will be reported in full in the *Annals of Occupational Hygiene*.

C. N. DAVIES

CLOSED CIRCUIT TELEVISION IN THE MEDICAL SCHOOL

A SYMPOSIUM on the applications of television in medical research and teaching was organized at the London Hospital Medical College during May 10–11 by the Medical Committee of the Scientific Film Association in collaboration with the Association for the Study of Medical Education. Since the 2-hr. demonstration of a land-line colour broadcast by a team from Guy's Hospital in 1957 (*Nature*, **181**, 91, 1958) no collective attempt had been made to evaluate and discuss the potential usefulness of closed-circuit television in medicine. This meeting is therefore a welcome sign that the universities are ready to concede that television need not necessarily be equated with mass entertainment. In fact, the conference was well timed, as many of the seventy senior representatives from British medical schools who participated are concerned with the planning of new buildings and the possible incorporation of closed-circuit television.

At least three schools are about to install such facilities and several others may shortly follow their example.

Apart from isolated *ad hoc* demonstrations by manufacturers of electronic equipment, and the somewhat elaborate presentations organized at congresses by a pharmaceutical firm, there is little practical experience in Britain. To ensure, therefore, that facts rather than opinions could be discussed, the organizers invited the co-operation of acknowledged experts in television engineering: on the use of television in a medical school in the United States, on research applications and on its uses in a military medical centre—both from the United States—and a surgeon in charge of television facilities at a German university.

While television has serious limitations, such as restricted resolving-power and relatively high cost, the conference has shown that television offers considerable advantages in a number of fields—with the obvious reservation that the usefulness of any device must depend on the ability and knowledge of the user, whether research worker or teacher. The main properties of television are: its ability to convert invisible radiation into visible images, its high sensitivity to light, electronically adjustable contrast, and above all, its ability to present instantaneously moving images, even of very small subjects, to an unlimited audience, while the camera may well be in a location too restricted or too dangerous for direct human observation.

Radiology makes full use of these properties. Small 'Vidicon' tube cameras can display enlarged pictures from the X-ray image converter. Similarly, large 'Orthicon' tube cameras equipped with systems of wide-aperture mirror lenses can reproduce the radiographic image from a life-size fluorescent screen with sufficient brilliance so that the radiologist need no longer work in the dark, and consultants and students can study simultaneously the same information on receiver screens in any number of different rooms. These methods make it possible to reduce the radiation received by the patient, so that the film records from the television screen can be used almost as a matter of routine for the study of processes within the human body. Image storage on special tubes, on ferro magnetic disks and on magnetic tape ('Video' tape) are now well beyond the laboratory stage, and the development in the United States of a really large television tube sensitive to X-rays will probably replace the use of the conventional fluorescent screen in the none too distant future.

Ultra-violet radiation, sufficient for direct photomicrography, will destroy biological tissues in a very short space of time, and similarily cine-micrographic studies of the retina would require an impracticable intensity of light. It is in these examples that the enlarging, intensifying and radiation-converting properties of television can be of value to research work. Camera tubes sensitive to ultra-violet radiation will produce images of the contents and behaviour of cells with greatly reduced radiation, and highly sensitive 'Orthicon' tubes can be used to record colour images of retinal blood vessels with light intensities which are well tolerated by the human eye. Tubes sensitive to infra-red radiation may be used instead of infra-red photography for the direct examination of the subcutaneous venous circulation.

A straightforward electronic method of superimposition makes it possible to display and record in accurate register on one receiver-screen two images from separate television cameras. Eye movem can thus be studied by superimposing the reflexio of a spot-light on an eye on to the image of the object which is being scanned by the subject.

Filming from the television receiver can also be used for selective studies of movements or behaviour. The television camera, with its automatic aperture compensation for changes in the intensity of light, can be operated from a distance by remote control. While the camera is in a relatively inaccessible or even dangerous location, the observer can aim and focus accurately by watching a television screen and record the action with a film camera in front of another receiver.

Applications in university teaching are obvious and numerous if it is remembered that television can ensure that every member of the audience can see equally as well as the demonstrator; the teaching of dental procedures is an outstanding example. The lecturer can use this enlarging device either in the classroom itself or in another room while he directs the demonstration with the help of a two-way communication system. The teacher can determine the area and degree of magnification of the subject to be displayed on a television projection screen or on receivers by adjusting the zoom lens on the camera from a small remote control panel. Chemical reactions, anatomical dissections or experiments under the microscope can be televised from within the lecture theatre itself, but other demonstrations, such as a psychiatric interview or a surgical operation, must take place elsewhere and are then relayed to the students and lecturer through closed circuit television.

Endoscopy, the exploration of body cavities, is perhaps a good example where television is equally applicable in both research and teaching. Here the television camera enables several research workers or a virtually unlimited number of students to study simultaneously what, until recently, could be seen by the endoscopist alone. Both in Britain and in the United States flexible bundles containing several thousands of very thin glass-fibres are being developed. Each fibre will, by internal reflexion, transmit a part of the image from a small lens to the television camera tube. The diminutive diameter and flexibility of these bundles make it possible to explore normal as well as pathological processes of organs inside the body which are not readily accessible to conventional optical endoscopes.

Like any other device, television should only be used where it is superior to other methods. It does not take the place of lantern slides or films, but there will clearly be occasions when an enlarged and detailed display of something which is happening now is likely to be more effective. Few films suit more than one teacher. They are too rigid, and it is impossible to modify what they present to suit the reaction of a particular audience.

Relatively inexpensive equipment, which is simple to operate and maintain, is now available, so that active experimentation should shortly replace the somewhat theoretical arguments on the assumed merits and demerits of television. Baylor University, where basic instruction on techniques in physiology are shown to students on television receivers in their individual laboratories, has demonstrated that television may contribute to better and more effective teaching, without in any way attempting to take the place of the teacher or individual practical experience by the student.

C. E. Engel

THE FOURTH WORLD FERTILIZER CONGRESS

IT is generally believed that nitrogen is a key element in crop production. This is evident from the figures in Table 1, showing the yield in kilograms in different countries expected for an application of 1 kgm. of plant nutrient:

Country	Crops in rotation			Permanent pastures		
	N	P	K	N	P	K
Norway	9	3	5	11	6	4
Sweden	14	11	7	14	11	7
Denmark	18	4	2	12	5	3
U.K.	16	5	5	—	—	—
Ireland	20	8	8	—	—	—
Holland	19	6	3	10	6	4
France	19	5	2·1	—	—	—
Germany	19	8	4	9	10	—
Switzerland	18	8	4	9	10	5
Greece	15	5	3	—	—	—
Italy	11	3	—	12	4	3
Average	16	8	4	11	7	4

In the *Oxford Economic Atlas of the World* (Oxford University Press, 1959) the following increased yields per kilogram of nitrogen are recorded:

	Wheat	Rice	Potatoes	Grass (or hay)
Kgm. per hectare	17	17	84	17

The Indian Council of Agricultural Research has reported that the average production of rice in India is ten times the amount of nitrogen applied. The United Nations Korean Reconstruction Agency has stated that 1 kgm. of nitrogen as ammonium sulphate produces 12–14 kgm. of brown rice and 14–28 kgm. of rough barley in South Korea. Moreover, 1 kgm. of phosphate as superphosphate can yield 4–18 kgm. of brown rice. In the United States large amounts of fertilizers have been applied in special cases and the results show a big response to nitrogen, but the responses to phosphate and potash are smaller. Doses in amounts larger than 200 lb. of nitrogen or phosphate or potassium per acre show a depressing effect in ordinary soils, but in soils of prairie lands naturally rich in humus, beneficial results are obtained with heavy doses of fertilizers.

Because of the importance of fertilizers in crop production, the world fertilizer industry is well organized by the International Confederation of Engineers and Technicians of Agriculture (C.I.T.A.) at the International Centre of Chemical Fertilizers (C.I.E.C.), Zurich. During May 9–12, the fourth World Fertilizer Congress, organized by the International Centre, met in Opatija on the Adriatic coast of Yugoslavia, under the presidency of Prof. S. Nikolic of Belgrade. Some 290 scientists, industrialists and technicians from twenty-eight countries met to consider six general reports and sixty-five special communications. At this Congress, besides French, English and German, Russian and Yugoslav were also recognized as official languages.

Prof. Nikolic gave an account of the soils of Yugoslavia and the application of fertilizers, micronutrients and organic matter. Prof. M. R. Braconnier, of Paris, reported on fertilizer production and consumption, and stated that in 1958–59, 8·75 million tons of nitrogen, 9·03 million tons of phosphate and 7·88 million tons of potassium were produced by the world fertilizer industries, and the average $N : P_2O_5 : K_2O$ ratio of fertilizers applied has shifted from 1 : 3·85 : 0·77 in 1900 to 1 : 1·03 : 0·9 in 1958–59. In Holland the ratio is 1 : 0·5 : 0·7. Prof. Y. Coic, of Versailles, discussed the adaptation of fertilizers by cultivated plants. Prof. L. Schmidt, of Darmstadt, discussed the experimental results obtained by compound fertilizers and trace-elements. The influence of irrigation on mineral fertilization was dealt with by Prof. L. Cavazza, of Italy. The application of radioisotopes was introduced by Prof. A. C. Schuffelen, of Holland; papers on work with phosphorus-32 carried out in Italy, Germany, Hungary, Poland and Yugoslavia were given.

The functions of light, temperature, acidity, coatings on fertilizers and humus in the absorption of nutrients by plants were discussed in several papers.

From a survey of crop production and fertilizer application in different countries, it appears that in countries not using large amounts of fertilizers the nitrogen response to cereals is very marked; the law of diminishing return is in operation in Holland, Belgium and Norway, where large amounts of nitrogen are applied. But in Japan, China and Taiwan, where composts and other plant and animal wastes are utilized along with fertilizers, better crop yields per unit nitrogen are still obtained. In the United States, yields of wheat and corn are increased by producing organic matter through rotations.

Approximately 1,000 million tons of cereals, 700 million tons of pulses, potatoes, vegetables, sugars, etc., are being produced annually in the world, and the world grassland production is about 1,600 million tons. Hence assuming the yield is 15 times the nitrogen application, the production of the world's food, fodder and fibre requires approximately 250 million tons of available nitrogen. It has been already stated that the industrial supply of nitrogen is only 8·75 million tons; legumes contribute 5 million tons and precipitation 7–10 million tons of nitrogen. Hence the world soil humus is the chief supplier of crop nitrogen. It is well known that the recovery of nitrogen by crops is smaller than that of phosphate and potash, chiefly due to loss of nitrogen as nitrogen gas in the processes of nitrate formation from manures and fertilizers, and this loss of nitrogen is retarded by organic matter and minerals. Experiments have shown that all nitrogenous fertilizers and manures when applied to land intensify the oxidation of soil humus due to the formation of nitrates in the soil. Organic matter such as straw, plant residues, grasses, etc., when incorporated in soils, not only improve the physical properties of the soil but also fix atmospheric nitrogen and protect the soil nitrogen and increase the humus capital and this is aided by different calcium phosphates. The world reserve of phosphate rocks is of the order of 21,000 million tons and its present utilization is 30 million tons annually. Moreover, the expanding world steel industry is supplying large amounts of basic slags rich in phosphate, lime, magnesia, manganese, copper, vanadium and other useful nutrients. Hence increased utilization of these cheap phosphates incorporated with organic matter could go a long way towards meeting the world-wide lack of nitrogenous fertilizers.

N. R. DHAR

THE HAFFKINE INSTITUTE

THE annual report of the Haffkine Institute for 1959, which refers to the continued difficulty of recruiting qualified staff, includes lists of grants and research fellowships and scholarships as well as of papers published during the year[*]. Research activities in the Department of Antitoxins and Sera included the antigenic analysis of cholera vaccine and the use of submerged or shaken cultures for growing diphtheria toxin and pertussis vaccine. In the Department of Chemotherapy, the synthesis of compounds of possible anti-tubercular activity continued, including heterocyclic derivatives of thiourea and thiocarbanilide. Compounds with the *p*-nitrophenyl and/or dichloroacetyl groups attached to the pyrimidine, thiazole and pyrazole ring were also synthesized and tested *in vitro* against *Salmonella typhosa*, while other pyrazole and pyrazolene derivatives have been synthesized for examination as anti-convulsants. Two 1 : 3-disubstituted sulphonyl ureas have shown promise as antidiabetics.

The Department of Clinical Pathology and Diagnostic Reagents has finally identified *E. coli* from urine by sero type (preliminary) of 'O' antigen determination and is pursuing its investigations on the antigenic structure of the typhoid–paratyphoid group under partial anaerobiosis for possible application in preparing improved agglutinable suspensions. Besides epidemiological studies of enteric infection, it has continued its antigenic work on cholera vaccine, its investigations on otomycoses and, in collaboration with the Entomology Department and the Director's Laboratory, on the alimentary canal of the different rat-fleas with reference to the growth-promoting factors of some protozoa and bacteria. The Department of Entomology completed its studies on *Drosophila muris*, and started work on the morphological structure of the salivary glands of different non-poisonous snakes in comparison with the parotid glands of the poisonous snakes. Besides work on cholera autotoxin, the Department of Pharmacology continued its work on indigenous drugs, and has developed a new colorimetric method for determining 5-chloro-7-iodo- and 5 : 7-diiodo-8-hydroxyquinoline by coupling with *p*-nitroaniline-2-sulphonic acid, and modified methods for determining *m*-aminophenyl in *p*-aminosalicylic acid have been examined as well as methods for determining 'Novalgin', 'Avil' and thymol.

In the Department of Virus Diseases the immunogenicity of viral vaccines was investigated with the view of standardizing testing procedures and work on the adaptation of locally isolated rabies street virus strains to embryonated eggs. The Biochemistry Section reports on preliminary methods of preserving tissues from cadavers, the screening of vegetable extracts for blood-group activity and the preparation of anti-*A* and anti-*B* serum, while the Department of Nutrition continued its nutritional evaluation of foodstuffs commonly consumed in Bombay State, and its investigations into the nutritive value of some leafy vegetables and their supplementary effect, as well as its work on fermented foods and on the effect of commercial sterilization on the nutritive value of milk.

HOSPITAL IN-PATIENTS IN ENGLAND AND WALES

THE hospital in-patient inquiry for the years 1956–57 was organized jointly by the Ministry of Health and the General Register Office to provide statistics which will assist in the administration of the hospital services and contribute towards the knowledge of illness (morbidity) in the community[*].

Information for the inquiry is supplied by hospitals, where the form is completed for one patient in every ten discharged, giving a confidential summary of the case record. Hospitals of all types except psychiatric take part in the inquiry which, since 1958, has covered virtually all hospitals in England and Wales. In 1956 and 1957, the years to which the present report relates, the inquiry covered 68·5 and 82·1 per cent respectively of all hospital discharges and deaths in England and Wales.

Apart from the main reference tables the report contains, for 1957, a series of tables devoted to duration of stay. This is related directly to bed-usage, and the figures should be of value for planning purposes.

Other features of the report are: a discussion of the statistical and other problems which arise in the interpretation of hospital morbidity data; some analyses according to the type of hospital in which patients were treated, and, for 'acute' hospitals, their size; a table showing age distribution for the 800 categories of the *Detailed List of the International Statistical Classification of Diseases*, and tables for six of the fully represented regions showing the local administrative area in which patients resided and the hospital group in which they were treated. These help to determine the 'catchment areas' of hospital groups.

Altogether, there were 3,485,000 discharges and deaths in 1957 in hospitals during the inquiry. The average duration of each spell of hospital care was slightly shorter than in 1955 or 1956, being 22 days for males compared with 24 days in each of the two preceding years and 20 days for females compared with 22; in half the cases the duration of stay was less than 10½ days.

During 1957 maternity cases stayed an average of 10 days after delivery compared with 11 days in 1955. The proportion of mothers discharged within 7 days of delivery increased from 7 per cent in 1955 to 13 per cent in 1957. 51 per cent of mothers stayed very in 1957 and 36 per cent 11 ged 5–9 years, had the shortest average spital (11 days) and patients, aged 75 and longest (45 days for men and 63 for women). h this is mainly due to more chronic illness in r people, small children and older people stayed nger than older children and young adults for treatment of the same condition.

---

[*] Ministry of Health; and General Register Office. *Report on Hospital In-Patient Enquiry for the two years 1956–1957*. Pp. vii+335. (London: H.M.S.O., 1961.) 18*s*. net.

Of the patients aged 65 and more, women usually stayed longer than men; for circulatory diseases the average stay for men was 53 days and for women 72, and for injuries other than head injuries 29 days for men and 41 days for women.

In 'acute' non-teaching hospitals the average length of stay was shortest in medium-sized hospitals. The same was true at all ages and for both sexes, and for many specific diagnoses.

From data on the duration of stay, the number of hospital beds required by different groups of patients can be calculated. The number of beds required per 10,000 population increases greatly with the patient's age, ranging from 20·8 at ages 15–24 to 188·88 at ages 75 and more for men, and from 18·7 at ages 5–14 to 187·3 at ages 75 and more for women.

Of the 40·8 beds per 10,000 population used for male cases, 13 per cent were taken up by cases of respiratory tuberculosis; 7 per cent were occupied in treatment of malignant neoplasms, 13 per cent for cardiovascular diseases, 10 per cent for respiratory diseases and 11 per cent for digestive diseases. For females, 48·9 beds per 10,000 population were in use; 7 per cent of them for respiratory tuberculosis, 6 per cent for malignant neoplasms, 8 per cent for digestive diseases and 15 per cent for maternity cases.

RESPONSE TO HOT ENVIRONMENTS

A REPORT* prepared by the Medical Research Council owes its origin to the concern felt by the Board of Admiralty regarding the thermal conditions to which men were exposed during the Second World War when serving in His Majesty's ships in tropical waters. This led, in 1944, to the appointment of a committee to inquire into and advise on the problems in this field. It was recognized from the outset that investigations would eventually have to be made in a tropical climate, and, in 1948, the Royal Naval Tropical Research Unit was established in Singapore under the joint auspices of the Admiralty and the Medical Research Council.

Before the establishment of the unit at Singapore, however, investigations were initiated in London at the National Hospital for Nervous Diseases. In the experiments carried out in London, the physiological effect on men wearing different types of clothing of exposure to high air temperatures was examined at different humidities and air speeds, both when the men were resting and when they were working. On the results of these experiments, for which the subjects had been artificially 'maximally acclimatized' by previous exposure to hot conditions in the laboratory, it was possible to base tentative recommendations concerning the conditions of warmth that were acceptable in ships at sea in tropical waters. The results also seemed to indicate that the 'effective temperature scale', which had been accepted for use as a measure of the severity of environment in ships, was misleading in certain respects. This led Dr. B. McArdle to devise a new index, the 'predicted four-hour sweat-rate' (P4SR), for the assessment of hot environments.

With the establishment of the unit at Singapore similar investigations were carried out. These confirmed largely the previous findings in London and, though they did not entirely support the criticisms of the 'effective temperature scale', they did demonstrate that the 'predicted four-hour sweat-rate' was an accurate and convenient measure of the severity of indoor hot-environments. The work at Singapore was, however, extended to compare the relative tolerance to heat of men who had been artificially 'maximally acclimatized' in the laboratory, with those who had been 'naturally acclimatized' by residence in a tropical climate. Investigations were also made of the stress imposed by radiant heat of long wavelength and by different rates of energy expenditure. Work carried out to determine the upper limits of warmth to be permitted in ships was extended to determine the upper limits that could be physically tolerated and the position of the 'comfort' zone. In addition, a number of physiological problems associated with these main lines of research was examined.

Now that the results of all the investigations in London and in Singapore have been brought together, it is clear that considerable additions to knowledge have been achieved. Much information has been obtained on the relative effects of various levels of air temperature, humidity, air speed, and radiant heat, and about the limits of heat which people can tolerate.

Answers have been provided to some of the practical problems of the Navy; the critical examination of a widely used scale of environmental heat-stress and the production and testing of a new index have improved and added to the techniques available for evaluating the severity of different climatic environments. As well as achieving these practical ends, this work has extended knowledge of the physiological mechanisms involved in the process of adaptation to hot environments and has indicated the direction for future research.

The report has been compiled by Dr. R. K. Macpherson with the assistance of an editorial board composed of Dr. T. Bedford, Dr. O. G. Edholm, Surgeon Captain F. N. Ellis, and Dr. N. H. Mackworth. It brings together much patient and arduous work by a number of service-men and civilians, and it is a fine example of how long-term investigations should be planned, organized and controlled. Many of its findings should be of interest to industrial organizations where hot processes are involved; managements in the new Indian steelworks should find much of value.

SEA SURFACE TEMPERATURE IN COASTAL WATERS OF T BRITISH ISLES

INVESTIGATIONS of the sea temperatures in British coastal waters have hitherto been neglected despite their value to workers interested in the ecology of the seashore and to meteorologists in connexion with fog forecasting. Mr. Lumb's short paper on the variations of these temperatures is therefore to be welcomed*.

The paper is really concerned with the whole of the shelf seas around the British Isles and not just with the waters within a few miles of the coasts. The typical winter and summer isotherm patterns, as derived from charts published by the International Council for the Exploration of the Sea, are first discussed. The winter pattern is explained in terms of cooling and vertical mixing in relation to the depth of the water column, but no mention is made of the part played by currents. In the North Sea, for example, the winter isothermal pattern is dominated largely by two tongues of warm water which are the result of currents bringing water into the sea from the Altantic through the Straits of Dover and to the north of Scotland. To explain the summer pattern the work of Dietrich is used: this shows that stratification of the water column due to the absorption of solar radiation cannot take place in areas where the tidal streams are sufficiently powerful to provide a strong vertical mixing agency. In this connexion it is stated that the English Channel is nearly isothermal throughout the year. This is not so, as a thermocline develops in the western English Channel in summer.

The possibility of drawing quasi-synoptic temperature charts for five-day periods on the basis of sea-temperature observations made by light-vessels and a few selected ships is then examined, the typica seasonal isotherm patterns being taken as a guide to the course of the isotherms in places where the observations are scanty. Such charts are considered to be a possible aid to local weather forecasting. Five examples of the charts that can be produced by using this technique are given, and at first sight they appear to give reasonable pictures of the prevailing conditions. If, however, one goes beyond this paper and compares them with the corresponding monthly charts published by the International Council for the Exploration of the Sea, a few discrepancies are found even when allowance is made for the fact that the Councils' charts are based on a thirty-day period. They are probably due to different observational methods being employed. Indeed, the relative merits of the various ways of taking sea surface temperatures are a vexed question, but Mr. Lumb does not discuss the accuracy of the observations on which his charts are based. Further, there is some loss of detail, particularly as regards temperature gradients, in his charts compared with those of the Council, as the latter are based to a large extent on observations made by research vessels and merchant ships fitted with recording thermographs or sampling at close intervals. This loss might be important in so far as local forecasting is concerned. However, if charts are needed for forecasting purposes they must be produced rapidly, and the delay which usually occurs while oceanographic data are processed cannot be tolerated. Mr. Lumb is therefore wise to use only data which are readily available; but it would appear that if further investigations of this nature are to be carried out, then the marine meteorologists and oceanographers concerned should endeavour to standardize their methods and pool their data.

CORRECTION FOR EXTINCTION ERRORS IN CRYSTAL STRUCTURE ANALYSIS

By S. CHANDRASEKHAR and D. C. PHILLIPS*

Davy Faraday Research Laboratory, The Royal Institution, 21 Albemarle Street, London, W.1

IT was shown recently[1,2] that it is possible to correct for primary and secondary extinction errors in the X-ray analysis of crystals by the use of plane polarized X-rays. If the incident beam is polarized with the electric vector perpendicular to the plane of incidence the integrated reflexion from a crystal suffering from primary or secondary extinction, or a combination of the two, is:

$$\rho'_{\perp} = \alpha|F|^2 - \beta|F|^4 \qquad (1)$$

to a good approximation when the proportional reduction of intensity by extinction ($\beta|F|^2/\alpha$) is not greater than about 25 per cent. If, on the other hand, the incident beam is polarized parallel to the plane of incidence, the polarization factor is $|\cos 2\theta|$, where θ is the Bragg angle, and since all other factors remain unchanged:

$$\rho'_{\parallel} = \alpha|F|^2\cos^2 2\theta - \beta|F|^4\cos^4 2\theta \qquad (2)$$

The true integrated reflexion for normal polarization:

$$\rho_{\perp} = \alpha|F|^2 = \frac{\rho'_{\parallel} - \rho'_{\perp}\cos^4 2\theta}{\cos^2 2\theta - \cos^4 2\theta} \qquad (3)$$

thus may be determined from measurements of $\rho'_{\perp}$ and $\rho'_{\parallel}$.

The theory has been verified experimentally in the determination of extinction in small crystals of rock-salt[2,3]. The main advantage of the technique is that

* External staff of the Medical Research Council.

it corrects for both primary and secondary extinction simultaneously in a crystal of any shape. Its principal limitation is that the equations become ill-conditioned for values of θ approaching 0°, 45° and 90°; the exact limits of applicability depend on the accuracy of the intensity measurements.

This article describes a simple apparatus which can be used conveniently in crystal structure analysis. The apparatus is shown in Fig. 1. Use is made of the fact that the angle 2θ for the 311 reflexion of copper K_a rays by diamond is close to 90° (actually 91° 34′ mean for $\alpha_1\alpha_2$). The reflected X-rays are therefore almost completely polarized with the electric vector perpendicular to the plane of incidence. The X-ray tube and diamond crystal are mounted on a disk which can be rotated about a horizontal axis collinear with the collimator of the diffractometer, in such a way that the reflected beam passes along the axis for every setting of the disk. The diamond is in the form of a plate (approximately 8 × 7 × 2·5 mm.) with (111) faces and the asymmetry of the 311 reflexion produces a broad beam convenient for use with small crystals completely bathed in X-rays. This beam is sufficiently strong for measurements of reflexions from a crystal mounted on the diffractometer to be made in the usual way by means of a proportional counter and crystal oscillation mechanism[4].

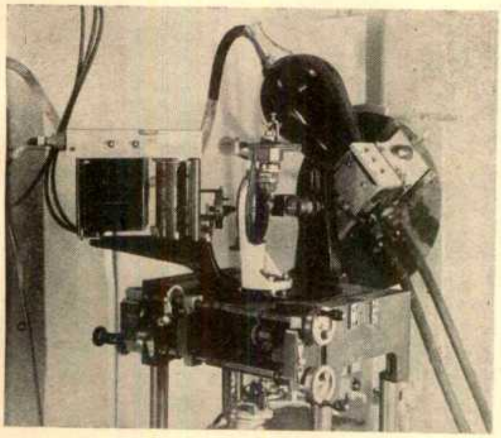

Fig. 1. Single-crystal diffractometer with apparatus for rotating plane of polarization of incident X-ray beam

The apparatus has been tested by performing Barkla's polarization experiment, using the 311 reflexion from small diamond crystals mounted on the diffractometer. The variation of integrated intensity with polarization angle was found to agree closely with the theoretical value and the ratio of the intensities of the two perpendicularly polarized components of the incident beam was estimated to be 0·0064.

The elimination of extinction errors by means of this technique has been tested in a study of reflexions from hexamethylene tetramine[5]. These crystals were chosen because some reflexions are known to suffer heavily from extinction[6], and because it seemed likely that liquid air shock treatment[7] would change the state of perfection of the crystals and enable a comparison to be made of corrected intensities from the same crystal with different amounts of extinction.

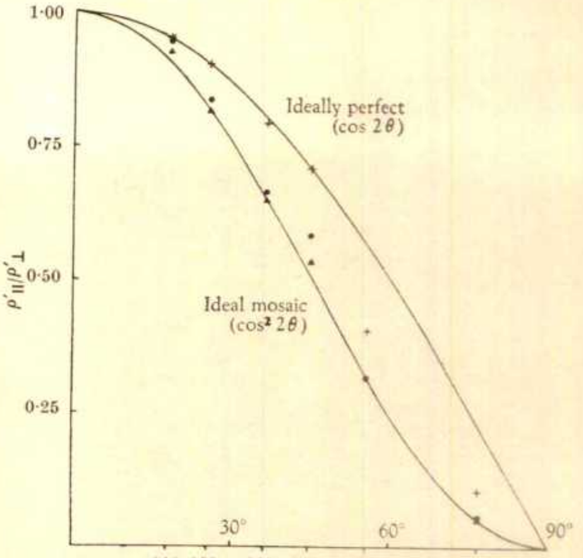

Fig. 2. $\rho'_{\|}/\rho'_{\perp}$ for reflexions from hexamethylene tetramine: +, freshly grown crystal; ●, after one liquid air treatment; ▲, after two liquid air treatments

Fig. 2 illustrates the application of the method to one crystal with diameter about 0·05 cm. The ratio $\rho'_{\|}/\rho'_{\perp}$ for a range of reflexions is plotted against 2θ. The upper curve is the theoretical curve for a perfect crystal, the lower that for an ideal mosaic. The measured values are those for a fresh crystal (crosses), and for the same crystal after one liquid air treatment (circles) and after a second treatment (triangles). Clearly strong reflexions from the fresh crystal have values appropriate to a perfect crystal, but the double liquid air treatment has reduced all the reflexions to values near those for an ideal mosaic. It must be remarked, however, that the strongest two reflexions 110 and 222 were found to be extinguished even after repeated liquid air treatment. Seven other crystals of different sizes were examined and in none of them was it possible to eliminate the extinction completely

440	2,792	147	0·053	0	2,792		

Further liquid air treatment did not increase the intensities of any reflexions.

for these two reflexions by liquid air treatment. Nor was there any relationship between crystal size and the amount of residual extinction, indicating that primary extinction was probably taking place in these crystals[3]. These results again bring out the well-known fact that a crystal may behave as an ideal mosaic for a weak reflexion and yet show a high degree of perfection for a very strong one.

The measurements for this crystal are shown in Table 1, together with the integrated intensities corrected for extinction by the use of equation (3). These corrected values agree well for the different states of perfection of the crystal when the extinction is less than 25 per cent.

The complete set of measurements on this crystal took 8 hr. (with no breaks). There was evidence of a slight decrease in the intensities of reflexions from hexamethylene tetramine on prolonged exposure to air—approximately 6 per cent in 24 hr. No allowance has been made for this effect in the results presented here. Furthermore, the measurements have not been corrected for normal crystal absorption and they are, of course, on an arbitrary scale. The data have been corrected, however, for the small depolarization of the incident beam and the results for the seven other crystals, appropriately scaled, are in very good agreement.

We thank Dr. H. J. Milledge for the loan of the diamond plate, Dr. U. W. Arndt for help in setting up the counting system, Prof. R. King for his support, and finally, Sir Lawrence Bragg, whose interest and advice have been of the greatest value.

GIANT GRAIN GROWTH IN ALPHA FERRIC OXIDE

By R. F. G. GARDNER and D. W. TANNER

Warren Spring Laboratory, Department of Scientific and Industrial Research, Stevenage

AN investigation of the electrical properties of α ferric oxide revealed an anomalous resistivity-temperature curve for semi-spectroscopically pure iron oxide supplied by Johnson, Matthey and Co., Ltd. (Fig. 1, *b*). Roasted ferric oxide gel gives a linear plot over the same temperature-range (Fig. 1, *a*). The deviation shown by the curve *b* material is consistent with inhomogeneity of composition within the grains.

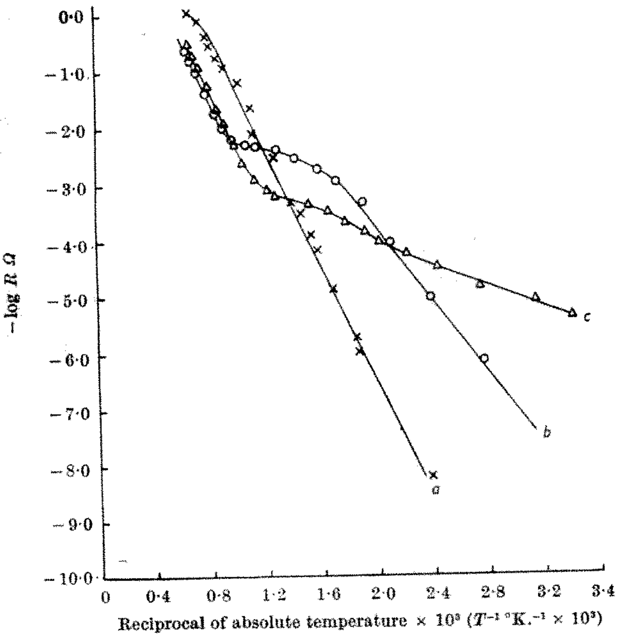

Fig. 1. The variation of resistivity of α ferric oxide with temperature: rectangular pellets, four probe. *a*, Ferric oxide from ferric nitrate by precipitation and roasting at 1,180° C. for 16 hr. in air; *b*, semi-spectroscopically pure ferric oxide 'as received'; roasted at 1,200° C. for 19 hr. in air; *c*, semi-spectroscopically pure ferric oxide treated as aqueous slurry with ultrasonic waves, 20 kc./s., 500 W. for 10 min.; roasted at 1,200° C. for 14 hr. in air

Attempts to remove the inhomogeneity included treatment of the material with ultrasonic waves prior to firing. A tuned stainless steel rod attached to an ultrasonic transducer (500 W., 20 kc./s.) was dipped into a slurry of 20 gm. semi-spectroscopically pure iron oxide in 200 ml. distilled water in a 'Pyrex' beaker. The slurry was agitated by slowly moving the beaker during the 10-min. treatment ; the temperature rose to 40° C. The oxide was separated by decantation and dried in an air oven. Pellets were pressed without binder at 25 tons/in.^{2} and fired in air at temperatures from 1,100° C. to 1,400° C.

The resistivity-temperature curve is modified by the treatment (Fig. 1, *c*). A polished section of this pellet showed giant grain growth throughout. The grains are distinguishable by anisotropy in polarized light and by etching with hydrochloric acid. Contrary to the usual pattern of crystallite growth, the inner grains are larger than those at the surface ; the grain sizes in a pellet of unirradiated material are much smaller. Giant grain growth in ultrasonically treated material has been observed several times (Fig. 2*a* and 2*b*). The effect is not destroyed by preheating the ultrasonically treated material at 700° C. for 15 hr. before pelleting. After firing at 1,300° C. the unirradiated material shows hexagonal grains with straight sides, ranging from 10 to 40μ in diameter. The grains in the ultrasonically treated material show very irregular grain boundaries and contain many pores ; the range in size is from 20μ for occasional grains near the periphery to 500μ for grains at the centre. The large grains show cracking both along grain boundaries and across grains, suggesting comparable strength of intra- and inter-crystalline material. The cracks probably occur during cooling, due to the anisotropy of the oxide. The temperature at which giant grain growth occurs in semi-spectroscopically pure iron oxide has been observed to vary from 1,200° C. to 1,375° C. The general appearance of the grains suggests rapid and irregular movement of the grain boundaries unhindered by pores.

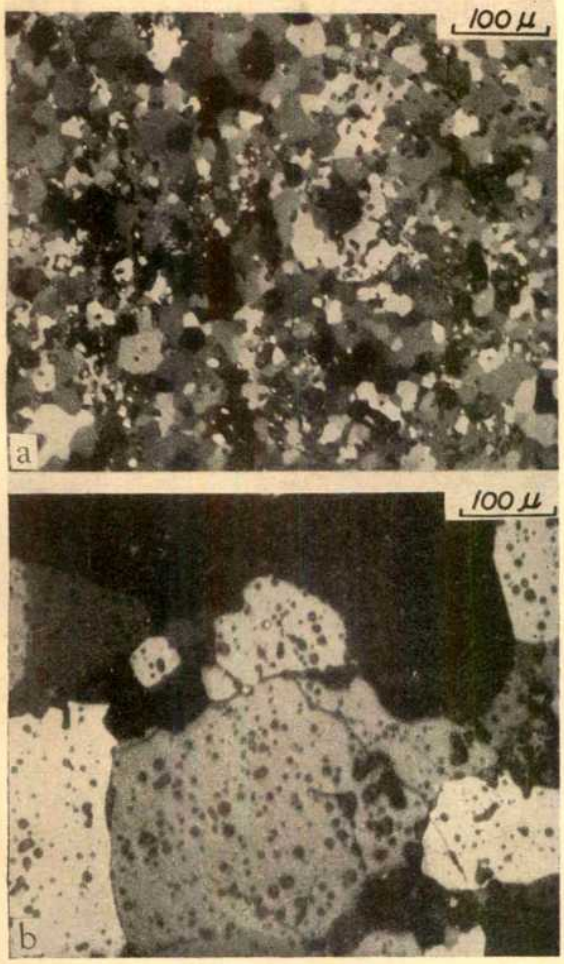

Fig. 2. Polished sections of pellets of semi-spectroscopically pure iron oxide fired in air at 1,300° C. for 15 hr.; incident polarized light: *a*, untreated; *b*, treated with ultrasonic waves before pressing and firing

Giant grain growth has not been observed in 'as-received' semi-spectroscopically pure iron oxide at temperatures up to 1,400° C., nor in the oxide slurried and dried without ultrasonic treatment.

Four possible explanations can be suggested. The first is that some impurity has been introduced during the ultrasonic treatment. The addition of 0·2 per cent titania to alumina causes giant grain growth[1], probably due to the formation of a eutectic melting below the firing temperature and assisting secondary crystallization. Spectroscopic analysis of semi-spectroscopically pure iron oxide gave: calcium, sodium $\leqslant$ 0·1 per cent; silicon $<$ 0·05 per cent; chromium, manganese, aluminium, titanium, lead, each $<$ 0·02 per cent; nickel, copper, tin, each $<$ 0·01 per cent; molybdenum $<$ 0·005 per cent. No difference could be detected between the untreated and the treated material.

Two other explanations, that grain-growth is due to improved crystallite orientation, or to cleaning of the grain surfaces, are not easily evaluated. Cavitation will clean and probably de-gas the surface of a solid, will de-gas a liquid and produce very localized high temperatures. Chemical effects in aerated distilled water include the formation of traces of hydrogen peroxide. The iron oxide surface may be chemically modified, increasing the number of carriers (Fig. 1, *c*). Increased conductivity may also be due to the elimination of grain boundaries.

Finally, excessive growth might be attributed to a change in particle-size distribution. The fines in the slurry settle more slowly after ultrasonic treatment. Although ultrasonic waves in the 20 kc./s. range will de-laminate graphite and mica[2], it seems unlikely that comminution occurs at these wave-lengths. The fines probably result from the dispersion of agglomerates. Giant grain growth occurs in beryllia if the starting material has a wide particle-size distribution[3], though other factors are important[4]. Giant grain growth in iron oxide may be due to separation and dispersion of the fines throughout the material: it is observed in a temperature-range where grain growth becomes visible and where dissociation is incipient. Fine particles will be thermodynamically less stable at these temperatures and their resistance to re-orientation by an advancing grain boundary may be correspondingly reduced.

This work forms part of the research programme of Warren Spring Laboratory and is published by permission of the director.

We are greatly indebted to Mr. Owen-Roberts of Mullards, Ltd., for providing facilities for ultrasonic irradiation and for his helpful discussion ; and to Mr. L. D. Muller of Warren Spring Laboratory for preparing the sections.

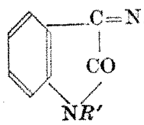
DERIVATIVES OF ISATIN BETA-THIOSEMICARBAZONE WITH ANTI-VIRAL CHEMOTHERAPEUTIC ACTIVITY AGAINST ECTROMELIA INFECTION

By DR. D. J. BAUER and DR. P. W. SADLER

Wellcome Laboratories of Tropical Medicine and the Middlesex Hospital, London

THE anti-viral chemotherapeutic activity of isatin β-thiosemicarbazone (I) in mice infected intracerebrally with neurovaccinia virus was investigated by Bauer[1], who found that mice infected with 100,000 *LD*50 of neurovaccinia virus could be protected against death by the repeated subcutaneous administration of the compound in doses of 2 mgm. Bock[2] also studied the effect of isatin β-thiosemicarbazone in mice infected intracerebrally with vaccinia, and made the additional observation that the compound had no antiviral effect in mice infected with ectromelia. In view of the close antigenic relationship between the two viruses, this finding was very surprising, and cast the first doubt on the generally held view that an anti-viral compound would have to act by selectively affecting some host-cell system which was required for the multiplication of the virus. The observed fact that isatin β-thiosemicarbazone is active against vaccinia but not against ectromelia suggests that it is acting against the virus rather than against the host cell, which is the same in both infections. The force of this argument is not essentially reduced by the subsequent observation of Sheffield, Bauer and Stephenson[3] that isatin β-thiosemicarbazone is active against ectromelia virus in tissue culture, since the activity was very low and at the very limit of detectability. Bauer and Sadler[4] tested 19 derivatives of isatin β-thiosemicarbazone and related compounds for activity against ectromelia in mice, but none showed any evidence of activity. It is therefore of considerable interest that further work on the modification of the molecule of isatin β-thiosemicarbazone has now revealed a series of derivatives with high activity against ectromelia infection, and with little or no activity against vaccinia.



(I)

The compounds so far found to possess anti-ectromelia activity are all 4′ : 4′-dialkylthiosemicarbazones of isatin, N-methylisatin or N-ethylisatin. Dimethyl-, diethyl- and dibutyl-thiocarbamylthioglycollic acids were obtained by Jensen's method[5]. These, when heated in aqueous alkaline solution under reflux with excess hydrazine hydrate, produced the corresponding 4 : 4-dialkylthiosemicarbazides. The dibutyl compound, which is an oil, was converted to the hydrochloride by passing dry hydrogen chloride through its benzene solution. The 4′ : 4′-dialkylthiosemicarbazones (Table 1) were prepared by heating under reflux equimolar quantities of the isatin and reagent in ethanolic solution. In the case of the dibutyl derivatives, 50 per cent aqueous ethanol was used with the addition of one equivalent of sodium acetate. The melting points and analytical results for the 4′ : 4′-dialkylthiosemicarbazones are shown in Table 1.

Table 1. ANALYTICAL RESULTS FOR 4′: 4′-DIALKYLISATIN β-THIOSEMICARBAZONES

R	*R′*	Melting point (°C)	Formula	Required percentages C	H	S	Found percentages C	H	S

The tests of anti-viral activity were carried out by two methods. In the first method, serial decimal dilutions of ectromelia virus (Sandom strain of pseudolymphocytic choriomeningitis virus) in the form of a suspension of infected mouse brain were inoculated intracerebrally or intraperitoneally in parallel in two series of mice of uniform weight, two groups of 6 mice being infected with each dilution; one series was treated with the compound under investigation and the other served as a control. The compound selected for test was inoculated subcutaneously twice daily for 5 days, the first dose being given some hours after infection. The mice were observed over a period of 14 days and the deaths were recorded. The results of five typical tests are given in Table 2. Isatin β-4′ : 4′-dimethylthiosemicarbazone (I; $R = CH_3$, $R' = H$) confers a significant degree of protection in mice infected with 100 *LD*50 of virus intracerebrally, and N-methylisatin β-4′ : 4′-dimethylthiosemicarbazone (I; $R = CH_3$, $R' = CH_3$) confers some protection against 1,000 *LD*50. With intraperitoneal infection the results were less regular, but the first compound nevertheless gave some protection against 1,000 – 10,000 *LD*50, and the second against 1,000 *LD*50. In the tests described so far the compounds were given at dose-levels of 25 and 50 mgm./kgm., but an antiviral effect was still

Table 2. EFFECT OF ISATIN AND N-METHYLISATIN 4′: 4′-DIMETHYL THIOSEMICARBAZONES IN MICE INFECTED WITH ECTROMELIA VIRUS

Compound	Dose of compound (mgm./kgm.)	Route of infection	Dose of virus (*LD*50)	Treated	Control
Isatin β-4′: 4′-dimethylthiosemicarbazone	25	Intracerebrally	1,000	6/6	6/6
			100	3/6	6/6
			10	0/5	6/6
			1	0/6	3/6
	25	Intraperitoneally	10,000	2/5	6/6
			1,000	5/6	6/6
			100	5/6	6/6
			10	0/6	5/5
N-methylisatin β-4′ : 4′-dimethylthiosemicarbazone	50	Intracerebrally	1,000	3/5	6/6
			100	1/5	6/6
			10	0/5	6/6
			1	0/5	3/6
	50	Intraperitoneally	1,000	0/6	12/12
	25		1,000	3/6	12/12
	12·5		1,000	4/6	12/12

Numerator, number of mice dying; denominator, number in group.

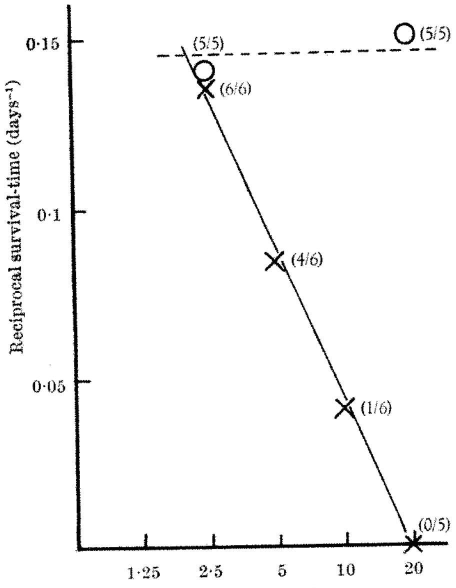

Fig. 1. Dose-response curve of antiviral chemotherapeutic effect of isatin β-4′ : 4′-diethylthiosemicarbazone in mice infected intracerebrally with 100 *LD*50 of ectromelia virus
○, control; ×, treated. Numerator, number of mice dying; denominator, number of mice in group

observed with the N-methyl derivative at a dose-level of 12·5 mgm./kgm. as shown in the last test of Table 2.

In tests carried out by the second method, six groups of mice of uniform weight were inoculated intracerebrally with about 100 *LD*50 of ectromelia virus; the first and last groups were left untreated as controls and the remaining groups were treated with the test compound in doses increasing by multiples of 2 given subcutaneously twice daily for 5 days. The animals were examined for 14 days; the times of death were recorded to the nearest half-day and converted to reciprocals and the mean reciprocal survival-time for each group was plotted against the dose on a $\log_2$ scale. A result obtained with isatin β-4′ : 4′-diethylthiosemicarbazone (I; $R = C_2H_5$, $R' = H$) is shown in Fig. 1. The dotted line represents the mean response (reciprocal survival-time) obtained in the two control groups, and the continuous line has been fitted to the combined responses of the treated mice by the method of least squares. The responses do not differ significantly from linearity, and the anti-viral action of the compound can thus be represented by a linear dose-response curve, with complete protection against 100 *LD*50 of virus at a dose-level of 20 mgm./kgm., as represented by a reciprocal survival-time of zero.

In further tests carried out by one or both methods, marked activity against intracerebral or intraperitoneal infection with ectromelia virus was also found with isatin β-4′ : 4′-dibutylthiosemicarbazone (I; $R = C_4H_9$, $R' = H$), N-methylisatin β-4′ : 4′-diethylthiosemicarbazone (I; $R = C_2H_5$, $R' = CH_3$), N-methylisatin β-4′ : 4′-dibutylthiosemicarbazone (I; $R = C_4H_9$, $R' = CH_3$), and the three corresponding N-ethyl derivatives (I; $R = CH_3$, C_2H_5 or C_4H_9, $R' = C_2H_5$). Anti-viral activity of the same extent was also found in similar experiments with the Hampstead and Moscow strains of ectromelia virus. The compounds so far described had little or no activity against vaccinia infection in tests carried out by the same method.

The discovery of high activity against ectromelia in compounds of this type thus significantly extends the spectrum of anti-viral action of the isatin β-thiosemicarbazone derivatives, and gives reason for supposing that further modifications may lead to the acquisition of activity against other viruses.

NEURAMINIDASE IN THE CHORIOALLANTOIS OF THE CHICK EMBRYO

By Dr. G. L. ADA and Dr. PATRICIA E. LIND
Walter and Eliza Hall Institute of Medical Research, Melbourne

IN 1941, Hirst[1] and McClelland and Hare[1] described hæmagglutination by influenza virus. The enzymic nature of this reaction was first suggested by Hirst[2], who showed that following agglutination of red cells, the virus eluted spontaneously, leaving the cells inagglutinable by the same strain of virus; the liberated virus could agglutinate fresh red cells. Following the discovery that other viruses (including mumps and Newcastle disease) had similar activity, Burnet, McCrea and Stone[3] found that cells from which one strain of myxovirus had eluted were still agglutinable by certain other strains; the arrangement of virus strains in the order of their progressive action on cellular receptors was termed the 'receptor gradient'. In 1946, Burnet, McCrea and Stone[3] discovered in filtrates of *Vibrio cholerae*, a soluble factor, the receptor-destroying enzyme[4], which rendered red cells inagglutinable by myxovirus: the progressive action of this enzyme destroyed the agglutinability of the cells for different virus strains in a characteristic sequence—the receptor-destroying enzyme receptor gradient—and this differed in some respects from that of myxoviruses. Both viral and bacterial enzymes are now called neuraminidase[5] or sialidase[6], as their action has been identified as the hydrolytic cleavage of the glycosidic bond joining the keto group of sialic acid to D-galactose or D-galactosamine[5].

Myxoviruses are commonly grown in cells present in the chorioallantoic membrane (hereafter referred to as membrane) of chick embryos 10–12 days old. A previous attempt using biological methods to show the presence of neuraminidase activity in normal membrane was unsuccessful[7]. In this article we report the presence of neuraminidase activity in such extracts. The enzyme has been partially purified and concentrated, and its activity is described in biological and chemical terms. The possible relationship between this enzyme and the myxovirus enzyme is discussed.

Detection of the enzyme. The enzyme was detected by incubation of a sterile brei of membranes from 12-day-old embryos with excess sialyl lactose, a substrate of neuraminidase. The mixture was incubated (20 hr., 37° C., *p*H 5·7), samples taken at intervals and the amount of split product determined by the Warren test[8]. At a concentration of 1 mgm./ml. of sialyl lactose, the rate of release of split product, estimated as N-acetylneuraminic acid, was about 1·5 μgm./ml./hr.; the rate of action decreased slowly over the 20 hr. period. This activity was shown to be present in extracts heated to 56° for 30 min., but absent in extracts heated at 80° C. for 15 min.

Age of the membranes. The neuraminidase activity was found to vary with the age of the embryos from which the membrane was obtained. In one experiment, membranes from 8, 10, 12, 15, 18 and 19 day embryos (3 membranes of each group) were collected and ground with powdered 'Alundum' into *tris*-maleate buffer (0·1 *M*, *p*H 5·7, 2 ml./membrane). After clarification, the enzymic activity of each extract was determined (Table 1). In another experiment, twelve membranes from 19-day-old embryos were collected and extracted separately. All showed high levels of enzymic activity although the values showed considerable spread as would be expected. (Rate of release of N-acetylneuraminic acid (μgm./ml./hr.) = 18 ± 3·8 *S.D.*; average protein concentration = 4·0 mgm./ml.). Membranes of 19-day embryos from two different poultry farms showed similar high levels.

Table 1. Liberation of Split Product estimated as N-acetylneuraminic Acid (N-ANA) from Sialyl Lactose (1 mgm./ml.) by Extracts of Avian Chorioallantoic Membrane

The reaction mixtures were incubated at 37° C. for 4½ hr. Protein was estimated by the method of Lowry *et al.* (ref. 24)

Age of embryo (days)	Protein concentration of extract (mgm./ml.)	Release of N-ANA (μgm./ml./hr.)
8	3·1	< 1·0
10	2·7	< 1·0
12	4·0	1·2
15	3·5	2·8
18	5·1	16·1
19	4·5	19·0

Addition of a membrane extract from 10-day-old embryos to a membrane extract from 19-day-old embryos did not significantly depress the enzymic activity of the latter. Membrane extracts from both 11- and 18-day-old embryos were found to contain approximately similar amounts of N-acetylneuraminic acid–aldolase, the enzyme which splits N-acetylneuraminic acid to N-acetylmannosamine and pyruvate[9]. The amount present was not sufficient to interfere seriously with the estimation of neuraminidase at pH values of 5·7 or lower.

Bacterial sterility of membranes and extracts. To eliminate the possibility that bacterial contamination of membrane or extract was responsible for the enzymic activity, four membranes from 19-day embryos were ground with 'Alundum' under aseptic conditions, clarified and enzyme assays carried out on each extract (37° C., 2 hr.; no antibiotics added). Each extract showed a high enzymic activity. Samples of the extracts before clarification and after the assay procedure were tested for aerobic and anaerobic bacteria, for fungi and for pleuropneumonia-like organisms. No growth of any organisms was detected over a period of 2 weeks incubation. In most work penicillin (100 units/ml.) and streptomycin (50 units/ml.) were included in the reaction media.

Concentration and purification of the enzyme. Membranes from 250 embryos (19 days old) were ground with 'Alundum' and the mixture extracted with *tris*-maleate buffer (pH 5·7, 0·1 M). The mixture was centrifuged and to the supernatant (about 1 litre) was added calcium chloride to a final concentration of 0·1 per cent (w/v). The solution was heated (56° C., 30 min.), centrifuged (70,000g, 10 min.) and ammonium sulphate added to the supernatant to a final concentration of 60 per cent (w/v). After standing (0° C., 16 hr.), the suspension was centrifuged (70,000g, 10 min.), and the precipitate dissolved in and dialysed against potassium phosphate buffer (0·1 M, pH 6·8). The solution was clarified by addition of protamine sulphate (0·3 gm.) and chromatographed on a column of hydroxyl apatite[10] (gradient 0·1 M – 2·0 M phosphate buffer, pH 6·8). The enzymically active fractions were pooled and concentrated to about 5 ml. The enzyme was purified about 50-fold in this way and was suitable for the tests described below.

Properties of the membrane neuraminidase. Action on sialyl lactose. Purified enzyme (0·5 ml.) was incubated with 10 mgm. of sialyl lactose (37° C., 16 hr.). The identity of the split products was established as follows. In the Warren test, the absorption spectrum (500–600 mμ) of the chromophore derived from the enzyme substrate mixture was identical with that given by crystalline N-acetylneuraminic acid. Following paper chromatography in butanol/pyridine/water (6 : 4 : 3), three spots corresponding in R_F to sialyl lactose, N-acetylneuraminic acid and lactose were observed. In these experiments, more than 50 per cent of the sialyl lactose was split. The pH of optimum activity was about 4·5. The rate of action of the membrane enzyme was unaffected by 0·01 M ethylenediamine tetraacetate. K_m at pH 4·4 was about 1×10^{-3} M.

Action on ovine submaxillary gland mucin. Ovine submaxillary gland mucin was dissolved in the purified enzyme to a final concentration of 0·15 per cent (w/v) and the solution incubated (37° C., 16 hr.). Samples taken before and after incubation showed that (1) more than 60 per cent of the bound N-acetylneuraminic acid was liberated from the ovine submaxillary gland mucin. (2) The capacity of the treated ovine submaxillary gland mucin to inhibit hæmagglutination by heated *WSE* virus[12] was abolished (inhibitory titre reduced from $1{\cdot}56 \times 10^5$ to < 50).

Action on fowl red cells. The agglutinability of the fowl red cells for the different strains of myxovirus was removed in the order shown in Table 2. This receptor gradient was not the same as that given by neuraminidase from *V. cholerae* determined under the same conditions. It is also different in several respects from the receptor gradient established by enzymic treatment of red cells with myxoviruses[3]. It is difficult, however, to obtain a satisfactory gradient following viral action when the technique used in the present work is adopted, so the virus results are not fully comparable to those obtained with soluble neuraminidases.

Table 2. Receptor Gradient of Fowl Red Cells treated either with Neuraminidase from the Chorioallantois of the Chick Embryo or with Neuraminidase from *V. cholerae*

Source of neuraminidase	Receptor gradient					
Membrane	*MEL*	*NDV*	$\frac{Mu}{WSE}$	*LEE*	*MIL*	
V. cholerae	*MEL*	*WSE*	*NDV*	*LEE*	*Mu*	*MIL*

Serial two-fold dilutions of the purified enzyme and the crude enzyme from *V. cholerae* were allowed to act at pH 6·2 on 0·05 ml. amounts of washed packed red cells. The cells were then washed thrice with saline and their reaction to different strains of myxovirus tested (ref. 13).

Discussion

The results show that the chorioallantois of the chick embryo contains an enzyme which, in many respects, behaves like bacterial and viral neuraminidases. Thus the membrane enzyme splits both sialyl lactose where the carbon atom 2 of N-acetylneuraminic acid is linked (α) to carbon atom 3 of galactose and also ovine submaxillary gland mucin where the carbon atom 2 of N-acetylneuraminic acid is linked (α) to carbon atom 6 of N-acetylgalactosamine[14]; it also abolishes the capacity of ovine submaxillary gland mucin to inhibit hæmagglutination by heated influenza virus (although it has not been formally excluded that this may be due to a contaminating protease[15]) and destroys receptors of red cells for viral hæmagglutination. In contrast to the neuraminidase from *V. cholerae*, the activity of both the membrane and viral neuraminidases are unaffected by ethylenediamine tetraacetate[16].

We have been very much aware of the possible objection that the neuraminidase discovered in the membrane is of bacterial origin. It should be pointed out that the enzyme content of unconcentrated extracts of membranes from 19-day-old embryos is equivalent to about 400 biological units/ml. of bacterial (*V. cholerae*) neuraminidase[17]. Heavy growth of an organism such as *V. cholerae* would be required to yield this amount of neuraminidase. Careful bacteriological examination failed to detect any micro-organisms in the membranes or in the incubated extracts. We have not tested for latent viruses, but, for several reasons, this seems a very unlikely possibility.

The chief interest of this report is the finding for the first time of neuraminidase in vertebrate tissues. The possibility that it is present in all or most warm-blooded vertebrate cells cannot be excluded. One aspect which may be functionally significant is the demonstration that, as the fertile egg progresses to the stage where hatching of the embryo will occur, the neuraminidase content of the membrane increases ten- to twenty-fold. There is a suggestion here that the enzyme may play a part in preparing the membrane for its rather sudden loss of function as soon as the chick becomes air-breathing.

The possibility of a relationship between the membrane neuraminidase and the viral enzyme requires some consideration. At present it is reasonable to assume that the membrane enzyme is present in those cells which serve as host cells for the virus. The first question that arises is whether viral enzyme represents a component non-specifically adsorbed to the virus particle. This is most unlikely; the evidence is overwhelmingly in favour of the view that the enzyme is an integral component of the virus itself. Both serological[18] and chemical[19] analyses of purified myxoviruses support the view[20] that certain fractions of the myxovirus particle are very similar to components present in the normal host cell. Is the virus enzyme also in this category? Does virus invasion stimulate a change in cell metabolism which results in greatly increased neuraminidase production—a change that may in some way be analogous to the increase that takes place during the last days of incubation? In developing this suggestion we have to bear in mind: (*a*) that the enzymic activity of different myxoviruses shows a wide range of quantitative and qualitative differences; (*b*) that according to most authors the viral enzyme is related to the protein surface antigen *V*. To accommodate these findings, our hypothesis could take the form that the specific enzyme structure is determined by genetic information provided by the host but that this is incorporated into the virus under the influence of the virus genome, either during the intracellular synthetic process or during emergence from the host cell surface. If the specificity of the viral enzyme were of host origin this would help to explain why the myxovirus particle contains such a small proportion of ribonucleic acid[21]—an amount per virus particle of the same order as that present in much smaller viruses such as poliomyelitis[22], and presumably containing an equally limited amount of genetic information.

The present work does not, of course, exclude the possibility that the viral enzyme is as fully determined by the viral genome as any other component of the virus. It does, however, raise an important alternative. To choose between them will become easier if neuraminidases from the membrane and from representative myxoviruses are obtained in such a form as will allow a valid comparison of their physical, enzymological and serological properties.

While this work was in progress, Warren and Spearing[23] reported the presence of neuraminidase in commercial preparations of bovine and human serum glycoprotein. The enzyme was not detected in unprocessed plasma or serum. Their enzyme is stimulated by calcium ions and inhibited by ethylenediamine tetraacetate, so is different from the factor described in this report.

We are grateful to Sir Macfarlane Burnet for helpful discussions and to Dr. E. L. French, who carried out many bacteriological examinations for us. The work was supported by a grant from the National Health and Medical Research Council, Canberra, Australia.

MECHANISM OF THE TRANSFORMATION OF THE POLYSACCHARIDE CAPSULE IN PNEUMOCOCCUS

By Dr. D. M. KOHOUTOVÁ

Institute of Biology, Czechoslovak Academy of Science, Prague 6

AFTER an interval of more than a year in the transformation of the heterologous polysaccharide capsule I found that the *R* form, which was obtained in our laboratory in 1957, and which prior to this had been very easily transformable into the encapsulated form of the type III pneumococcus with the aid of the transforming principle isolated from the same by use of the transforming medium in the presence of salts with univalent cations[1–3], is now not easily transformable when using similar conditions as before. Either it does not transform at all and remains in the *R* form, or changes more or less massively into the encapsulated form of type II, that is, into the original parental strain. Only very rarely, and no longer under control or to a very small extent, if at all, is it transformed into the encapsulated form of pneumococcus of type III with the aid of the transforming principle isolated from this strain.

Ravin[4], using the strain *R36A* obtained originally in the laboratory by Avery *et al.* and successfully transformed in other laboratories[5,6] into various capsular states, found that the factor for antibiotic resistance was still transferable but not the capsular factor. I am of the opinion that the strain *R36A* may possess a gross deletion at one or more capsule-influencing loci.

Now the question arose whether in the course of preservation my *R* strain did not change to such a degree that it is unable to accept the transforming principle and to incorporate the relevant segment of deoxyribonucleic acid (DNA) into its genome or whether it had not been changed in another sense; on the other hand, whether my transforming principle had not been damaged (for example, by deoxyribonuclease) even though the isolation was always carried out in citrate medium and using all necessary precautions for the maintenance of its biological activity[7]. If this were the case, the damaged transforming principle would not function as a carrier of genetic information, that is, of information for the synthesis of the polysaccharide capsule of type III, but having been damaged would serve rather by its breakdown products to stimulate the synthesis of a non-specific DNA and thus also of a non-specific polysaccharide capsule in the recipient cell, in this case of type II.

I have in mind a similar effect to that described by Firshein and Braun[8], where the DNA, partly digested by enzyme and its products of cleavage, stimulates selectively the synthesis of the DNA in the *S* cells, in a mixture where there is a preponderance of *R* cells over *S* cells.

I examined first my *R* form, which had been originally fully avirulent, and found that, by testing in a solid medium or in glucose blood broth, the *R* form is not changed, but that in a selective medium, for example, in broth with anti-*R* serum, it is possible to intercept sporadically the maternal *S* form of type II both after 72 hr. of growth and *in vivo* when infecting mice.

The transforming principle was also checked. I investigated whether mild lesions of the polymeric molecule of the principle, due to small doses of deoxyribonuclease, would not result rather in a non-specific stimulation of the synthesis of the polysaccharide capsule of type II than in an induction of the synthesis of type III. I used a transforming principle (crude extracts of the DNA with 11 deproteinizations[7]) with a content of 2 μgm. DNA in 0·025 M veronal buffer *p*H 7·5 per 1 ml. of the medium and of deoxyribonuclease in a magnesium sulphate solution of a final concentration of 0·003 M. The transformation test was carried out either in the presence of sodium citrate of a final concentration of 0·01 M[9] or without it. The mixture of transforming principle and deoxyribonuclease with the citrate as well as without it had been activated for 15 min. at 30° C. and inactivated for 15 min. at 60° C. The control with the same content and with citrate in the medium had been neither activated nor inactivated. It was surprising to find that in the presence of deoxyribonuclease with a content of approximately 0·01 μgm./1 ml. of the medium and with a lower content (10^{-4}–10^{-5} μgm.) in the presence of citrate and in test-tubes, where the activation and inactivation had been carried out in the stated time-intervals, transformation of the *R* form into the *S* form of type III occurs regularly.

It is evident from Table 1 that the citrate added alone to the transforming medium inhibits the growth of the pneumococci and the test-tubes remain sterile. Among all variations of arrangements of components newly introduced into the transforming medium, transformation occurs solely in the presence of deoxyribonuclease in the concentrations already given in the presence of citrate and only when the mixture of the transforming principle and the deoxyribonuclease had been activated and inactivated, or only inactivated. If the deoxyribonuclease is left in the medium without inactivation in the presence of citrate, it prevents the transforming reaction.

Table 1. EFFECT OF THE COMPONENTS ADDED TO THE TRANSFORMING MEDIUM

(Composition of the medium (ref. 2): beef heart infusion, 1 per cent neopeptone (Difco), 0·5 per cent sodium chloride, potassium chloride, 1·5 × 10^{-4} M, 10 per cent anti-*R* serum), *p*H 7·6–7 8

TP	*R* rarely *S* III
TP activ. and inactiv.	*R*
TP + $MgSO_4$	*R*
TP + citrate	0
TP + $MgSO_4$ + citrate	*R*
TP + $MgSO_4$ + citrate + DNase	*R*
TP + $MgSO_4$ + citrate + DNase activ.	*R*
TP + $MgSO_4$ + citrate + DNase inactiv.	*S* III
TP + $MgSO_4$ + citrate + DNase activ. and inactiv.	*S* III
TP + $MgSO_4$ 3 × 10^{-5} M + DNase + citrate activ. and inactiv.	*R*
DNA + $MgSO_4$ + DNase + citrate 10^{-4} M activ. and inactiv.	*R*
DNA + $MgSO_4$ 3 × 10^{-5} + DNase + citrate 10^{-4} M activ. and inactiv.	*R*

$MgSO_4$ in the final concentration 0·003 M; sodium citrate in the final concentration 0·01 M; transforming principle (TP) (2 μgm. DNA/ml.) in veronal buffer 0·025 M, *p*H 7·5, if DNase is present, otherwise in physiological solution; deoxyribonuclease (Light, and Hungarian lyophil.) in a concentration from 10^{-2} to 10^{-5} μgm./ml. of the medium. The transformation was carried out in 2–3 control series with 1,000–3,000 cells of the recipient *R* cultures and the results read off after 16–96 hr. of growth in a liquid medium by sub-culturing twice daily on to glucose blood agar twice from each test-tube. The macroscopic identification was confirmed by agglutination with a homologous immune serum.

R, non-encapsulated form of the pneumococcus; *S* III, encapsulated form of the type III pneumococcus; 0, sterile growth.

The question has been posed whether a similar mechanism, that is, the mutual interaction of the DNA and the deoxyribonuclease with the participation of the blocking system, acts also normally in the processes of transformation. The problem of the penetration of the DNA as a high polymeric molecule into the cell still remains unknown. In experiments with newly isolated 9 new *R* strains, of which 12 single-colony cultures were chosen for the experiment, it was found that both the stable and the unstable strains are liable to transformation into the heterologous type, and that out of the twelve single-colony *R* cultures examined only 4 were transformed without deoxyribonuclease; the remainder only when it was present. As the experiments were carried out with two transforming principles obtained from the isolation of the same culture of the pneumococcus of type III, differing from each other only in age by 3 hr. (6 and 9 hr. culture) it was ascertained that it was possible to transform without deoxyribonuclease the newly gained strains only when the principle isolated from the younger culture was used.

It is evident from the experiment that the process of transformation of the heterologous polysaccharide capsule is by no means simple. There exist mutual interactions between the physiological state of the recipient cell and the biological activity of the transforming principle, certainly depending on the ucture of the DNA, which depends again on the ysiological state of the cells from which the transorming principle had been isolated. It is possible that the deoxyribonuclease which those who work with pneumococci have always strived to eliminate by using only a small number of recipient cells, to avoid the depolymerization of the DNA by the deoxyribonuclease which is liberated by those cells, plays an active part in the transformation, even though the deoxyribonuclease in minimal concentration, acting only within a certain time-span, is blocked moreover by citrate (or another blocking system). Details of this work will be published in *Folia Microbiologica*.

PROTEINS OF HEN'S EGG YOLK

IN a recent communication on the proteins of the plasma and egg yolk of the hen, Schjeide and Urist[1] remark that much confusion exists in "the nomenclature, chemical constitution and physical orientation" of these proteins. As the portion of their analysis dealing with current knowledge of the yolk proteins is limited in scope and somewhat speculative, another view of the biochemistry of yolk proteins is offered here. While this article is based largely on experience in this Laboratory, I do not regard these findings as absolute and irrefutable facts; but the criticisms of this work implicit in the article by Schjeide and Urist do not suggest to me any radical revision of our views.

Fevold's[2] review of ten years ago provides an adequate reference to earlier investigations. At that time, four proteins had been isolated from egg yolk, although it was recognized that none of these had been shown to be homogeneous by modern criteria. Recently, Schjeide and Urist[3] detected, by ultracentrifugation, both a floating and a sedimenting component in the fluid portion of egg yolk and two more sedimenting components in a solution of the solid granules. The nomenclature used infers that these components differ from the known fractions of egg yolk, although most of their distinguishing properties appear to be the same. Similar flotation patterns of the low-density fraction (about 90 per cent lipid) have been published[4], and this fraction has been shown[5,6] to yield lipovitellenin (about 40 per cent lipid) on ether extraction. They[3] called the sedimenting component in the fluid fraction 'ovalbumin' and defined it as "one of the components of livetin", a statement that does little to clarify nomenclature, but quite correctly suggests that there is more than one livetin. In the granule fraction their phosphoprotein X_1 is said, indirectly, to be an impure form of Mecham and Olcott's[7] phosvitin (containing 9·7 per cent phosphorus) and that their lipoglycoprotein X_2 "seems to be synonymous with" the α-lipovitellin of Sugano[8], or lipovitellin. Evidently Schjeide and Urist have detected four ultracentrifugal components corresponding to the four proteins previously isolated and described by other workers. This is in general agreement with earlier reports[4,9] which, depending on the conditions employed, indicate the resolution of three to five ultracentrifugal components in solutions of egg yolk.

The ultracentrifuge, however, cannot resolve all the yolk proteins shown to be present in substantial proportions by electrophoretic analysis. Sugano's[8] patterns suggest at least five components in ether-extracted egg yolk, and Bernardi and Cook[10] identified six in the sedimenting material from which the floating fraction, containing lipovitellenin (β-lipovitellin of Sugano), had been removed. These components have all been isolated and characterized[7,10–15] as to molecular weight, N-terminal amino-acids, as shown in Table 1; and some by amino-acid composition or other properties. Clearly, seven proteins are present in egg yolk, and there are indications that some of these are not homogeneous. Consequently, one or more of Schjeide and Urist's four ultracentrifugal components must have contained more than one protein.

The procedures developed in this Laboratory for the isolation of these proteins (Table 1) are typical of widely used biochemical techniques. The usual precautions were taken at all stages with respect to temperature and other conditions. Naturally, some of the steps must be repeated to obtain homogeneous preparations, and some may be omitted; for example, the chromatographic procedure can be used directly to obtain certain proteins. Schjeide and Urist[1,3] term these 'chemical' procedures and state that it is 'obvious' that at least phosvitin so obtained is a derived protein that loses most of its calcium, often part of its phosphorus, and may even be derived from breaking the 'phosphoprotein backbone'. In support of these statements they point to the lower sedimentation coefficient of our isolated preparations. Phosvitin is a polyelectrolyte that occurs in egg yolk as an insoluble salt, which is converted partly to the sodium salt with a loss of calcium when dissolved in sodium chloride solutions, the commonly used solvent also employed by Schjeide and Urist for their sedimentation experiments. They have not demonstrated the loss of phosphorus but rather the reverse, since they state[1] that their X_1 phosphoprotein and phosvitin, prepared according to Joubert and Cook[11], had the same phosphoserine content. Later they say that both phosvitin and lipovitellin are 'known' to be altered to a greater extent than other proteins isolated from physiological fluids, regardless of the method employed for their isolation. This may be so; but, as no evidence is presented to support this generalization, the reader must decide *quaecumque vera*.

With a knowledge of the N-terminal amino-acids of the several proteins[15,16], the protein phosphorus content of α- and β-lipovitellin (Burley, R. W., and Cook, W. H., unpublished work) (Table 1), and further physical determinations[10,14], it has been possible to estimate the composition of the ultracentrifugal components in solutions of the high-density fraction of egg yolk. Clearly, six proteins are present in this

Table 1. PREPARATIVE PROCEDURES AND PROPERTIES OF EGG YOLK PROTEINS

Preparative procedures Egg yolk dissolved in 0·45 *M* magnesium sulphate; centrifuged at high speed	Designation	Characteristic properties				Refs.
		$M \times 10^{-4}$	Principal N-terminal amino-acids	Lipid content (per cent)	Protein phosphorus content (per cent)

fraction, although they sediment as only two major components (S_1 and S_2) in 5 per cent sodium chloride. The faster sedimenting S_1 component is a complex of α- and β-lipovitellin with phosvitin, plus an aggregated form of γ-livetin, a protein which has been isolated and described[13], but which is not resolved from this complex by ultracentrifugation in 5 per cent sodium chloride. After precipitation by dilution, the S_2 component is absent and other analyses show that α-, β- and γ-livetin and part of the phosvitin are removed. Evidently γ-livetin does not interact strongly with the lipovitellins, as originally suggested[9]. The original S_1 component obviously contains phosvitin, since its protein phosphorus content approaches 2 per cent, and is only reduced to about 1 per cent after repeated precipitation from 5 per cent sodium chloride by dilution, a result in agreement with the protein phosphorus content reported by earlier workers who used this method[17]. Since this is twice the phosphorus content of the mixed lipovitellins prepared from magnesium sulphate solutions[9], or by chromatography (Table 1), this complex, which sediments as one component, must contain about 5 per cent phosvitin of 10 per cent phosphorus content. In fact, the protein phosphorus contents reported[14] for isolated α- and β-lipovitellin are now known to be high owing to the difficulty of removing phosvitin from lipovitellin by hydroxyapatite chromatography, and more accurate values are reported (Burley, R. W., and Cook, W. H., unpublished work) in Table 1. Schjeide and Urist[1] state "that no significant amount" of phosvitin is complexed with lipovitellin. A complex containing 5 per cent phosvitin is not likely to be detected by sedimentation, but this amount is highly significant analytically. These authors do not report the results on which their conclusion is based, but it seems doubtful that the partition-cell procedure would yield their X_2 (lipovitellin) free of X_1 (phosvitin).

In alkaline solvents a third component of about 7 *S* (not 4–5 *S*) appears in the high-density fraction and increases in amount as the *p*H is increased. At *p*H 7·6 (pattern reproduced as Fig. 2 by Schjeide and Urist), this component is predominantly a non-aggregated form of γ-livetin[14]. At higher *p*H values a second component of about 7 *S* also appears in lipovitellin solutions now known to be free of phosvitin and γ-livetin by protein phosphorus and end-group analyses. We have also used the method of Schmidt, Bessman, Hickey, and Thannhauser[18] employed by Schjeide and Urist for isolating the yolk granules, and found that the three livetins are absent from solutions of the granule proteins. Without the livetins, phosvitin and the lipovitellins are clearly evident as two components in neutral solvents, but in alkaline solvents a third component of about 7 *S* is also present.

Clearly, the additional ultracentrifugal component observed in alkaline lipovitellin solutions is not γ-livetin. Before the present criteria were available, we erroneously called this 7 *S* component γ-livetin, since it had a similar sedimentation-rate, was reduced in amount by repeated precipitation[9], and had a type of dependence on *p*H suggesting that lipovitellin contained two distinct proteins. Moolenaar[19] also observed this second component in lipovitellin at *p*H 7·8 or higher and correctly called it a sub-unit of lipovitellin. The identity of this 7 *S* component was clarified by the work of Bernardi and Cook[10,14,20], who found that lipovitellin had two electrophoretic components, α- and β-, separated them by chromatography, and established that both forms dissociate reversibly into two sub-units in alkaline solvents. Both lipovitellins behave as *p*H-dependent reversible association-dissociation systems, but β-lipovitellin dissociates at a lower *p*H than α-lipovitellin. These findings explain our earlier observations indicating that lipovitellin contained two proteins.

I cannot reconcile these results with those reported by Schjeide and Urist[1]. They claim discovery of an alkaline breakdown product of lipovitellin of 4–5 *S* and suggest this may be the second component called γ-livetin by Joubert and Cook[9]. Evidently they have observed the second component reported earlier[9,19], and correctly identified by Moolenaar[19]; but they do not describe its properties. They do report the isolation of a trailing component which was found to be the natural form of phosvitin containing 10 per cent phosphorus. Clearly, this was not the 7 *S* component observed in alkaline solutions of our phosvitin-free lipovitellin. In fact, it appears that these workers isolated their trailing component from a solution of the granule proteins in 10 per cent sodium chloride, a solvent in which the sub-unit of lipovitellin does not exist. Alternatively, if they did use an alkaline solvent, they should have resolved three components in the granule proteins. Their results appear, therefore, to have no bearing on the identification of the 7 *S* component under discussion.

Since lipovitellin, the classical lipoprotein of egg yolk, has now been fractionated, it is desirable to clarify nomenclature. Although the three fractions that have been characterized are, correctly speaking, lipoglycophosphoproteins, in this Laboratory we have continued to use modifications of the older, simpler names, α- and β-lipovitellin, and lipovitellenin; corresponding names for the three lipid-free protein moieties are provided by omitting the prefix 'lipo'. Our α- and β-lipovitellin are not identical with those so designated by Sugano[8], who used ether-extracted egg yolk and identified his α- and β-components as purified forms of lipovitellin and lipovitellenin, respectively. In our work lipovitellenin was removed by centrifugation and the terms α- and β- used to describe the two electrophoretic components of lipovitellin proper. Our α- and β-forms are not resolved by ultracentrifugation in sodium chloride solutions, but the parent molecules and their dissociated sub-units can be resolved in alkaline solvents. Lipovitellin may therefore occur in at least four forms.

Since the second component in lipovitellin solutions is a dissociated sub-unit and not γ-livetin, the molecular weights observed in sodium chloride solutions are now quite consistent[4,9,14]. Those reported by Joubert and Cook[9,11], however, are subject to correction for a computational error affecting the diffusion coefficient, which increases all those reported by about 15 per cent. The correct values have been published[14]. The phosvitin–lipovitellin complex precipitated from, and examined in, sodium chloride solutions had $M = 4\cdot0 \times 10^5$ by light scattering[4], and $4\cdot1 \times 10^5$ by sedimentation-diffusion[9]. At *p*H 9·0 the presence of 10 per cent or more of the dissociated sub-unit reduced the molecular weight of lipovitellin to $3\cdot7 \times 10^5$ (corrected value), but in sodium chloride solutions both α- and β-lipovitellin had $M = 4\cdot0 \times 10^5$ (Table 1)[14]. Since the lipovitellin–phosvitin complex contains only about 5 per cent phosvitin, its molecular weight would not be expected to differ, beyond experimental error, from that of undissociated lipovitellin.

The molecular weights of X_1 and X_2 proteins are reported by Schjeide and Urist[3] to be $7\cdot7 \times 10^4$ and $2\cdot0 \times 10^5$, respectively, which differ considerably from our values of $3\cdot6 \times 10^4$ and $4\cdot0 \times 10^5$ for phosvitin and lipovitellin. They suggest that our phosvitin was degraded, but do not advance a specific reason for the discrepancy in the estimated size of lipovitellin. An evident explanation is that their X_2 contained X_1, since the latter could not have been completely removed by separation in a partition cell. They found that X_1, X_2 and serum albumin all showed comparable boundary-spreading in the ultracentrifuge, but do not report diffusion coefficients. The molecular weights were evidently calculated from the sedimentation coefficients and the "reasonable assumption" that the X_1 and X_2 proteins have an axial ratio comparable with serum albumin. This assumption, however, is neither reasonable nor adequate for the estimation of molecular weights. It is not reasonable for phosvitin, since the results of Joubert and Cook[11] show that this protein and its soluble complexes with calcium all had frictional ratios far larger than that of serum albumin, and no evidence is presented to show that X_1 differs in this respect. The assumption is inadequate, since this calculation also assumes that both X_1 and X_2 have the same partial specific volume as serum albumin, which is neither in accord with expectation (composition) nor experimental observation[9,11]. These considerations also have a bearing on their conclusions[3] regarding the relative sizes of their X_1 and X_2 proteins in egg yolk and hen plasma.

Dr. Cook's article constitutes an excellent summary of the large amount of work that he and his associates have carried out on the subject of egg yolk proteins, and brings into focus several crucial points where disagreements seem to exist among workers in the field. We shall take these up, but first would like to recapitulate the reasons why we submitted our original communication[1].

Basically, we were concerned with what seemed to be a general failure to recognize that the chemically derived phosvitins and lipovitellins of serum and egg yolk may be considerably different from these proteins as they occur in the native state. Secondly, we wished to explain our reasons for employing the serum and egg yolk X_1–X_2 nomenclature, and wished to caution against use of terms already ascribed to the chemically derived proteins when referring to the 'native proteins' as they might be resolved during gentler procedures of ultracentrifugation, etc. Thirdly, we wished to explain our view that serum X_1-phosphoprotein and serum X_2-lipoglycoprotein do not exist together as complexes in serum and that egg yolk X_1-phosphoprotein and egg yolk X_2-lipoglycoprotein are not present as complexes in 5 per cent sodium chloride at neutral *p*H as suggested by Cook and by Common and co-workers[2]. We wished, further, to make it clear that the reasons for the non-existence of such complexes constitute some of the most important facets of our understanding of the nature and role of those unique proteins adapted to the sustenance of the embryo bird, reptile and amphibian.

In the preceding article Dr. Cook has reopened certain of these issues. For the sake of brevity, we shall mention only a few points on which we still differ:

(*a*) We have not changed our view that both phosvitin and lipovitellin obtained chemically as described by Joubert and Cook in 1958 (ref. 3) differ in certain respects from the ultracentrifugally resolved X_1 and X_2 proteins and are probably (at least in the case of the phosphoprotein) less 'physiological'. (i) Phosvitin definitely lacks most of the calcium which was originally associated with this molecule, and because of its lower sedimentation constant appears to be either (or both) broken or of increased axial ratio. (The loss of calcium, in its simplest terms, would result in only a 5–7 per cent reduction in molecular weight.) (ii) Joubert and Cook[3] have shown that the correct molecular weight for phosvitin is about 36,000. Thus, it appears that phosvitin obtained chemically is at most only half the molecular weight of its counterpart obtained more simply by dissolution of the yolk granules with 10 per cent sodium chloride followed by differential ultracentrifugation. Our estimation of the molecular weight of egg yolk X_1-phosphoprotein (77,000) was based on the premise that the phosphoprotein was as globular in shape as albumin. If a greater axial ratio actually obtains, the molecular weight of X_1-phosphoprotein is even greater than indicated by our original estimate. (iii) With respect to lipovitellin, Joubert and Cook[3] have, themselves, pointed out that, as originally obtained, it was not a pure fraction.

(*b*) Another of the views that has been strictly maintained by Dr. Cook and co-workers is that their faster sedimenting S_1 component of whole egg yolk in 5 per cent sodium chloride (our X_2-lipoglycoprotein) is a complex of the 'alpha' and 'beta' lipovitellins with phosvitin. (i) It has been our experience that the association of phosphoprotein with lipoglycoprotein (as by dilution or change in *p*H in the presence of sodium chloride) results in macro-complexes possessing sedimentation constants considerably in excess of S 10. Even if a complex of only one molecule of phosvitin per molecule of 'alpha' or 'beta' lipovitellin were postulated—such a physical orientation should produce a detectable difference in the rate of sedimentation as compared with phosvitin-free lipovitellin. (ii) Dr. Cook states specifically that "the S_1 [our egg yolk X_2] component obviously contains phosvitin since its protein phosphorus content approaches 2 per cent and is only reduced to about 1 per cent after repeated precipitation from 5 per cent sodium chloride by dilution".

Two misconceptions are evident here: in the first place, the S_1 material (S 10) as present in the preparatory ultracentrifuge tube necessarily contains phosvitin since the S_1 deflexion simply defines the boundary of a molecular species which is sedimenting through a medium containing sodium chloride, phosvitin, etc. The material causing the S_1 deflexion cannot be isolated from the centrifuge tube alone. Only a mixture of this component together with the other materials in the medium through which it is passing can be obtained.

In order to ascertain which component in the centrifuge tube contains phosphorus or calcium (and hence phosvitin) one can proceed indirectly as follows: the mixture of proteins is centrifuged in a partition cell for the preparatory ultracentrifuge[4] and is then partitioned into several vertical sections. Differing amounts of the various proteins in the mixture are present in each section, their concentrations being functions of their rates of sedimentation. The content of each section is ascertained by analytical ultracentrifugation and analysis for protein phosphorus. One can now determine by inspection whether the phosphorus rises in proportion to the deflexion caused by a given protein component. Neither protein phosphorus nor calcium increases detectably when the S_1 (our X_2) component is present in greater concentration in any particular segment[5].

Secondly, our experimental results[5] indicate that the reason the S_1 (our X_2) component is precipitated with dilution is that large complexes form between X_1-phosphoprotein on one hand, and X_2-lipoglycoprotein on the other. Hence, repeated precipitation should not result in complete elimination of phosvitin phosphorus from lipovitellin prepared by the method of dilution.

(iii) The occurrence of a precipitate is apparently due to the many negative charges appearing on the X_1-phosphoprotein (following the removal of calcium by dilution) reacting with positive charges on the X_2-lipoprotein. So long as these two molecules are present in a neutral medium of high ionic strength such as 5 per cent sodium chloride, the complexes do not form, even when much of the calcium has been removed. We have successfully separated each of these molecules (X_1 by differential ultracentrifugation and X_2 by extraction from frog larvæ cells (tail-bud stage) in which X_1 is absent[6] and have found that they are each perfectly soluble in distilled water by themselves. However, mixing the two clear solutions will cause the formation of a copious precipitate.

(*c*) It cannot be reasonably disputed that the following sedimentation differences exist when egg yolk and serum components are centrifuged in the same 5–10 per cent sodium chloride medium: egg yolk X_1 sediments faster (S 4·7) than phosvitin (S 3·5); serum X_1 sediments faster (S 8–9) than egg yolk X_1 or phosvitin derived from serum (S 3·5); serum X_2 sediments faster (S 16·5) than egg yolk X_2 (S 10). However, the sedimentation constants of Dr. Cook's purified lipovitellin and our egg yolk X_2 agree exactly (S 10), indicating that they may be identical substances. Also, our latest calculations of the sedimentation constants for the alkaline-produced sub-units of X_2 agree exactly (S 7) with those of Dr. Cook's sub-units of α- and β-lipovitellins. All molecular weights of the above substances, given in our papers, have been approximations and this has been so stated.

THE DISTRIBUTION OF ANTIGENIC GROUPINGS ON MOUSE GAMMA-GLOBULIN MOLECULES

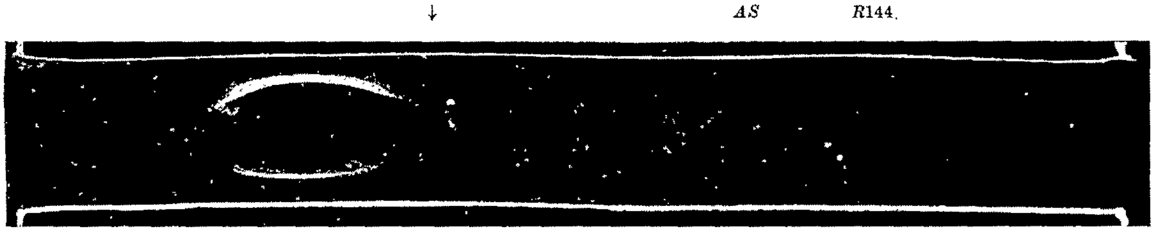
By Dr. BRIGITTE A. ASKONAS and Dr. J. H. HUMPHREY

National Institute for Medical Research, Mill Hill, London, N.W.7

EDELMAN *et al.*[1] observed that certain antisera prepared in rabbits against human γ-globulin or human γ-myeloma proteins consistently gave two precipitation lines when tested by immunoelectrophoresis against normal human γ-globulin. When the antigenic properties of human γ-globulin fragments, obtained by digestion with papain and cysteine by the method of Porter[2], were examined by means of these antisera, the papain digests were found to contain fragments with two distinct antigenic groupings; these were referred to as 'fast' or *F* fragments and 'slow' or *S* fragments according to their relative rates of migration towards the anode during electrophoresis. Immunoelectrophoretic comparison of the original human γ-globulin with the papain digest indicated that the two precipitin lines given by human γ-globulin were due to antibodies against antigenic groupings shared exclusively with the *F* fragments and exclusively with the *S* fragments respectively. These findings are hard to explain if all molecules of undigested human γ-globulin have both *F*- and *S*-antigenic groupings on the same molecule, but would easily be accounted for if the *F*- and *S*-antigenic groupings were present on distinct γ-globulin molecules.

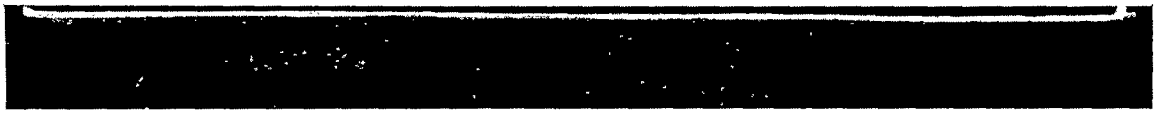
In the course of experiments on normal mouse γ-globulin and γ-myeloma globulins formed by transplantable plasma cell neoplasms, it was observed that rabbit antisera against normal mouse γ-globulin or the γ-myeloma protein formed by the plasma cell tumour line 5563 in C_3H mice[3] could also give double precipitation lines with normal mouse γ-globulin on immunoelectrophoresis (Fig. 1). Mouse γ-globulin and myeloma protein, on treatment with papain and cysteine, have been found to form fragments with distinct antigenic groupings (*S* and *F* groupings)[4]. It was therefore possible to design an experiment to test directly whether *F*-antigenic groupings and *S*-antigenic groupings are present on distinct molecules in the undigested γ-globulin.

Normal mouse γ-globulin, prepared by zone electrophoresis on 'Geon 425' (British Geon Co.) by the method described by Fahey and Horbett[5], and 5563 myeloma protein purified by fractionation on

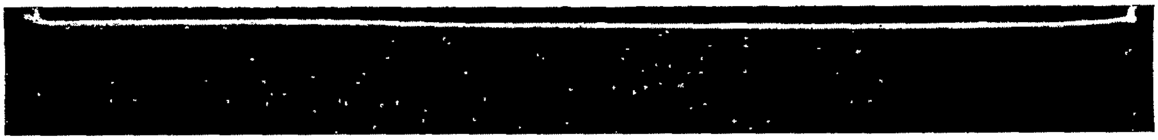


AS partly absorbed with *S* fragment

AS absorbed with excess of *S* fragment



AS partly absorbed with *F* fragment



AS absorbed with excess of *F* fragment

Fig. 1. Double precipitin lines with normal mouse γ-globulin and absorbed antisera on immunoelectrophoresis. The arrow indicates point of application of purified normal mouse γ-globulin at a concentration of 5 mgm./ml. *AS R*144 rabbit antiserum against purified 5563 myeloma protein. This antiserum was absorbed with *S* and *F* fragments isolated from 5563 myeloma protein after treatment with papain and cysteine

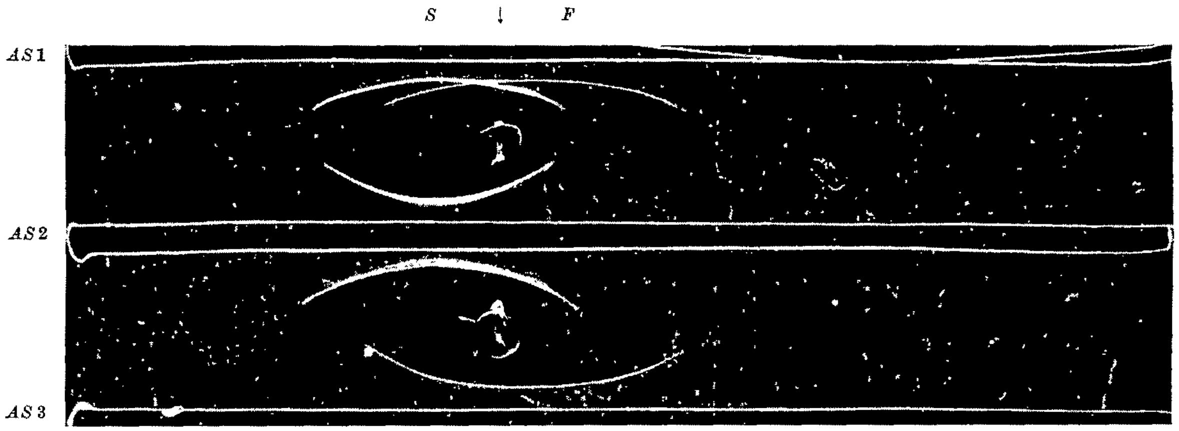


Fig. 2. Immunoelectrophoretic analysis of absorbed antisera. Arrow indicates point of application of papain and cysteine-treated 5563 myeloma protein. Fragments with distinct *S*- and *F*-antigenic groupings may be seen
AS 1, rabbit antiserum (*R* 91) against purified 5563 myeloma protein diluted by 1/2; *AS* 2, R 91 absorbed with a slight excess of fragment with *F*-antigenic grouping from papain and cysteine-treated 5563 myeloma protein.; *AS* 3, *R* 91 absorbed with fragment with *S*-antigenic grouping

DEAE cellulose[6] were labelled with iodine-131 at an average level of 0·5 atom/mole using the technique of McFarlane[7]. At least 99 per cent of the radioactivity was attached to protein having electrophoretic mobility characteristic of normal mouse γ-globulin and 5563 myeloma protein respectively. Samples of one rabbit antiserum prepared against normal mouse γ-globulin (*R*15) and of two antisera against 5563 myeloma protein (*R*144, *R*91) were absorbed with a slight excess of fragments (papain digest of 5563 myeloma protein) which had been purified so as to contain either *S*- or *F*-antigenic groupings only[4]. The absorbed antisera reacted exclusively with fragments possessing either *S*- or *F*-antigenic groupings, in contrast to the unabsorbed sera which reacted with both (Fig. 2).

Aliquots of the unabsorbed and of the absorbed antisera were mixed in a standard volume of saline with varying amounts of iodine-131 labelled normal mouse γ-globulin or iodine-131 labelled 5563 myeloma protein, giving ratios of antigen to antibody ranging from less to more than equivalence, and after 24 hr. at 2°, the proportion of iodine-131 labelled protein precipitated was estimated by centrifuging at 0°, and measuring the distribution of radioactivity between the supernatant and the antigen–antibody precipitate. The results (Table 1) showed that not only the unabsorbed antisera but also the absorbed antisera, specific for either *F*- and *S*-antigenic groupings, could precipitate 95 per cent or more of the normal mouse γ-globulin or 5563 myeloma protein labelled with iodine-131. Furthermore, by analysis of the precipitates at the equivalence points (Table 2), it was apparent that the total precipitable antibody was, within experimental error, equal to the sum of the antibody precipitable after each absorption, and there was no significant antigenic overlap between *S* and *F* fragments.

Table 1

Rabbit antiserum	Absorbed with 5563 papain digest fragment	Per cent iodine-131 labelled protein precipitated in antibody excess	
		Normal mouse γ-globulin (iodine-131 labelled)	5563 myeloma protein (iodine-131 labelled)
R 15	—	98·4	99·2
R 15	*S*	98·3	99·2
R 15	*F*	99*	95·8
R 91	—	98·9	99·5
R 91	*S*	99*	99·7
R 91	*F*	99*	99·1
R 144	—	97·3	99·5
R 144	*S*	92·6*	99·5
R 144	*F*	98·5*	99·5

* Only 89–96 per cent of the iodine-131 labelled normal mouse γ-globulin was precipitated under the conditions described, but a further amount was co-precipitable with the rabbit antibody, on adding excess of goat antibody against rabbit γ-globulin. Iodine-131 labelled normal mouse γ-globulin in normal rabbit serum was not precipitated in these circumstances.

Table 2. AMOUNT OF γ-GLOBULIN AND MYELOMA PROTEIN PRECIPITATED BY ANTISERA REACTING ONLY WITH *S*- OR *F*- ANTIGENIC GROUPINGS

Antiserum	Mgm. antibody per ml. antiserum precipitated at equivalence by:	
	normal mouse γ-globulin	5563 myeloma protein
R 91 (anti-5563 myeloma protein)	5·74	6·9
R 91 absorbed with *S* fragment	2·76 } 5·42	3·28 } 7·4
R 91 absorbed with *F* fragment	2·66 }	4·12 }

Our conclusion is that, in normal mouse γ-globulin as well as in the 5563 myeloma protein, the antigenic groupings of both the 'fast' and 'slow' papain digest fragments must be present on all the molecules. The double precipitin lines which we observed to occur between normal mouse γ-globulin and rabbit antisera cannot therefore be explained simply as due to a heterogeneous distribution of *F*- and *S*-antigenic groupings in the original normal mouse γ-globulin molecules. In fact we found (Fig. 1) that antisera partially or completely absorbed with *F* or *S* fragments still gave double lines with normal mouse γ-globulin on immunoelectrophoresis, although none of our antisera gave double lines with the 5563 myeloma protein. It is possible that an alternative explanation may lie in the presence in the antisera of antibodies with varying avidity for groupings the availability of which depends on the folding of the γ-globulin molecules, which is likely to be much more variable in normal mouse γ-globulin than in the more homogeneous myeloma protein.

FAVISM AND THALASSÆMIA IN SARDINIA AND THEIR RELATIONSHIP TO MALARIA

By M. SINISCALCO and L. BERNINI
Istituto Genetica, University of Naples

B. LATTE
Clinica Oculistica, University of Sassari

and A. G. MOTULSKY
Department of Medicine, University of Washington, Seattle

GLUCOSE-6-PHOSPHATE dehydrogenase deficiency of the red cell is a hereditary trait that predisposes to hæmolytic anæmia from *Vicia faba* beans, drugs (see review by Beutler[1]), and infections[2]. It has been suggested that this trait[3] and thalassæmia[4] have attained their world distribution by protecting their carriers against death from malaria. It would therefore be expected that populations exposed to severe and intense malarial infections in the historical past would have a high incidence of these traits—provided that the appropriate mutations had occurred or had been introduced into such populations. Inhabitants of the Sardinian plains, which until 1946 were among the most highly malarial areas in Europe[5], are known to have a high incidence of thalassæmia and favism. The island is even further suited for study because of the existence of isolated mountain villages where malaria is not prevalent.

Male school children of nineteen Sardinian villages that had in the past experienced varying incidences of malaria were studied. A dye decoloration test was used to detect glucose-6-phosphate dehydrogenase deficiency[6,7], and an osmotic fragility screening test and blood films served for the diagnosis of thalassæmia[8]. More detailed preliminary tests for thalassæmia, involving red cell enumeration, hæmoglobin, hæmatocrit, and hæmoglobin A_2 determination, and calculation of red-cell constants showed that the error of misclassification with the more rapid screening tests did not exceed 1 per cent[8]. The type of thalassæmia seen in one hundred randomly chosen families in different areas in Sardinia was associated with increased hæmoglobin A_2 levels[8,9].

Investigation of fifty-two families confirmed the fact that the enzyme deficiency is inherited as a sex-linked trait[10]. Linkage investigations in which colour-blindness was used as an X-chromosome marker showed no instance of recombination in 12 families among 4 large kindreds in which the two traits co-existed[10]. This finding formally rules out sex limitation or partial sex-linkage and indicates close linkage of the genes for colour-blindness and enzyme deficiency.

The data on the incidence of thalassæmia and enzyme deficiency are summarized in Table 1. Previous work on blood group distribution had indicated the similarity between populations in the central mountain villages (Desulo and Tonara) and east coast villages (Orosei and Galtelli)[4]. When this work was extended to west-coast villages (Terralba and Cabras), the low *Rh* (*cde*) and high blood group *M* gene frequencies characteristic of Sardinians were again found, suggesting that all population groups studied were ethnically homogeneous[11].

Fig. 1 demonstrates the positive correlation between thalassæmia and enzyme-deficiency gene frequencies, suggesting selection by a common ecological agent, namely, malaria by *Plasmodium falciparum*. It is apparent that the maximum gene frequency for thalassæmia (14 per cent) is significantly lower than that for enzyme deficiency (35 per cent). This finding is assumed to be related to the lethality of the thalassæmia gene in the homozygote state in contrast to milder selection against enzyme deficiency. It is also possible that the rate of accumulation of the thalassæmia gene is slower in populations with higher frequencies of enzyme deficiency, since this less harmful gene may already provide sufficient protection against malarial mortality.

Estimates of malarial morbidity were derived from the data of Fermi and Missiroli (see ref. 11 for literature), whose extensive investigations, carried out between 1929 and 1938, provide detailed information on the incidence of malaria in Sardinian villages. The relationship of the two genetic traits to the past incidence of malaria is shown in Fig. 2. There is good positive correlation between past malarial incidence and glucose-6-phosphate dehydrogenase deficiency

* For refs. see Bernini *et al.*, ref. 11. † The gene frequency was calculated as one-half the heterozygote frequency because of lethality of homozygous thalassæmia. ‡ From Ceppellini, 1956 (includes both sexes).

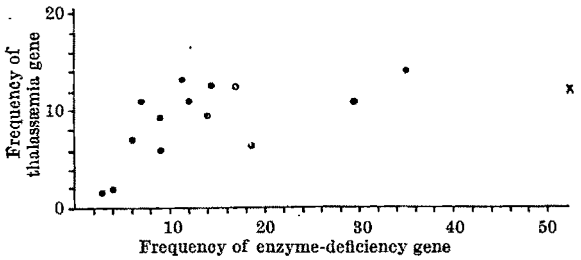

Fig. 1. Gene frequencies of thalassæmia and enzyme deficiency. Each dot represents one Sardinian village. The X refers to the data by Cohen *et al.* (ref. 15) on Kurdish Jews in Israel. (Note that the gene frequency of thalassæmia is approximately one-half the trait frequency, while the gene frequency of enzyme deficiency is identical with the trait frequency in males)

(or negative correlation with altitude; Table 1). To a lesser extent a similar correlation was observed for thalassæmia. Since the malarial frequency index refers to all malarial species, a still better correlation might have been obtained if the data could have been restricted to the lethal *P. falciparum* malaria. It is of interest that the sickling and the enzyme deficiency genes show a similar positive correlation in African populations[3]. There is extensive evidence now that sickle-cell heterozygotes are protected against death from *P. falciparum* malaria[12]. Data suggesting a similar protective effect on the part of the enzyme deficiency are now accumulating for African populations[3,7,13,14]. These results, as well as those presented here, therefore strongly implicate *P. falciparum* malaria as a selective agent for the maintenance of these red cell polymorphisms.

It was found that the presence of thalassæmia increased enzyme-levels, as measured quantitatively, in all genotypic classes, but especially in heterozygote females[8]. This increase probably was related to the presence of young blood cells, which are known to contain high enzyme-levels. Similar findings, based on the glutathione stability test, were obtained by Cohen *et al.*[15] in Kurdish Jews with the combined traits of thalassæmia and enzyme deficiency. Such an increase in enzyme-levels might be expected to decrease the frequency of clinical episodes of favism, and we investigated this possibility by surveying the medical records and carefully questioning 295 males and females more than fifty years of age in Lodè, where there was a frequency of enzyme deficiency of 29 per cent among males and a 22 per cent trait frequency of thalassæmia. No favism had occurred in individuals without enzyme deficiency. Of 50 subjects with both enzyme deficiency and thalassæmia, only 3 had had hæmolytic episodes, while among 121 with enzyme deficiency alone, 23 had had such episodes ($\chi^2 = 4\cdot6$, $P = < 0\cdot05 > 0\cdot02$ for 1 d.f.). It is therefore suggested that the presence of thalassæmia makes enzyme-deficient individuals less liable to acute hæmolysis from *V. fava* beans and probably also from infections and drugs. On the other hand, if malarial protection is related to low enzyme-levels[3], the presence of thalassæmia would partially deprive enzyme-deficient individuals of the malarial protection afforded by the enzyme deficiency while maintaining that given by thalassæmia. These considerations indicate the intricate interaction of two polymorphic red cell traits in a population. It is likely that full understanding of the population dynamics of these and many other human genes will require further detailed investigation of interactions of this type.

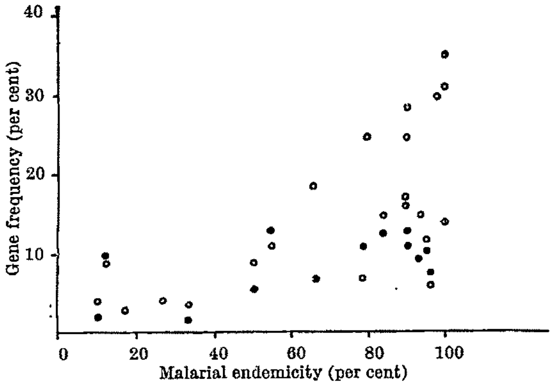

Fig. 2. Present gene frequency of enzyme deficiency (○) and thalassæmia (●) against malarial prevalence before eradication of malaria in Sardinia. Each dot represents a village. Not all villages were screened for both traits

These investigations were supported by grants of the Rockefeller Foundation, the Italian National Research Council, and Grant *H*-3091 of the U.S. National Institutes of Health.

Note added in proof. The very close linkage between the genes for enzyme deficiency and colour-blindness is supported by additional observations made during the past nine months or so by us in Sardinia. From these it has become clear also that the incidence of colour-blindness itself is positively correlated with the past incidence of malaria and therefore with the frequency of the enzyme deficiency. The situation is interpreted as an example of the selection of a neutral gene through the close linkage with a highly adaptive one. The hypothesis is further strengthened by the finding of an excess of families of the coupling type in the isolated village so far studied with almost complete ascertainment (Lodè), as would be expected if the fittest genotype versus malaria were represented by the enzyme-deficient male.

The recent results of Adam (*Nature*, 189, 686; 1961) confirm the close linkage between the two genes in Israel but show an excess of families of the repulsion type. It would be interesting to know in this connexion: (i) whether or not this was due to ascertainment; (ii) if all the families reported were derived from a single breeding unit and if this is of recent formation; (iii) if the propositi are the sons of people coming from different populations where the frequencies of the two genes were fixed at different equilibrium-levels.

Further discussion on these problems and the additional results from Sardinia will be reported in detail elsewhere.

Coesite as an Inclusion in G.E.C. Synthetic Diamonds

In the course of X-ray diffraction work on synthetic diamonds[1], many specimens were found to contain polycrystalline inclusions. A sample of coesite[2] made at the National Physical Laboratory, and kindly given to us by Sir Gordon Sutherland, has enabled us to identify it as the most prominent of the inclusions encountered (see, for example, ref. 1, Plate X, Figs. 1, 2).

This result is of interest for two reasons. In the first place, coesite has recently been identified in the Meteor Crater in Arizona[3], where its presence is taken as evidence of the occurrence of an impact shock-wave of sufficient intensity to result in the production of crypto-crystalline diamond[4], a possibility which has actually been demonstrated by de Carli and Jamieson[5]. One specimen in which coesite was found was actually the first synthetic diamond we ever examined, being a group of parallel black cubes which was selected from a batch in the G.E.C. Laboratories in Schenectady because of its superficial resemblance to cliftonite, the cubic graphite found in meteorites[6]. However, no graphite was detected in this specimen.

The second reason is that geologists have long suspected that reported inclusions of quartz in natural diamond were in reality *intrusions*, as quartz could scarcely be expected under the conditions likely to prevail during the genesis of diamond[7]. The identification of coesite strongly supports this point of view, since it indicates that if crystalline SiO_2 were present at all, it would almost certainly have been the high-pressure form. Some X-ray photographs of natural diamonds indicate the possible presence of coesite. A search for further specimens is in progress. If substantiated, this would represent the first natural occurrence of coesite except in meteor craters.

Thermal Diffusion of Oxygen and Nitrogen in Zirconium

The diffusion of oxygen in zirconium under the influence of an electric field has already been studied qualitatively[1]. Before beginning a further investigation of this phenomenon, it seemed worth while to find out whether a diffusion of the 'Ludwig Soret-type' occurred. If, under the influence of a temperature gradient, oxygen were indeed to diffuse preferentially in the direction of increasing or decreasing temperature, such an effect would be superimposed on the diffusion under the influence of an electric field if resistance heating were applied on the zirconium wire or sheet. The reason for this is that when the oxygen moves to the anode, the concentration of oxygen in that region rises, the electrical resistance increases locally and thus a temperature gradient develops along the wire or sheet. Darken and Oriani[2] have found a thermal diffusion of carbon and nitrogen in iron under the influence of a temperature gradient. They could show that both nitrogen and carbon diffuse to the region of the highest temperature. In order to evaluate such an effect in the case of oxygen in zirconium, we tried several experimental methods. The most reproducible results were obtained in the following circumstances.

As the hardness of zirconium and of tantalum is very sensitive to small amounts of oxygen (or nitrogen)[3], we used measurements of the hardness to determine the oxygen content. We carried out our experiments with ribbons of zirconium (free of hafnium, brand I.C.I. and Hereaus) first 140μ thick and 6 mm. broad, later 200μ thick, 6 mm. broad and in both cases 70 mm. long. An amount of oxygen was measured by volume and pressure and then absorbed in the zirconium by subjecting the strip to resistance heating (a.c.) at about 1,200° C. The solution was homogenized by subsequent heating at 1,350° C. during 4 hr. in a high vacuum. At various sites on the strip the homogeneity was checked with hardness measurements.

It proved very difficult to operate a furnace (to obtain a temperature gradient) in a vacuum of about 10^{-7} mm. mercury, without producing contaminating gases. Zirconium readily absorbs these gases. Therefore, resistance-heating (with a.c.) was applied in the experiments on thermal diffusion. The temperature gradient was realized by cutting away part of the ribbon so as to decrease its width towards one end, or so that the width diminished from both ends towards the centre (Fig. 1). In cases where the sheet was too brittle (more than 5 atm. per cent oxygen) to be cut, part of the material in the middle was etched away. After the gradient heating, several micro-hardness tests were made on each of a number of distances from one of the ends of the ribbon. Good reproducibility was obtained in the tests at constant distance from the end.

It was found that the oxygen moves in the direction of the lower temperature. Strips of zirconium with 1 and 2 at. per cent oxygen subjected to heating with a temperature gradient of 1,100–1,700° C. over a length of 50 mm. gave a decrease of the hardness (or oxygen content) on the site which had been at

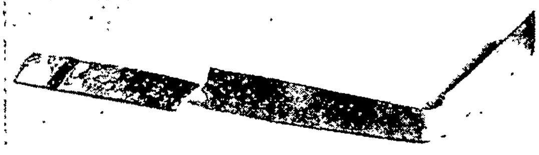

Fig. 1. Strip of zirconium with 6 at. per cent oxygen. after gradient-heating. The thinnest part is ductile and bent, the thick parts remain brittle and one end is broken

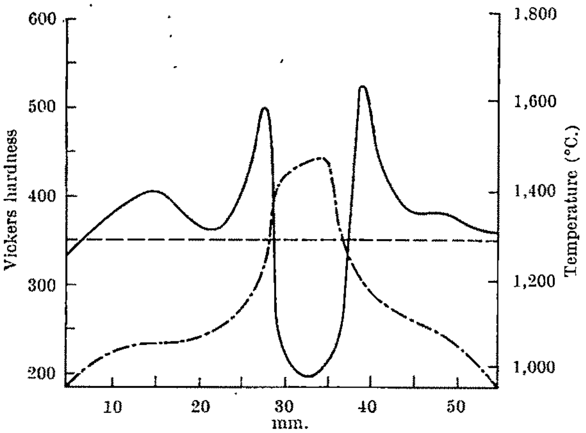

Fig. 2. Hardness and temperature along a strip of zirconium with (initial) 6 at. per cent oxygen. Annealing for 20 hr. at 1,000°–1,460° C. — — —, Hardness before annealing; ——, hardness after gradient annealing during 20 hr.; — · —, temperature along the strip during annealing

the highest temperature, and a rise in hardness (oxygen content) in the region which had been at a lower temperature. The same phenomenon occurred in strips with an oxygen content of 4 at. per cent after gradient-heating 1,350–1,700° C. In all these cases every part of the strips could be assumed to be in the region of the β-phase, according to the phase diagram of zirconium–oxygen as given in ref. 4. Strips with 4 at. per cent oxygen or more, heated for 20 hr. with a gradient 900–1,450° C., had (according to the same phase-diagram) their high-temperature parts in the β-region. The low-temperature part would be in the α-region, therefore the different solubilities of oxygen in the α- and in the β-phase (more oxygen will dissolve in the α-phase of zirconium) would have a part to play. This difference in solubility of the oxygen in α- and β-zirconium might enhance the movement of the oxygen away from the high-temperature part.

In some experiments the diffusion reduced the oxygen content of the high-temperature part almost to zero and, as a result, this part became as ductile as pure zirconium, whereas the other parts remained brittle. The phenomenon is demonstrated in Fig. 1, Fig. 2 giving the plot of hardness and temperature along the length of the strip. A strip of zirconium not loaded with oxygen, but subjected to the same gradient heating, showed scarcely any difference in hardness along its length.

There are indications that nitrogen in zirconium and oxygen in titanium behave in the same way as oxygen in zirconium.

We conclude, therefore, that when oxygen or nitrogen is dissolved in zirconium a 'Ludwig Soret-effect' occurs, which causes the oxygen or nitrogen to move to that part of the metal which has the lower temperature. We shall report more extensively on these experiments and also try to determine this diffusion effect quantitatively.

Elastohydrodynamic Lubrication of Rollers

It is now well known that the lubrication at such nominal line contacts as are found in roller races and between gear teeth is hydrodynamic in character. It is also known that this lubrication possesses peculiar features not found in journal bearings and which arise from the high pressure—a pressure, for example, of tens of tons per square inch as compared with 100 lb. in.$^{-2}$. Because of the pressure the surfaces are deformed, in general elastically, and in addition within the pressure zone the oil acquires a much higher viscosity than it normally possesses; the viscosity might be greater by a thousand-fold. These circumstances have excited much inquiry as to the shape in cross-section of the hydrodynamic film. This communication reports an experimental measurement of that shape.

The measurements have been made with 3-in. diameter disks, one of which was of glass and which rolled with other disks of hardened steel. All were polished. The glass disk carried the evaporated chromium electrode shown in plan in Fig. 1*a* and electrical connexions were made as shown in Fig. 1*b*. As the leading edge of the electrode approaches and passes through the conjunction of the surfaces the capacitance formed by the electrode and the steel disk rises, and it may be shown that to a sufficient accuracy the potential appearing across the resistor is proportional to ε/h, where h is the gap separating the disks at the leading edge and ε is the dielectric constant of the intervening medium. Results have been obtained up to loads of 600 lb. per in. of face-width and peripheral speeds of 30 ft. per sec.

A typical result is shown in Fig. 2. This is an oscillograph showing the potential across the resistor as a function of time and will be treated as a plot of ε/h against distance. The film has a parallel section which, in the example shown, was found to be 1μ in thickness in agreement with previous measurements

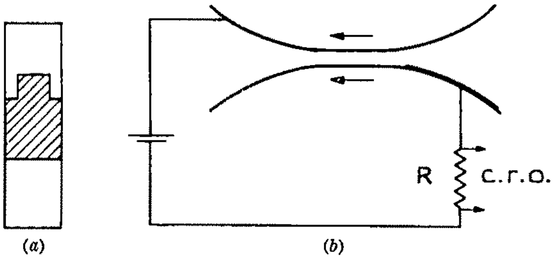

Fig. 1. *a*, Plan of chromium electrode; *b*, electrical connexions

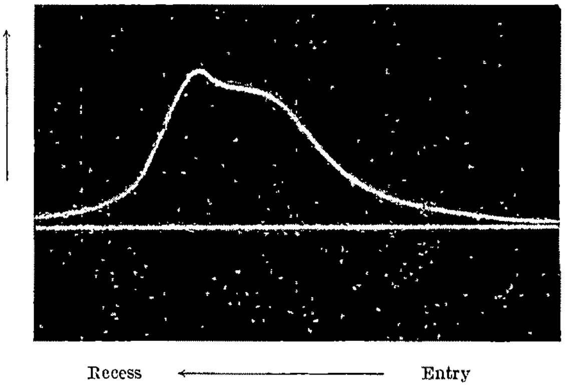

Fig. 2. Oscilloscope trace of potential across *R* (Fig. 1*b*)

by another method[1]. Another notable feature of the figure is that the parallel section is followed by a constriction in which the film thickness falls by approximately 10 per cent. These features confirm qualitatively theoretical ideas propounded in an approximate analysis by Grubin[2] and recently by Dowson and Higginson[3] and Archard, Gair and Hirst[4] in more exact analyses. The parallel section confirms that the pressure distribution is approximately Hertzian, while the constriction implies that somewhere towards the recess edge the pressure exceeds that of the Hertzian distribution. The practical implication of the excess pressure is that the material of the disks might be more severely stressed than is suggested by the Hertzian analysis on which design is at present based. The practical implication of the constriction is that it is the most probable site for breakdown of the oil film and the initiation of surface damage. A fuller account of the results will be published later.

Phase-Velocity of Ultra-sound in the Primary Aliphatic Amines

Continuous-wave electronic measurements of the speed of sound in liquids commonly depend on the presence of appreciable standing-waves in paths of low absorption, the half-wave-length being determined by detection of successive resonances as the path-length[1] or frequency[2] is changed. Alternatively, for liquids of high absorption in which the energy content of the standing-wave is necessarily small, the wave-length may be found by direct comparison of the phases of the transmitted and received signals. In conditions of very high absorption it has been necessary to use pulse techniques to obtain adequate acoustic intensity at the receiving transducer consistent with tolerable energy dissipation in the medium.

I have devised an alternative method of measurement employing continuous-wave frequency-modulated ultra-sound. The lower permissible signal/noise ratio in a frequency-modulation system allows operation at much-reduced acoustic intensities. The path occupied by a complete period of the modulation in a liquid sample is determined. The liquid is contained in an interferometer having separate transmitting and receiving quartz transducers. The frequency of the ultra-sound is varied sinusoidally by approximately ±40 kc./sec. about a mean of 10·7 Mc./sec. The modulation of the received ultra-sound is detected by a ratio discriminator preceded by a limiting stage. The observed absence of distortion of the detected modulation indicates that any dispersive effect in the liquids tested is too small to have appreciable effect for the frequency deviation used. Phase-lag of the received modulation is measured by inversion and linear addition to a sample of the transmitted modulation of equal amplitude. In the absence of phase-shift of electronic origin, the resultant is zero when the time of transit is an integral number of periods of the modulation, a condition obtained by adjustment of the modulating frequency. The phase-velocity is then given by:

$$v = Lf/N$$

where L is the length of the column, f is the modulating frequency and N is an integer. A range of path-lengths is used as a check on diffraction effects, and N-values are varied up to 4 as a check on consistency of behaviour of the electronic equipment. The temperature of the liquid is stabilized at 19·3 ± 0·1° C.

The first application of the method has been to the homologous series of primary aliphatic amines. Measured phase-velocities (v) appear in Table 1, the uncertainties being about 3 m.sec.$^{-1}$.

Table 1

Liquid	v (m.sec.$^{-1}$)	R $\frac{\text{cm.}^3}{\text{mole}}\left(\frac{\text{m.}}{\text{sec.}}\right)^{1/3}$	ΔR $\frac{\text{cm.}^3}{\text{mole}}\left(\frac{\text{m.}}{\text{sec.}}\right)^{1/3}$
n-Propylamine	1,234	877	194
n-Butylamine	1,269	1,071	187
n-Amylamine	1,296	1,258	186
n-Hexylamine	1,317	1,444	189
n-Heptylamine	1,345	1,635	191
n-Octylamine	1,354	1,826	198
n-Nonylamine	1,372	2,024	

Values of the molecular velocity defined in ref. 3 as:

$$R = v^{1/3} M/\rho$$

appear in the second column, M being the molecular weight and ρ the density. The increments ΔR with addition of successive $-CH_2-$ groups are tabulated in the third column. It is evident these are approximately constant, the mean being 190.

The constancy of ΔR was demonstrated by Rao[4] for six homologous series, an overall average of 195 being obtained. Weissler[1] obtains 190 for series of alcohols including branched isomers and ring molecules. More recently, Leon[5] quotes Mikhailov and Nizhin (1947) as obtaining 189 for the *l*-olefines, and gives an average of 188 for some higher paraffins.

It is hoped to publish a detailed account of the research elsewhere.

METALLURGY

Effect of a Thin Oxide Film on the Reaction of Iodine Vapour with Copper

In experimental work on the oxidation of metals the preparation of specimens is directed to the removal of contaminants such as grease, the production of a consistently smooth or rough surface and the realization of a stable metallurgical structure defined by the grain size and texture. The congenital

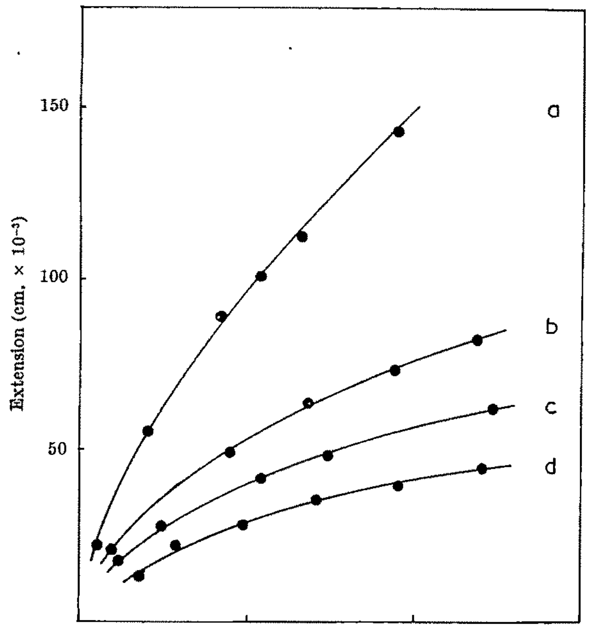

Fig. 1. Reaction of iodine vapour with copper at 285 ± 1° C., iodine reservoir at 16 ± 0·2° C. Times of room temperature exposure of specimens to the atmosphere before reaction: *a*, about 10 min.; *b*, 1 day; *c*, 3 days; *d*, 8 days

thin oxide film, which may increase in thickness on abrasion and polishing, or change in identity on electrolytic treatment, or disperse on heat-treatment *in vacuo*, is recognized as influencing the extent of the subsequent oxidation, but is largely ignored in discussions of the oxidation mechanism. In cases where the gaseous reactant is not oxygen, the thin oxide film, having no identity with the reaction system, assumes a different significance. Intuitively this is thought of in terms of protection and some results obtained in a preliminary study of the reaction between copper and iodine vapour demonstrate this.

Specimens (1 × 3 cm.) were cut from the centre of a 6-in. wide strip of 0·004-in. thick cold-rolled copper, de-greased with acetone and heated in an evacuated glass capsule at 500° C. for 1 hr. After cooling and opening the capsule the specimens were stored in a desiccator until required. The reaction was followed gravimetrically using a calibrated 'Pyrex' glass spring of sensitivity 17·37 cm.gm.$^{-1}$, and a cathetometer which could be read to 0·001 cm. The specimen was suspended from the spring by a thin silica rod which carried a fiduciary mark, and this assembly was further suspended in a vertical glass reaction tube, the lower closed end of which served as the iodine reservoir. The reaction zone was provided by a tube furnace, its temperature being controlled with a conventional circuit incorporating an auto transformer and 'Electroflo' controller. Temperature measurement was carried out potentiometrically, using a calibrated platinum – 13 per cent rhodium couple placed in a well extending into the reaction zone and sealed into the reaction tube.

With an acetone–solid carbon dioxide bath surrounding the iodine reservoir and a specimen in position, the apparatus was evacuated (10^{-3} mm. mercury) while the reaction zone was heated. When the steady controlled temperature was achieved, the reaction tube was isolated from the pump, the cold bath replaced by a water jacket, and readings of the cathetometer were made at suitable intervals.

The reactions were carried out at 284 ± 1° C. with the iodine reservoir at 14 ± 0·2° C. The results of these measurements are shown in Fig. 1, where the extension of the spring is plotted as a function of time, and each specimen is identified by the time of its exposure to the atmosphere between its removal from the heat treatment capsule and its suspension in the reaction tube.

It is seen that the increase in this time of exposure results in a retardation of the formation of cuprous iodide, which is due apparently to the presence of an oxide film of increasing thickness. This explanation requires the disappearance of the original oxide film during the vacuum heat-treatment at 500° C. in favour of a solution of oxygen in copper, with the internal precipitation of oxide at concentrations above the solubility limit; the continuous growth of a new oxide film at room temperature over these times of exposure to the atmosphere; and the diffusion processes above to take place at such a low rate at the reaction temperature that the new oxide film remains intact. This leads to a picture of the reaction in which the oxide film is conferring some protection on the copper, and from which it may be inferred that in the absence of such a film, as would obtain with hydrogen reduction of the specimen within the apparatus, the reaction would be very fast.

It would appear further that transport through the oxide film is largely determining the rate of reaction, superimposed on the characteristic diffusion kinetics in the growing iodide film. In view of the lack of knowledge of the thickness of the oxide films and the inherent uncertainty in this experiment of establishing precisely the time of commencement of the reaction, an analysis of these measurements has not been made. A more detailed study is, however, now in progress.

GEOLOGY

Determination of the Age of a Basic Igneous Intrusion by the Potassium–Argon Method

Potassium–argon age determinations have been carried out mainly on minerals with a high potassium content, particularly micas and potassium feldspars, found in intermediate to acid igneous rocks, but little work has been done on minerals with a low content of potassium, such as occur in basic igneous rocks. However, Hart *et al.*[1] have shown recently that it is possible to obtain reliable ages using hornblende and pyroxene. I decided to investigate the relative argon retention properties of pyroxene, plagioclase and sanidine in two specimens from a Tasmanian dolerite body, and in so doing hoped to determine the time of intrusion of the dolerite. The presence of chilled margins to these dolerite intrusions also suggested the possibility of carrying out potassium–argon dating on a whole rock sample from such a contact.

Table 1. POTASSIUM–ARGON AGE MEASUREMENTS ON TASMANIAN DOLERITES

$\lambda = 5{\cdot}304 \times 10^{-10}$ yr.$^{-1}$ $\lambda_e = 0{\cdot}584 \times 10^{-10}$ yr.$^{-1}$

The Tasmanian dolerites, which are tholeiitic in composition[2], were intruded into an essentially flat-lying sequence of Permian and Triassic sediments approximately 4,000 ft. in thickness, as sheets up to 2,000 ft. thick, as large transgressive bodies and as dyke-like intrusions which exceptionally may be one mile in width. The dolerite crops out over an area exceeding 6,000 square miles, mainly in the eastern half of Tasmania. The youngest sediments which the dolerite intrudes are considered to be Middle or possibly Upper Triassic in age[3], on the basis of the plant fossils present, so that the dolerite is younger than this. Lower Tertiary fresh-water sediments occur overlying dolerite in northern Tasmania[3], placing an upper limit on the age of the dolerite. By analogy with the Karroo dolerites, which are Liassic to Lower Cretaceous in age[4,5], and which are quite similar in composition to the Tasmanian dolerites, a Jurassic age has generally been assigned to them. Analyses of the chilled dolerites from the contacts of the intrusions are all closely similar[2], suggesting that the Tasmanian dolerite magma was intruded over a relatively short period of time.

Two specimens of fayalite granophyre and a chilled contact dolerite from the large Red Hill Dyke, 20 miles south-west of Hobart in southern Tasmania, were chosen for the age determinations. The fayalite granophyre is a differentiate of the dolerite magma and consists essentially of plagioclase (anorthite$_{60}$) comprising 48 per cent by volume, pyroxene—a ferroaugite (8 per cent), fayalite (4 per cent), potassium feldspar (16 per cent), quartz (19 per cent) and iron ore (2 per cent). The potassium feldspar, which has a composition about orthoclase$_{60}$, belongs to the sanidine-anorthoclase cryptoperthite series of Tuttle[6], and by the definition of MacKenzie and Smith[7] it is a sanidine from its optical properties. The chilled dolerite is composed of microphenocrysts of plagioclase, orthopyroxene and clinopyroxene amounting to about 7 per cent of the rock, set in a microcryptocrystalline ground-mass which has the appearance of devitrified glass.

The fayalite granophyres were crushed to -60 $+100$ mesh, and plagioclase, pyroxene and sanidine were separated using bromoform. The separated minerals were split into two portions, one of which was used for duplicate potassium analyses and the other for the argon extraction. In some cases duplicate argon runs were made. The argon extraction on the chilled dolerite was run on a single uncrushed piece of the rock and the potassium on a sample crushed to -100 mesh.

The potassium analyses were made by using a Perkin–Elmer flame spectrophotometer with lithium as an internal standard. The R_2O_3 group and lime were removed by precipitation before the potassium was determined. The argon extractions were carried out in a high-vacuum line originally at a pressure of about 10^{-8} mm. mercury, and the sample was fused by induction heating. A tracer of argon-38 was added to the evolved gases, which were cleaned up by reaction in copper oxide and calcium furnaces. The isotopic composition of the purified argon was determined by means of a Reynolds-type mass spectrometer[8].

The results are set out in Table 1. The agreement between duplicate potassium analyses is in all cases better than 2 per cent of the amount present, except for pyroxene *KA* 813. The low concentration of potassium in the pyroxenes makes it difficult to attain high precision in the analysis. The rock was only crushed to -60 $+100$ mesh in order that losses of argon due to grinding would be negligible, so that some composite grains were present in the pyroxene concentrates, which could not be removed by the usual methods of purification. In both pyroxenes the impurities, which consisted mainly of plagioclase with minor sanidine, accounted for less than 5 per cent of the sample. However, because of the relatively high potassium content of the impurities, compared with the pyroxene, about half of the potassium in *KA* 813 and approximately one-third of the potassium in *KA* 835 is attributable to the impurities. The plagioclase separates were better than 98 per cent pure and those of sanidine contained approximately 5 per cent impurity of altered plagioclase.

The calculated ages range from 143 to 168 million years, but the plagioclase and pyroxene results gave ages ranging from 159 to 168 million years, a spread of less than 6 per cent. As these two minerals have quite dissimilar crystal structures this small spread of calculated ages suggests that argon retention, in both minerals, is high. Therefore it is considered that the calculated age approaches the true age closely, and that the time of intrusion of the Tasmanian dolerites was near 167 million years ago, the higher figure being preferred, as any loss of argon which may have occurred would lower the age. This corresponds to an age approximately at the boundary of the Lower and Middle Jurassic[9,10]. Although difficult to place probable errors on the physical measurements, replicate argon determinations, in all cases, agree to within 1 per cent, indicating a very high precision. The reproducibility of the potassium analyses is generally less than that in the argon measurements, showing that greater attention must be paid to refining the techniques for the determination of potassium.

The calculated ages for the sanidines are somewhat lower than those for plagioclase and pyroxene, suggesting some leakage of argon. The very low calculated age for sanidine *KA* 811 as compared with *KA* 833 is surprising, as both minerals appear to be very similar in thin section. They both appear to be homogeneous, as no unmixing has been observed, although it may be present on a submicroscopic scale. The sanidines are slightly turbid as a result of deuteric alteration, and this has probably aided leakage of argon. A satisfactory explanation for the loss of argon from potassium feldspars and, in particular, loss from the high temperature, homogeneous, monoclinic sanidines has not yet been advanced ; a thorough structural study of this group of minerals in conjunction with their observed argon retention properties is urgently required. It may be noted, however, that some sanidines, and particularly those with a high potassium content, do retain argon quantitatively (ref. 11 and Evernden, J. F., personal communication).

The single chilled dolerite result gives 148 million years, which is a surprisingly good age considering that the rock is composed mainly of devitrified glass, and hence might be expected to lose considerable argon.

In conclusion it may be stated that the Tasmanian dolerites were intruded some 167 million years ago at approximately the boundary of the Lower and Middle Jurassic, and that it has been demonstrated that minerals with a low potassium content, such as occur in basic igneous rocks, can be used for age determinations by the potassium–argon method. Chilled dolerites and possibly glassy basalts will also give some aid in the elucidation of the age of basic igneous rocks by this method.

Grateful acknowledgment is made to Dr. G. H. Curtis and Dr. J. F. Evernden for the use of their facilities and to them and Mr. J. Obradovich for their interest and help in this work. This work was carried out while I held a Commonwealth Scientific and Industrial Research Organization (Australia) post-graduate overseas studentship, for which thanks are expressed.

Erosion Surfaces in the Caribbean and their Significance

ALTIMETRIC analysis of a series of topographic maps covering the main Cordillera of Puerto Rico indicates the existence of erosion surfaces, represented largely by concordant summit-levels, at the following average elevations : 760, 620, 470, 330 and 160 m. above present sea-level[1]. Field work at present in progress suggests that these elevations in fact represent mean elevations of groups of stepped surfaces, in some instances bearing sedimentary deposits which have been described previously as residual soils.

At the present time it is not possible to reach any firm conclusion as to the mode of origin of these surfaces ; but their distribution, at least in western Puerto Rico, suggests that they probably originated as marine cut surfaces, later modified by sub-aerial processes as they successively emerged from the sea. Whatever conclusion is eventually reached as to their origin, it seems fairly certain that they are related to changing sea-levels, the more widespread surfaces—particularly the 330 and 160 m.—presumably representing periods of relative standstill.

Examination of these surfaces was originally undertaken in the hope of determining the tectonic movements that had affected the island subsequent to middle Miocene times. However, Choubert[2] has described a series of surfaces in French Guiana with the following mean elevations : 600 (+), 500, 330, 235 and 160 m. These show a remarkable parallelism with the Puerto Rican levels, and this is borne out when the ranges of elevation of each surface are taken into account. In Puerto Rico, the 330- and 160-m. groups of surfaces are perhaps the most conspicuously developed and, from Choubert's map, this seems to be the case in French Guiana, too.

Furthermore, Martin-Kaye[3] has directed attention to the conspicuous concordance of summits in the northern Lesser Antilles at, or just above, 1,000 ft. This would seem to correlate with the 330-m. group in Puerto Rico and French Guiana. It seems scarcely likely that such correspondence of levels is a chance one, and I was reluctantly forced to the conclusion that these levels must be related to large eustatic lowering of sea-level and that the stage-by-stage emergence of Puerto Rico was not brought about by tectonic movements as had previously been taken for granted. An overall fall in sea-level since pre-glacial times has already been postulated by Wooldridge[4] and others, at least from 600 ft. above present sea-level, and even greater movements of sea-level have been hinted by Baulig[5] and Hollingworth[6].

The obvious difficulty in the way of accepting such large eustatic lowering of sea-level lies in the mechanism which would dispose of such large quantities of water. Geyl[7] has postulated a mechanism involving continental 'shift' induced by deep convection currents and isostatic readjustment of the continental areas. It seems doubtful if such readjustments, as between the continent of South America and the Caribbean islands, could be carried out without notably disturbing the relative heights of the erosion surfaces. Hence it is necessary to find a mechanism which would produce considerable eustatic lowering of the sea-level without relative vertical displacement of the land masses.

Heezen's[8] hypothesis of an expanding Earth, associated with the opening and widening of oceanic rifts, shows promise of providing such a mechanism. It is clear that, according to this hypothesis, every stage in the widening of the rift zones would add capacity to the ocean basins and thus would cause a lowering of sea-level.

A first approximation from available data indicates that a widening of the rift zones of about 150 km. would produce about 500 m. fall in sea-level. This is, of course, only a rough estimate ; but it does indicate that the order of magnitude is reasonable. As Heezen points out, the Iceland graben is opening at the rate of 3·5 m. per kilometre width per thousand years. Hence, it is not at all unreasonable to postulate widening of the oceanic rift zones by considerably more than 150 km. since middle Miocene time.

The interest in these observations is two-fold: (1) from the more general point of view, there is the further evidence of large eustatic lowering of sea-level since the middle Miocene and a possible mechanism to account for it; (2) from the regional point of view, there is the implication that the Caribbean, a tectonically active area, has suffered negligible vertical differential movements since the Miocene, and hence it would appear that any large displacements of more recent date must be confined to those in the horizontal direction.

CHEMISTRY

Comparison of Helium and Argon in Ionization Detectors

R. BERRY[1] has recently directed attention to the use of helium in place of argon in a conventional argon detector. All the rare gases should behave in the same manner as argon, that is, collision of metastable rare gas atoms with molecules of other gases should deactivate the metastables with the possibility of forming ions from the colliding molecules in the appropriate conditions.

Owing to the high ionization potential of metastable helium atoms, it should be possible to arrange conditions so that a collision with one of these will ionize all other molecules except neon. As has been pointed out, however, cylinder helium contains far too many impurities for this effect to be noticed, and it is obvious that a very considerable purification process has to be set up to obtain helium sufficiently pure for the effect to be observed. This purification process is regularly done by the British Oxygen Company, the prime use for the gas so produced being in discharge tubes and the electronics industry.

It was decided, however, to see whether this helium was of sufficient purity for an argon-type detector to be useful. The results can now be compared with the information given by Berry. The helium used in this work was analysed by conventional means and the results are shown in Table 1.

Table 1. ANALYSIS OF PURE HELIUM

	H_2	O_2	$CO_2 + CH_4$*	H_2O
Concentration in v.p.m.	< 1	< 2	2·3	< 3

* See text.

The oxygen was determined by Hersch cell and the carbon dioxide and methane (a term used here to include all other carbonaceous material) after oxidation to carbon dioxide, by titration, the method having been checked previously against infra-red. The notable absentee in the analysis is the neon content. The helium used here was not analysed for neon. Analyses for this gas have been carried out on previous batches by mass-spectrograph, but neon was not detected. None the less, it is possible that the differences in neon content can affect the results obtained and that discrepancies between my work and that of Berry could be explained on that basis.

The apparatus used included the normal argon cell (Type *IE*.10) as manufactured by Gas Chromatography, Ltd., and the electronic equipment was one of their standard amplifiers (Type *IE*.11) modified by having an input impedance of only 71 megohms. There was no linearizing resistance in the ordinary sense, only a resistance of about 20 megohms to protect the grid of the electrometer valve.

It should be pointed out, however, that in all cases where the properties of ionization detectors are being investigated, the inclusion of both linearizing and input impedances affects the voltage across the cell once the current approaches a certain figure. As can be seen from Table 3, currents of approximately 1 μamp. are developed in the detector. This means that the resistance of the cell is about 10^9 ohms, a figure comparable with the value of the linearizing resistance used by Dr. Lovelock in his original argon detector and, so far as can be gathered, in many other versions of this instrument, and it is of such magnitude that even an input impedance of 10^8 ohms can cause the potential across the cell to be substantially less than the apparent applied potential. However, this only applies here when the maximum current is flowing and, for the purposes of most of my experiments, the total impedance of 91 megohms can be ignored compared with the resistance of the cell.

Table 2 gives standing currents and noise-levels for both helium and argon and Table 3 gives typical results for permanent gases in helium and hydrocarbons in argon.

Readings at 600 V.

* Non-linear positively. † Not a useful range, otherwise as N_2, H_2.
‡ at 1,000 V.

The argon results give positive non-linearity above linear point, the helium results give negative, except as stated.

In Table 3, column 4 gives the dilution of the gas at maximum current; column 5 gives the dilution of the gas when the device turns linear; column 6 gives the current at 1 v.p.m. of impurity; column 7 is the (v.p.m. current + standing current) divided by the standing current (see Berry[1]). These results were obtained by a dilution technique.

It is immediately apparent from these results that the sensitivity and linearity of different gases varies enormously in contradiction to the implication given by Berry. On the other hand, the current at 1 v.p.m., with many of the gases tested, was much higher than the figures he quotes. It seems reasonably certain that this gas is substantially purer than the helium used by Berry. The figures in Table 2, particularly the large increase in standing current with increase in voltage, indicate that there are residual impurities in the helium, but that they can easily be accounted for by the "CO_2 plus CH_4". It is thought likely that water gives a high current in helium, and this will also undoubtedly contribute to the standing current. From the cross-section of helium, compared with that of argon, and the characteristics of the cell in argon, the standing current of pure helium at voltages less than 1,000 should be about $0·5 \times 10^{-8}$ amp. If this is so, then the ultimate sensitivity of this device is likely to be at least ten times higher than the argon detector, owing to the much greater currents produced in helium.

The sensitivity at 700 V. is increased approximately in proportion to the increased standing current, but it is thought that the linearity is somewhat better at a higher voltage. Linearity may be improved by further purification.

The linearities given in Table 3 have been confirmed by injecting known quantities of gas directly on to a chromatograph. The peak heights and areas are in complete agreement with the results of Table 3.

As regards the quantity of gas that can be injected into the chromatograph, it is difficult to compare my results with those of Berry. He gives no indication of flow-rates, retention times, etc., but in my work, oxygen reaches the limit of its linear range with about 1 μl., while nitrogen has not reached saturation limit with 6 μl. My column was 4 ft. long, 4 mm. diameter, packed with Linde molecular sieve, and it was operated at a room temperature and a helium flow-rate of about 130 c.c./min. Oxygen took about 20 sec. to emerge and nitrogen about 90 sec.

There were one or two small pieces of rubber tubing in the apparatus used which, it was felt, might contribute to the standing current. A new apparatus is being devised in which these are eliminated and further tests are to be carried out. It is certain, however, that helium of sufficient purity to obtain the sensitivity which one would expect from this type of device can be prepared. There is no doubt that this device is an extremely sensitive one.

In conclusion, it should be pointed out that the process of purification of the helium may be followed by using a detector cell of this type. As the purity of the helium rises, so does the standing current. At this stage the injection of a quantity of permanent gases or other substances produces a drop in current (cf. Willis organic bleed). As the level of impurities falls, the current rises and eventually passes a maximum. After this point, injections of substances produce a *W*-shaped peak with more and more on the positive side as the purity rises further.

Finally, large positive peaks of sufficient linearity are obtained.

W. A. WISEMAN

Gas Chromatography, Ltd.,
Boyn Valley Road,
Maidenhead, Berkshire.

---

[1] Berry, R., *Nature*, 188, 578 (1961).

IT is interesting to learn that Wiseman has obtained experimental results in general confirmation of my own. The only discrepancy concerns the sensitivity ratio for the different gases. Wiseman finds this ratio to increase through the series nitrogen, argon, oxygen, methane from 1·02 to 1·18, whereas I found the same value (1·05) for all four gases. Certainly some variation would be expected, but there is insufficient basic information available to permit this to be estimated with precision. One can say, however, on the basis of the work of Jesse and Sadauskis, that carbon dioxide would not be expected to give as high a value as 1·62, which Wiseman reports.

If no other factors interfere, the value of this ratio, for a given gas, should decrease as the impurity content of the helium increases. Since my result lies between the extremes quoted by Wiseman, deductions of the relative purity of his helium and mine cannot be made in this way. Neither does the analysis of the helium by conventional means give much help; my analysis (H_2, N_2, O_2, Ar and H_2O all < 1 v.p.m.) indicates that my helium carrier gas was of the same order of purity as Wiseman's. Since the methods are all at their limits of detection and, at these levels, contamination is very difficult to avoid, comparison is not really profitable.

It may be relevant that my method of determining the sensitivity ratio is to introduce sample volumes from 0·005 μl. (S.T.P.) upwards of the foreign gas into the helium immediately ahead of the column. Wiseman, since he injects quantities not less than 1 μl., must necessarily use a less-direct method of calibration, involving more lengthy extrapolation. It is encouraging that, despite these differences, our estimates of detection limits are of the same order of magnitude.

If helium requiring no further purification can be supplied at a price which is not prohibitive, the applicability of this method of detection will obviously be enhanced.

Determination of Uranium as Pyrophosphate

IN the gravimetric determination of uranium as phosphate, the ignited precipitate is commonly considered[1] to be the pyrophosphate $(UO_2)_2P_2O_7$ (U = 66·67 per cent). In recent work in these laboratories uranium was precipitated at *p*H 5·5 from solutions containing ethylenediaminetetraacetic acid, nitric acid and ammonium sulphate. The results were consistently low by 2·3 per cent relative when the precipitate was ignited to constant weight at 850° C.[2] and calculations made on the basis of the formula $(UO_2)_2P_2O_7$. As no significant quantities of uranium could be detected in the filtrates to explain the low results, the ignited precipitates were examined. They were dissolved in concentrated phosphoric acid and the solutions titrated with standard potassium dichromate solutions. From the observed titrations it was calculated that the ignited precipitates contained 33·2 ± 0·3 per cent quadrivalent uranium. For precipitates ignited at 1,000° C. the corresponding result was 33·9 ± 0·1 per cent quadrivalent uranium.

From these results it is apparent that the ignited compound cannot be represented by $(UO_2)_2P_2O_7$ and the most probable formula is UO.UO$_2$.P$_2$O$_7$ (U^{4+} 34·10 per cent; total U 68·205 per cent). Supporting evidence has been obtained by thermogravimetric analysis, but attempts to use X-ray diffraction were unsuccessful because of the non-crystalline nature of the compound.

The precipitate of uranyl ammonium phosphate is crystalline, settles readily and is easy to filter and wash.

Using the formula UO.UO$_2$.P$_2$O$_7$, quantitative recovery of uranium has been obtained from solutions of known uranium content. The results obtained on a variety of impure uranic solutions have shown good agreement with those obtained using cellulose chromatography and final weighing as U$_3$O$_8$.

An account of this work will be published in detail elsewhere.

We wish to thank Sir Leonard Owen, member for Production and Engineering, U.K. Atomic Energy Authority, for permission to publish this communication.

Control of Self-heating and Gas Emission in Nitrate-containing Fertilizers

THE concentration of plant food in mixed fertilizers can be increased by the replacement of ammonium sulphate, wholly or in part, by ammonium nitrate. Granular mixtures made, *inter alia*, from ammonium nitrate and superphosphate (a mixture of monocalcium phosphate and calcium sulphate) have been found to undergo spontaneous heating when stored in large heaps, rises in temperature of 20–30 deg. C. being recorded over periods of weeks.

This spontaneous heating is accompanied by the evolution of gas, and, by measuring the rate by a simple manometric technique, we have studied factors affecting the self-heating reactions. The rate of the reaction increases with the acidity and decreases with increasing moisture content of the fertilizer. A decrease of the acidity of the mixture, sufficient to prevent self-heating, leads to a large and undesirable loss in the water-solubility of the phosphate component owing to the formation of dicalcium phosphate. An increase in the moisture content of the fertilizer is not practicable, as it increases the tendency of the mixture to cake.

Phosphate rocks contain small amounts of organic matter of unknown composition[1], and we have confirmed that this material is not destroyed during the manufacture of superphosphate. Typical amounts of organic matter in some superphosphates used in the production of fertilizers in the U.K. are shown in Table 1.

Table 1. ORGANIC MATTER IN SUPERPHOSPHATES

Source of rock for superphosphate	Organic matter content (per cent carbon)
Morocco	0·10
Nauru	0·40
Florida	0·16
Gafsa	0·50

In a mixed fertilizer made, *inter alia*, from ammonium nitrate and one of these superphosphates, it might be expected that the organic matter would be oxidized by the nitrate under acidic conditions. We have shown that the gas evolved from the fertilizer consists mainly of carbon dioxide and nitrogen (ratio approx. 1 : 5), together with small amounts of nitrogen dioxide. Acidified mixtures of some organic materials and ammonium nitrate also liberate these gases. Powdered coal reacts similarly when incorporated into a nitrate-containing fertilizer. The amount of carbon dioxide evolved from the fertilizers shows that oxidation of the organic material is far from complete, and thermo-chemical calculations on model organic systems (for example, polynuclear hydrocarbons) show that partial oxidation, to products such as phthalic acid, would liberate sufficient heat to explain the observed rises in temperature.

The self-heating of nitrate-containing mixed fertilizers may be reduced by removing, or modifying, the organic material. We have achieved this by calcining the initial rock at temperatures of 800–1,000° C. and by other means involving oxidation of the organic matter before the superphosphate is mixed with the other components[3]. Of these methods, calcination is undesirable, as it decreases the reactivity of the rock towards sulphuric acid in superphosphate manufacture.

The auto-oxidation of some organic nitro-compounds can be prevented by the addition of substituted ureas or secondary amines[2], and we have found that addition of small amounts of urea, 0·25–0·75 per cent by weight, to mixed fertilizers effectively reduces the oxidation of the organic matter and hence the self-heating of the fertilizers[3]. The effect of urea on the reactivity of laboratory-prepared samples of a mixed fertilizer (N, 10 per cent : P$_2$O$_5$, 10 per cent : K$_2$O, 18 per cent) containing 20 per cent ammonium nitrate is shown in Table 2. Each fertilizer contains 0·25 per cent urea, and the activity of the material is assessed in terms of the gas pressure developed in 48 hr. at 50° C.

Table 2. EFFECT OF UREA ON THE REACTIVITY OF A MIXED FERTILIZER

Source of phosphate rock	Percentage reduction in reactivity
Morocco	70·5
Florida	88·5
Nauru	92·0

Incorporation of urea into these fertilizers also has a marked effect on the release of nitrogen dioxide. Table 3 shows results obtained with a mixed fertilizer (N, 10 per cent : P$_2$O$_5$, 10 per cent : K$_2$O, 18 per cent), the nitrogen dioxide being evolved into a stream of air drawn through the fertilizer.

Table 3. EFFECT OF UREA ON THE EVOLUTION OF NITROGEN DIOXIDE

Source of rock for superphosphate	Urea content (per cent)	NO$_2$ evolved (ml./kgm. fertilizer) in 14 days
Nauru	0·0	120·7

The oxidizing action of nitric acid involves the presence of trace amounts of nitrous acid, probably in the form of the nitrosonium ion[4]. It seems likely that, in the oxidation process we have studied, nitrous acid is formed autocatalytically, so that it should be possible to suppress the oxidation by removing the nitrous acid with, for example, urea. A small quantity of urea should be adequate to prevent the oxidation, and, in fact, we have observed no appreciable loss during long-term storage of fertilizers. The rate of the urea/nitrous acid reaction is undoubtedly fast enough to explain this inhibition effect[5]. It is well known that the oxidation of organic compounds during nitration can be prevented by the addition of small amounts of urea[6].

So far, approximately 1·25 million tons of mixed fertilizers containing urea as an inhibitor have been produced and have shown satisfactory storage properties, both in large heaps and in paper sacks. At the elevated temperatures attained in the absence of urea the caking tendency is increased, causing subsequent difficulty in reclaiming from the heap. Storage of the untreated fertilizer in paper sacks causes severe chemical attack on the paper (due to nitrogen dioxide) with subsequent breaking of the sacks when moved.

In conclusion, it may be noted that self-heating of fertilizer storage heaps can also occur if inter-ionic reactions (for example, between ammonium nitrate and potassium chloride) take place. Results of investigations into this problem, and a more detailed account of the urea inhibition work, will be published elsewhere.

Solid Solutions in the System Ammonium Nitrate–Potassium Nitrate

BY phase work on the system ammonium nitrate–potassium nitrate–water, Janěcke[1,2] showed that below 23° C. two types of solid solution can exist: potassium nitrate dissolved in ammonium nitrate (form III) and ammonium nitrate in potassium nitrate (form II). At higher temperatures there is an increasing amount of another phase which is of a different crystalline form from any of the normal modifications of the two salts. Janěcke suggests that this phase is a solid solution of ammonium nitrate in a metastable form of potassium nitrate, which is only formed on cooling, in the temperature-range 128°–115° C.

By using X-ray diffraction measurements, Janěcke's suggestion has been confirmed. Further, the limits of the composition of the solid solution have been determined and also its heat of formation from the individual salts.

Aqueous solutions of ammonium and potassium nitrates were evaporated to dryness at various temperatures between 25° and 120° C. After cooling, diffraction patterns were obtained using a Geiger diffractometer, radius 24 cm.; the radiation was copper $K\alpha$, the $K\beta$ component being removed by a nickel filter. From the diffraction patterns, the relative abundance of each phase was determined.

Samples produced at temperatures of 100° C. and above, from equimolar mixtures of the two salts, consisted almost entirely of a phase having a diffraction pattern similar to that found by Kracek *et al.*[3] and by Barth[4] for the metastable form of potassium nitrate. Hereafter, this phase will be referred to as (xKNO$_3$.NH$_4$NO$_3$). If more ammonium nitrate is added to an equimolar mixture, it does not dissolve in this phase, and increasing amounts of ammonium nitrate (form III) containing dissolved potassium nitrate are found. Thus, in (xKNO$_3$.NH$_4$NO$_3$) the value of x cannot decrease below approximately 1. When the molar ratio of potassium nitrate to ammonium nitrate is greater than one, the mixture still consists essentially of a single phase having a very similar diffraction pattern. In the phase (xKNO$_3$.NH$_4$NO$_3$), x can rise to a maximum of approximately 3, this change being accompanied by a slight shift in the diffraction pattern. In Table 1 the unit cell dimensions found for solid solutions of composition (3KNO$_3$.NH$_4$NO$_3$) and (KNO$_3$.NH$_4$NO$_3$) are compared with those of the high temperature and metastable forms of potassium nitrate; Table 2 shows the corresponding diffraction patterns. All lines are listed up to a maximum Bragg-angle of 35°, the values of 'd' being accurate to 0·01 Å.

Table 1. UNIT CELL DIMENSIONS OF THE HIGH-TEMPERATURE FORMS OF POTASSIUM NITRATE, AND RELATED SOLID SOLUTIONS

Material	Space group	Cell size Hexagonal axes (3 moles/cell)	Rhombohedral axes (1 mole/cell)
KNO$_3$ (form I) at 130° C.	D^5_{3d} — $R\bar{3}m$	a = 5·44Å. c = 9·76 Å.	a = 4·54 Å. α = 73° 24′
KNO$_3$ (metastable) at 120° C.	C^5_{3v} — $R3m$	a = 5·48 Å. c = 9·27 Å.	a = 4·42 Å. α = 76° 42′
NH$_4$NO$_3$3KNO$_3$ at 20° C.	C^5_{3v} — $R3m$	a = 5·52 Å. c = 9·09 Å.	a = 4·38 Å. α = 77° 42′
NH$_4$NO$_3$.KNO$_3$ at 20° C.	C^5_{3v} — $R3m$	a = 5·56 Å. c = 9·12 Å.	a = 4·42 Å. α = 77° 54′

The chief difference between the patterns of potassium nitrate (form I) and potassium nitrate (metastable) is the absence of the (0003) reflexion in that of the former. The presence of this reflexion in all patterns from the phase (xKNO$_3$.NH$_4$NO$_3$) indicates that its structure is derived from that of the metastable form. When solutions of composition (KNO$_3$.NH$_4$NO$_3$) and (3KNO$_3$.NH$_4$NO$_3$) are heated to 130° C., the diffraction patterns show that there is an abrupt expansion of the lattice, and a total disappearance of the (0003) line, that is, the transition to potassium nitrate (form I), occurs.

When ammonium and potassium nitrates react at temperatures below 100° C. the extent of conversion to the phase (xKNO$_3$.NH$_4$NO$_3$) is considerably less, and increasing amounts of ammonium nitrate (form III), containing dissolved potassium nitrate, are found. There is also a tendency for x to have a value less than the maximum possible.

The X-ray measurements show that the solution of ammonium nitrate in the metastable form of potassium nitrate causes the lattice to expand. This is to be expected, since the ammonium ion (radius 1·42 Å.) is slightly larger than the potassium ion (radius 1·33 Å.). On cooling metastable potassium nitrate the lattice contracts until, at approximately 115° C., it collapses into a more compact form. This change is delayed by the replacement of potassium by larger ions, and in the case of ammonium ions the change does not occur on cooling to room temperature. The stability of the solid solution increases

as more ammonium ions are added, and it is for this reason that there is a tendency for potassium nitrate to crystallize out from the phase (3KNO$_3$.NH$_4$NO$_3$), thereby increasing its content of ammonium ions. In the presence of traces of water, the phase (xKNO$_3$.NH$_4$NO$_3$) is unstable at room temperature and changes into solid solutions of potassium nitrate in ammonium nitrate (form III) and ammonium nitrate in potassium nitrate (form II).

The heats of solution in water of the phases (KNO$_3$.NH$_4$NO$_3$) and (3KNO$_3$.NH$_4$NO$_3$) were found to be − 13·4 and − 28·5 k.cal./mole respectively. In each case the material contained approximately 95 per cent of the phase (xKNO$_3$.NH$_4$NO$_3$). Using existing values for the heats of solution of potassium and ammonium nitrates, the heats of formation of the two solid solutions from the individual salts were calculated to be − 1·4 and − 3·2 k.cal./mole respectively. These values are accurate to within ± 10 per cent, and are comparable with that for the transition from the high- to the low-temperature form of potassium nitrate, + 1·19 k.cal./mole.

Banded Spherulites of Hippuric Acid

IT has long been known that under certain conditions many substances crystallize in the form of spherulites showing concentric extinction bands between crossed polars. The explanation of this effect, originally put forward by Michel-Levy and Munier Chalmas[1] for chalcedony, and later confirmed by other workers[2-5] for a number of substances of low molecular weight, was that the structure of the spherulite has a twist around any given radius, and that the bands correspond to those orientations in which an optic axis is parallel to the light beam. Thus, Gaubert[5] obtained spherulites of hippuric acid in which the radial twist was around the β-axis of the indicatrix, a fact which he established conoscopically, that is, by a study of the interference figures along the radii. More recently there has been a revival of interest in banded spherulites, since they are formed by many polymers (for example, polythene and terylene). These cases have been the subject of much investigation by, among others, Keller[6], and Point[7], who have shown convincingly, from the optical effects of tilting the preparations with respect to the direction of the light, that the spherulites have a radially twisted structure as for the low molecular weight substances referred to above.

In the course of a student's exercise in this Department on the crystal optics of hippuric acid we recently obtained (i) a spherulite, part of which showed a well-defined radial twist around the β-axis as observed by Gaubert (Fig. 1), and also (ii), on another preparation, a number of complete spherulites showing a radial twist around the α-axis (Fig. 2), in both cases as a result of allowing a melted film between a slide and cover slip to crystallize spontaneously on a slowly cooling metal plate. The existence of both kinds of twists, and also their sense, have been established directly from the interference figures shown by the spherulites at successive points along their radii. The figures were particularly clear in (i), in which the pitch of the twist was large (about 1 mm.). Different stages in the twist (right-handed in this case) along one radius are pointed out in Fig. 1; thus, starting with the central emergence of an optic axis A_1 (extinction band in parallel light), we pass in succession to an acute bisectrix view (Bx_a), the central emergence of the other optic axis A_2 (extinction band again), an obtuse bisectrix view (Bx_o), and, completing a rotation of 180°, axis A_1 again, and so on. (In Fig. 1 as reproduced the extinction bands are not appreciably darker than the bands marking the 'sensitive violet' tint between first order red and second order blue.) In confirmation of the evidence afforded by the interference figures, two determinations of the ratio of the path differences for adjacent Bx_o and Bx_a regions by means of a graduated quartz wedge gave values of 3·0, 3·1, while that calculated from the published refractive indices[8,9] is 2·9. Furthermore, rough measurements of the ratio of adjacent wide and narrow spacings of the extinction bands on Fig. 1 give an average value of 1·7, which agrees with that given by the published figure, 66°, for 2 V.[8,9].

In case (ii) (Fig. 2) there are no extinction bands, because the twist results in an alternation of the Bx_a (with β now normal to the twist axis) and optic normal views, and at no point does an optic axis

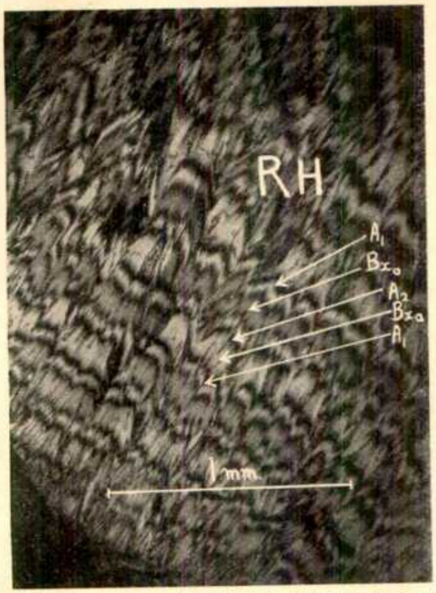

Fig. 1. Portion of spherulite showing radial twist about β-axis. Sense of twist right-handed (*RH*)

become vertical. Both right-handed and left-handed twists were found as indicated on the figure. The nature of the twist was confirmed by determinations of the path differences of adjacent optic normal and Bx_a regions, by direct identification of the polarization colours for the thicker spherulites, and by means of the graduated quartz wedge for thinner sections. Values of the ratio of these path-differences obtained were: 4·0, 3·9, 4·0; that calculated from the refractive indices is 3·9. The pitch was smaller than in (i) (for example, about 0·2 mm. for the middle region of the large central spherulite in Fig. 2) and it decreased as the borders of the spherulites were approached, that is, in the direction of falling temperature of growth. In some cases the prominent bands ceased altogether at the borders of the spherulite, and gave place to a more or less uniform structure which showed an optic normal interference figure. Examples are the two areas marked *ON* (optic normal) on the left of Fig. 2. These may have been regions in which the twisting process had ceased, or, more probably in view of the decreasing pitch in the regions which immediately preceded them, in which the pitch had become smaller than the limit of resolution of the microscope, so that the refractive index for light vibrating normally to the radii of the spherulites was an averaged value between β and γ. Whatever the explanation, it is probable that it applies also to the small unbanded spherulites seen along the left-hand margin of Fig. 2.

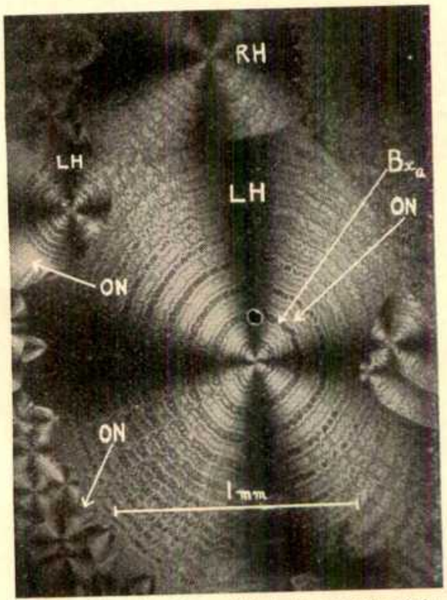

Fig. 2. Spherulites showing radial twist around α-axis. Both right-handed (*RH*) and left-handed (*LH*) spherulites present

The spherulites of both types (i) and (ii) had a markedly fibrous structure radially, as is commonly observed in spherulites, and it is of course possible that in these structures we are dealing with twisted linear aggregates of very narrow acicular crystals, which, individually, have little or no twist.

It is of interest that for both types the optical evidence suggests that it is the long axis of the molecule (presumably parallel, or nearly so, to the γ direction) which is oriented tangentially, as is the case in polymer spherulites.

Finally, it may be noted that hippuric acid belongs to class 222, one of the enantiomorphous symmetry classes[8]. Gaubert[5] was of the opinion that membership of such a class was conducive to the formation of twisted structures. It is tempting to go further, and suggest that the right- and left-handed spherulites are based respectively on the two enantiomorphous forms of the crystal.

I thank Dr. Keller for directing my attention to Gaubert's earlier work on hippuric acid.

BIOCHEMISTRY

Nucleotides and Other Phosphorus Compounds of Cockroach Nerve

A NUMBER of phosphorus compounds, some of which have a vital role in vertebrate nerve function, have been demonstrated in the abdominal part of the ventral nerve cord of adult male *Periplaneta americana*. An estimate of their relative tissue concentrations has been made by the labelled pool technique[1]. Groups of about ten cockroaches were injected with 400 μc. of carrier-free phosphorus-32 orthophosphate per individual. They were held for seven days on normal diet to permit equilibration between injected phosphorus-32 and phosphorylated metabolites. Part of the nerve cord of each animal was exposed *in situ* by removing a strip of abdominal wall, separated from the animal by a piece of black paper and dissected free from other tissues, hæmolymph being washed off with Ringer solution. The cord was monitored using a cathode ray oscilloscope to ensure that it was capable of conducting impulses. Each electrically normal cord was raised up on two hooks 8 mm. apart, and the preparation flooded with liquid nitrogen. The frozen cord sample was transferred quickly to a homogenizer tube itself immersed in liquid nitrogen. After breaking up the tissue in 50 per cent ethanol made 1 N with respect to formic acid, the homogenizer was kept at −30° C. for 15 min. to allow thorough penetration of the medium. The tissue was warmed to 5° C., thrice extracted with 0·2 ml. extraction medium, and the extract separated by paper and elution[2] chromatography into a number of fractions. By automatic scanning of paper chromatograms[1] and Geiger counting of column effluents in solution, the size of each fraction was estimated, the results being expressed as percentages of the extracted phosphorus-32. The principal constituents of the extract were identified by co-chromatography with known substances. Where a fraction was shown to contain substantial impurity, the fact is indicated in Table 1 by a question mark and a 'less than' sign, though there may be small amounts of unidentified material in any fraction. About 60 per cent of the total phosphorus-32 of the nerve is extracted by the above procedure. The total phosphorus of cockroach abdominal nerve cord was found to be 1·41 mgm./gm. wet weight using the method of Bartlett[3]. In calculating approximate tissue concentrations of substances from these data, it has been assumed that the quantities of phosphorus-32 assayed reflect the amounts of phosphorus-31 present, both in the extract and in the insoluble residue. This assumption is not strictly valid, so the figures quoted (Table 1) are an indication of the order of magnitude of concentration of the metabolites listed.

Using an independent technique based on perchloric acid extraction and firefly luciferin assay the level of adenosine triphosphate in cockroach nerve was found to be 1,350 μgm./gm. wet weight.

In some experiments an unlabelled extract was prepared from lobster, *Homarus vulgaris*, ventral nerve cord and added to the labelled cockroach extract to reduce adsorption losses during column chromatography. This precaution proved to be unnecessary, but six compounds, coenzyme 1, cytidine monophosphate, adenosine mono-, di- and tri-phosphates, and uridine diphosphate, were tentatively identified by co-chromatography in the lobster nerve extracts.

Table 1

	Percentage of extracted phosphorus-32 (No. of observations)	Approximate tissue concentration (μgm./gm. wet weight)
Adenosine-5-phosphate	0·3 (3)	30

Incorporation of Amino-Acids into Protein and Ribonucleic Acid of the Lens of the Rat ; Effect of Heavy Metals

THE distribution of nucleic acids and proteins within the cell varies from organ to organ. Tissues rich in ribonucleic acid (RNA) are particularly active in protein synthesis, thus indicating a close association between protein synthesis and RNA concentration[1-3]. Work from several laboratories now clearly shows that RNA is one of the essential components for protein synthesis[2,4]. Because of the relatively high concentration of RNA[5-7] and protein[8], and the absence of enzyme systems to hydrolyse adenosine triphosphate (ATP) and guanosine triphosphate (GTP) in the ocular lens[9,10], this organ may offer certain advantages for the investigation of protein biosynthesis as compared with a more complex organ such as the liver.

In order to investigate the incorporation of amino-acids labelled with carbon-14 into lens protein and RNA, lenses derived from Holtzman strain white male rats (6 weeks of age and weighing approximately 80 gm. each) were used. For the *in vitro* experiments these lenses were removed immediately after the animals were killed, weighed, and homogenized in Dounce microhomogenizers[11] at 0° C. in a medium consisting of 7 parts 0·03 M sucrose, 1 part 0·025 M potassium chloride and 1 part 0·03 M potassium bicarbonate. The capacity of such a system to catalyse the incorporation of ^{14}C-leucine, valine or histidine into lens RNA and proteins, and the experimental conditions, are summarized in Table 1.

Although the incorporation of amino-acids can occur over a broad pH range, from pH 6·0 to 10·0, all the foregoing experiments involving ^{14}C-leucine and valine were carried out at pH 8·5 in 0·1 M *tris* buffer since this was the pH optimum for the incorporation of these two amino-acids. The corresponding optimum pH for histidine was 9·0 and the experiments involving this amino-acid were all performed at this pH.

Incorporation of ^{14}C-leucine, valine or histidine into lens proteins and RNA could also be demonstrated by the injection of these amino-acids intraperitoneally into rats. The resulting *in vivo* incorporation was comparatively less than the results obtained with the *in vitro* studies, reaching a maximum 3 hr. after injection.

The results of the *in vitro* experiments carried out in the presence of cobaltous chloride are shown in Table 1. Without the addition of this metal the incorporation of carbon-14-labelled leucine, valine, or

* ml. of the reaction mixture contained 0·5 ml. lens homogenate (50 mgm./ml.), 20 μmoles *tris* buffer *p*H 8·5 (for leucine and valine) or *p*H 9·0 (for histidine), 5 μmoles Co^{++} (or 10 μmoles Mg^{++}), 10 μmoles ATP and 10 μmoles GTP (in the reactions indicated above), 0·56 μmole ^{14}C-valine ($8·56 \times 10^4$ c.p.m.), 0·65 μmole ^{14}C-leucine ($1·04 \times 10^5$ c.p.m.) or 1·30 μmoles ^{14}C-histidine ($9·52 \times 10^4$ c.p.m.). The reaction mixtures were incubated at 37° C. for 1 hr. and the reaction was terminated by adding 5 per cent TCA. The precipitate was washed four times with 5 per cent TCA, once with hot alcohol (50° C. for 10 min.), once with alcohol, twice with ether, and then plated and counted in a gas flow counter (Nuclear Chicago) as infinitely thick layers with a counting error of 6–8 per cent. Each result shown above represents the average value for 6–8 experiments.

histidine was low. Mg^{++} can to some extent replace Co^{++} but was much less effective; even by increasing its concentration ten-fold over the concentration of Co^{++} it was not possible to achieve an appreciable incorporation. Zn^{++}, Mn^{++}, and Ca^{++} did not have the stimulating effect of Co^{++} or the inhibitory effect of Ni^{++} on the incorporating system. Addition of 10 μmoles of Ni^{++} in the presence of 1 μmole of Co^{++} blocked 95 per cent of the incorporation of ^{14}C-leucine into lens proteins, and even in the presence of 5 μmoles of Co^{++} 90 per cent inhibition was still noted (Fig. 1).

The incorporation of labelled leucine, valine, or histidine into lens proteins and RNA was to a certain degree dependent on the addition of ATP. Furthermore, the addition of 10 μmoles of GTP instead of being stimulating actually inhibited the incorporation by 25–30 per cent. On the other hand, in experiments where Mg^{++} instead of Co^{++} was used, addition of ATP and GTP showed a stimulating effect. Activation of an amino-acid by *p*H 5·2 enzyme requires ATP[12] and for the transfer of the activated amino-acid from an AA-SRNA complex to ribonucleoprotein particles, both ATP and GTP are required[13]. The inhibitory action of GTP is not understood at the present time.

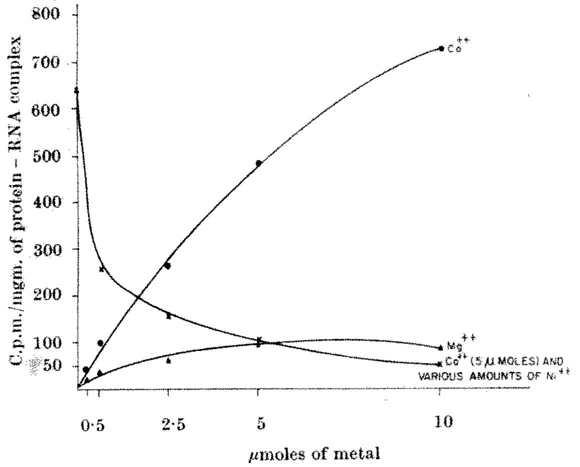

Fig. 1. Effect of Mg^{++} and Co^{++} with and without Ni^{++} on the incorporation of ^{14}C-leucine into lens protein and RNA. The assay method was the same as described above, except that varying amounts of Mg^{++} or Co^{++} were used; where the inhibitory effects of Ni^{++} were studied the latter's concentration varied as shown above. The concentration of Co^{++} was kept constant (5 μmoles). Every point represents an average of three separate experiments

In order to determine whether the effect of Co^{++} on the amino-acid incorporating systems previously described was an artefactual one (that is, due to some form of metal substrate complexing) the following experiments were performed.

(1) Two experiments were performed in which 5 per cent trichloracetic acid was added to the incubation media prior to the addition of the labelled amino-acid. After 1 hr. incubation the recovered activity was 4·6 and 6·6 c.p.m. per mgm. protein in contrast to the 540 and 432 c.p.m. obtained in the experimental reaction (cf. Table 1).

(2) There was no incorporation of these amino-acids when the incubations were performed at 0° C.

(3) Changes in the concentration of the enzyme (lens homogenate) resulted in a linear increase in the recovery of labelled amino-acids.

(4) Two experiments were performed in which the procedure was the same as originally described, but two final washings with ethyl mercaptan were added. There was no change in the recovery of ^{14}C-leucine following this procedure as compared with the values obtained when the ethyl mercaptan washings were omitted.

(5) In two experiments protamine sulphate was used instead of lens homogenate in the reaction mixture. No activity was recovered following the usual 1 hr. incubation.

(6) When Co^{++} activation was studied in rat liver microsomes and supernatant, in the presence of ATP and GTP, the count obtained was 6–8 c.p.m. and 75–80 c.p.m., respectively.

(7) The enzymic nature of the incorporating system was further indicated by the failure of this system to catalyse the incorporation of aliphatic amines such as cadaverine, putrescene and histamine labelled with carbon-14 into lens proteins. The conditions of these experiments were similar to those described by Sarkar *et al.*[14].

The results of these foregoing experiments indicate that the effects observed with Co^{++} were not artefactual. There is apparently a definitive increase in the uptake of amino-acids by lens protein and RNA which can be ascribed to Co^{++}.

The rat lens incorporating system is thus different from the rat liver incorporating system described by Zamecnik *et al.*[12]. The former does not require additional amounts of GTP, and unlike the latter requires Co^{++} instead of Mg^{++} for maximum activity. Furthermore, only 50–60 per cent of the capacity of lens protein–RNA system to incorporate amino-acids into lens proteins could be abolished by treatment with RNase prior to the addition of amino-acids. Another important property of the rat lens incorporating system is the remarkable ability of its RNA to bind amino-acids. About 80 per cent of the total amino-acid incorporated into material precipitable by trichloracetic acid is retained even after a 2 hr. incubation of the amino-acid with the rat-lens homogenate; in contrast, in the rat liver incorporating system a relatively high percentage of total amino-acid, found in TCA-precipitable material, is characteristically found in the protein fraction. Experiments are now in progress to determine whether the effect of Co^{++} can be obtained in a system in which a full complement of amino-acids are used in addition to the specific labelled ones.

Degradation of Deoxyribonucleic Acid in *Escherichia coli* Cells treated with Mitomycin C

IT has been shown[1,2] that treatment of growing cells of *E. coli B* (strain 9637 from A.T.C.C.) with mitomycin *C* (MC) results in inhibition of deoxyribonucleic acid (DNA) formation. The synthesis of ribonucleic acid (RNA) and protein was unaffected at low levels of MC. The addition of MC in higher concentrations also blocks the synthesis of RNA and protein.

In our work on the mode of action of antibiotics upon microbiological systems[3-5]—especially on nucleic acids—we have investigated the influence of MC on DNA, RNA and protein present in cells of *E. coli B* at the end of the logarithmic phase of growth. The strain of *E. coli B* was sensitive to MC (Fig. 1). Cells grown in a salt-glucose synthetic medium for 12 hr. at 37° C. and at pH 7·0 with aeration were then treated with increasing amounts of MC. Turbidity, protein, DNA and RNA were estimated in aliquots of bacterial suspensions immediately after the addition of MC and after 4 hr. and 8 hr. of incubation at 37° C. The pH was controlled and was found to be constant during the experiment.

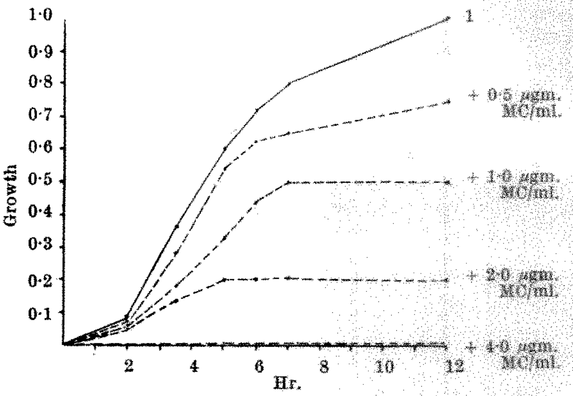

Fig. 1. Growth of *E. coli B* without (——) and with increasing amounts of mitomycin *C* added to the incubation medium (– – –). Turbidity measured at 578 mμ

Turbidity was measured photometrically at 578 mμ. Ribonucleic acid and deoxyribonucleic acid were determined after extraction (15 min. at 90° C. with 0·5 *N* perchloric acid) from acid-insoluble precipitates of bacteria with orcinol and diphenylamine respectively. The residue remaining after extraction of DNA and RNA was analysed for protein with the biuret method. The analytical values obtained in the untreated controls at the end of the experiment (8 hr.) were set at 100 and all other values were relative to them.

After the logarithmic phase there is only a slight incline in growth of the untreated control during time of incubation (Table 1). Mitomycin added to the incubation medium at the end of the logarithmic phase of growth caused a marked drop in DNA content. After 4 hr. incubation with 2·5 μgm. MC/ml. the DNA content was reduced to 60 per cent and after 8 hr. to 37 per cent.

During this time turbidity and protein content remain constant, whereas the RNA content shows only a slight decline. Furthermore, no lysis of the cells could be observed as indicated by cell count. The bacterial suspension contained 1×10^9 cells/ml., corresponding to an optical density of 1·00 at 578 mμ. The possibility that degradation of DNA was caused by induction of phage during incubation with MC—as is the case with the lysogenic *E. coli* strain K_{12} (ref. 6)—was excluded by electronmicroscopical and microbiological methods.

The remaining supernatants, after precipitation and centrifugation of DNA, RNA and protein, were checked for ultra-violet absorbancy. Aliquots taken just after the addition of MC were used for reference and the corresponding aliquots taken after 4- and 8-hr. incubation were compared with them. During incubation with MC, substances with an absorption maximum at 260 mμ appear and the ΔE values increase with increasing amounts of MC. This effect

Table 1. EFFECT OF MITOMYCIN *C* ON *E. coli B*. MITOMYCIN *C* WAS ADDED AT THE END OF LOGARITHMIC PHASE OF GROWTH (12 HR.)

Time	μgm. MC/ml.	Turbidity (per cent)	Protein (per cent)	DNA (per cent)	RNA (per cent)	ΔE_{260} mμ

	1·00	89	93	49	83	0·800
	2·50	89	105	37	76	1·000

may be caused partially by degradation products of DNA. A more detailed analysis of the acid-soluble fraction is now in progress.

These results are examples from a series of experiments under various conditions. Longer incubation of *E. coli B* cells with MC caused degradation of RNA and protein too. No degradation occurred when deoxyribonucleic acid from calf thymus and nucleic acid from herring sperm were incubated with MC *in vitro* under the same conditions as described here.

Takagi and Sekiguchi postulated that the inhibition of DNA formation in growing cells of *E. coli B* treated with MC is caused by an attack on synthesizing steps during DNA formation. However, they could not find any influence of MC on the polymerizing Kornberg enzyme. Furthermore, the block in DNA synthesis induced by MC was not overcome by the addition of thymine, thymidine or a mixture of deoxyribonucleotides to the medium.

The question arises: Is the inhibition of DNA formation in *E. coli B* treated with MC really caused by an attack in the synthesizing steps during DNA formation? The results presented here show that MC, under the experimental conditions described above, acts on the depolymerization of DNA*. If, in the presence of low levels of MC in the incubation medium of growing *E. coli B* cells, the synthesized DNA is partially degraded, the resulting picture is a block in DNA formation.

* *Note added in proof.* Tatum and co-workers obtained similar results (see ref. 7).

Ethanol Stimulation of Oxidative Metabolism in *Euglena gracilis*

Euglena gracilis, a flagellate protozoan, utilizes acetate and ethanol as energy and carbon sources. The acetate metabolism of *Euglena* grown on ethanol differs from that grown on acetate. Ethanol-grown cells have a rate of acetate oxidation at *p*H 7·0 lower than that of acetate-grown cells[1]. However, ethanol-grown cells incubated in the presence of acetate for about 80 min. often adapt to acetate, taking on characteristics similar to those of acetate-grown cells[1,2]. Thus, it was considered of interest to determine the respiration of *Euglena* in the presence of both acetate and ethanol.

Experimental and stock cultures of a streptomycin-bleached strain, *SM–LI*, of *Euglena gracilis* var. *bacillaris*, were grown axenically on the defined Cramer–Myers medium[3] with 0·061 *M* acetate as the sole carbon source for growth. The cells were gathered during the logarithmic growth phase, centrifuged twice in basal Cramer–Myers medium (minus acetate and vitamins B_1 and B_{12}), and re-suspended in a small volume of the basal medium. Cell concentrations ranged from 1·0 × 10^6 to 3·7 × 10^6 cells per flask. Absolute ethanol, in the amounts shown in Table 1, was added to Cramer–Myers medium which was then pipetted in 1-ml. quantities into the side-arms of the respiration flasks. The acetate concentration (0·061 *M*) was held constant in all experiments. Respiration-rates were determined by the direct method of Warburg[4]. After the substrate was tipped in, readings were taken at 10-min. intervals for 60 min. Respiration-rates were measured as µl. $O_2/10^6$ cells/hr. and are reported as per cent of the acetate control. All other conditions were as reported previously[5].

Table 1. ETHANOL AND ACETATE RESPIRATION* OF INTACT, ACETATE-GROWN *Euglena*

Average Qo_2 for the acetate control (no ethanol) was 22·8 µl. $O_2/10^6$ cells/hr. Acetate concentration (0·061 *M*) was constant in all experiments. The control for each experiment was standardized at 100 per cent

Ethanol molarity	No. of experiments	Average percentage of control
0	5	100·0
6·83 × 10^{-2}	4	108·0
3·41 × 10^{-2}	3	112·0
1·71 × 10^{-2}	3	122·0
3·41 × 10^{-3}	5	129·0
6·83 × 10^{-4}	4	113·0
3·41 × 10^{-4}	4	102·0
1·71 × 10^{-4}	3	97·2
3·41 × 10^{-5}	3	97·5

* Gas phase, air; temperature, 26·5° C.

It is evident from Table 1 that the respiration of *Euglena* in the presence of acetate is stimulated by ethanol, a finding not reported before in the literature. The maximum effect of ethanol in these experiments occurs at a concentration of 3·41 × 10^{-3} *M*. Higher and lower concentrations of ethanol result in a decreasing effect on the respiration of *Euglena*.

It appears that the ethanol may be affecting the cells by being oxidized within the cells to acetate, which in turn could enter the citric acid cycle or, perhaps, stimulate the formation of lipids. Bearing on this problem is a recent observation[6] which indicates that, in *Euglena* grown in the presence of both acetate and ethanol, more acetate carbon is assimilated into protoplasm than is oxidized as compared with cells grown in the presence of acetate alone. Although it has not been determined what substances are being formed in *Euglena* cells under these conditions, further work with labelled acetate and/or ethanol should help to explain these observations.

A Factor associated with 'Visking' Tubing capable of Antagonizing Insulin

DURING the investigation of the insulin antagonism associated with human serum albumin[1], 'Visking' tubing (Visking Corporation, Chicago, U.S.A.) was used for ultrafiltration and dialysis of protein solutions. The tubing itself has since been found to give rise to a substance which antagonizes insulin and which appears in the following circumstances:

Table 1. EFFECT OF DIALYSATES AND ULTRAFILTRATES FROM 'VISKING' TUBING ON THE GLUCOSE UPTAKE OF RAT DIAPHRAGMS, WITH AND WITHOUT THE ADDITION OF INSULIN TO THE INCUBATION MEDIUM

Mean glucose uptake above basal-level* ± *S.E.* (mgm. glucose per 100 ml. per 10 mgm. diaphragm)			
Buffer + insulin‡	Dialysate or ultrafiltrate in buffer† + insulin‡	Dialysate or ultrafiltrate in buffer† alone	Retentate in buffer† + insulin‡
16·58 ± 0·73 (10)	5·33 ± 0·86 (11)	−2·3 ± 1·5 (8)	715·90 ± 1·13 (3)

Number of experiments in parentheses.

* Amount of glucose taken up by the diaphragms when no insulin is added to the medium.

† Dialysates, ultrafiltrates and retentates were evaporated to dryness *in vacuo*, then dissolved in 9 ml. buffer for assay.

‡ Insulin added to make final concentration of 1,000μ units/ml.

(1) When distilled water is ultrafiltered through 7-ft. of heavy grade 'Visking' tubing (27/32 in. inflated diameter) supported by 'Terylene' net, under a negative pressure of 40–50 cm. mercury, over a period of three days. (2) When 7 ft. light grade 'Visking' tubing (18/32 in.) is filled with water and suspended in changes of distilled water for 2–7 days, that is, used as dialysis tubing.

The ultrafiltrate or dialysate is evaporated to dryness *in vacuo*, and the residue when dissolved in buffer[2] is found to antagonize the action of insulin in the rat diaphragm assay system[3]. Under these conditions there is no significant reduction in the normal glucose uptake (Table 1, column 3). If the wider tubing is used as a true dialysing membrane, for example the removal of trichloracetic acid and ethanol, there is no trace of this antagonist in the retentate after dialysis (Table 1, column 4).

We attempted to extract the insulin inhibitor from the 'Visking' tubing before use to avoid interference with the true insulin antagonist associated with albumin, which is dialysable. Soaking for 6 days in cold water extracted relatively little of the antagonist, for subsequent dialysates or ultrafiltrates of distilled water through the treated tubing continued to inhibit insulin action. Continuous internal and external circulation of cold water for 3 days using the wider tubing gave a similar result (Table 2). It is seen that the wash was not always collected, since more importance was attached to the effects obtained from subsequent dialysis and ultrafiltration.

Table 2. COLD AND HOT WATER WASHING OF 'VISKING' TUBING IN AN ATTEMPT TO REMOVE THE INSULIN ANTAGONIST

Experimental procedure	Mean glucose uptake above basal-level* ± *S.E.* (mgm. glucose per 100 ml. per 10 mgm. diaphragm)		
	Buffer + insulin†	Wash + insulin†	Dialysate or ultrafiltrate + insulin†
Cold water for 6 days			
18/32 in. 'Visking'	17·15 ± 1·05 (2)	3·2 (1)	11·75 ± 0·25 (2)
27/32 in. 'Visking'	22·7 ± 0·0 (2)	3·4 (1)	18·05 ± 0·75 (2)
Continuous circulation of cold water for 3 days			
27/32 in. 'Visking'	14·7 (1)	(—)	7·95 ± 0·15 (2)
Water at 80° C. for 1 hr.			
18/32 in. 'Visking'	18·40 ± 0·43 (4)	3.25 ± 1·50 (4)	16·85 ± 0·74 (4)
27/32 in. 'Visking'	20·97 ± 0·15 (3)	—	11·7 ± 1·6 (2)
Boiling in water for 30 min.			
27/32 in. 'Visking'	14·62 ± 0·77 (5)	−1·95 ± 0·50 (4)	12·58 ± 1·42 (4)

Each horizontal line represents one complete series of experiments, the figures in parentheses indicating the total number of separate determinations for each series.

* Amount of glucose taken up by the diaphragms when no insulin is added to the medium.

† Dialysates, ultrafiltrates and retentates were evaporated to dryness *in vacuo*, then dissolved in 9 ml. buffer for assay.

Soaking the 'Visking' tubing in hot water for 1 hr. also gave rise to washes inhibiting insulin action. With the lighter grade of tubing (18/32 in.) no significant insulin antagonism could be detected afterwards in the dialysate. In contrast, the ultrafiltrate of the heavier grade tubing was only rendered completely free of the antagonist if the tubing were first boiled for 30 min. (Table 2). In this case, the concentration of antagonist in the wash was probably high, and there appeared to be some inhibition of the normal glucose uptake in addition to the inhibition of insulin action. No check was made for any change in porosity of the tubing which may have resulted from the boiling.

The antagonistic substance may well be a hydrolysis product of sulphur, since 'Visking' tubing is stated to contain up to 0·1 per cent sulphur, partially extracted by a hot aqueous wash (manufacturer's specifications). However, we do not intend to investigate this further, being more concerned with the isolation and characterization of the previously reported hcrmone-dependent insulin antagonist associated with plasma albumin[4].

Calcium and Magnesium Contents of Various Secretions entering the Digestive Tract of Sheep

THE endogenous fæcal excretion of calcium and magnesium is derived from the various digestive secretions and the desquamated epithelial cells of the alimentary tract. The relative proportions of these two fractions is unknown, but the fact that in calves[1] endogenous fæcal excretion of magnesium increases during the first few weeks of life suggests that the contribution by the digestive juices is important. There is very little information on the calcium and magnesium content of the digestive secretions of ruminants beyond the values of 1·6–3·0 and 0·6–1·0 mgm./100 ml. for calcium and magnesium respectively in mixed saliva of sheep[2]. For this reason estimates of the probable quantities of these elements secreted into the alimentary tract of sheep were made. Calcium and magnesium were estimated in solutions of the ashed secretions.

The composition of the secretions collected from the various preparations is given in Table 1 and the daily output of calcium and magnesium as a result of these secretions has been assessed in Table 2 using representative volumes per 24 hr. of the various salivary secretions[3], gastric juice[4] and bile[5,6]. The range given for bile varied from 400 to 1,140 ml. per 24 hr., which may be accounted for by the fact that in some experiments collected bile was not returned to the duodenum. A daily volume of 1 litre was considered reasonable. Estimates of the daily secretion of pancreatic juice[5,7,8] vary from 275 to 600 ml., and a conservative value of 300 ml. was used in the with

Table 1. CALCIUM AND MAGNESIUM CONTENT OF VARIOUS SECRETIONS FROM THE SHEEP'S DIGESTIVE TRACT

Secretion	No. of animals examined	No. of samples analysed	Calcium* (m.equiv./l.)	Magnesium* (m.equiv./l.)
Parotid saliva	9	12	0·74 (0·30–1·75)	0·45 (0·17–1·32)
Submaxillary saliva	8	10	1·88 (0·96–2·66)	0·50 (0·10–1·00)
Residual saliva	1	2	1·26 (1·12–1·40)	1·36 (1·06–1·66)
Gastric juice	2	45	1·68 (1·04–2·20)	0·66 (0·52–0·88)
Bile	3	30	4·56 (1·76–8·94)	1·76 (0·50–3·90)
Pancreatic juice	2	26	4·74 (3·96–5·82)	1·13 (0·66–2·38)
Brünner's glands	2	12	2·82 (2·56–3·18)	0·90 (0·68–1·22)
Cæcum	1	5	3·64 (2·24–5·66)	2·53 (1·24–3·26)
Mixed secretions:				
Bile + pancreatic juice + Brünner's glands	2	38	3·40 (1·08–6·32)	1·48 (0·20–4·32)
Bile + pancreatic juice	1	30	4·47 (3·60–5·84)	1·12 (0·72–1·44)

* Figures in parentheses denote maximum and minimum concentrations found.

given in Table 2. The volumes representing cæcal secretion and the secretions from Brünner's glands were obtained from the volumes collected from a cæcal pouch representing about half the whole organ (prepared by Dr. R. N. B. Kay) and from an isolated loop of duodenum which excluded the common opening of the bile and pancreatic ducts. The secretions of the cæcum have previously been estimated to amount to 180 ml. a day[8], a figure that is similar to the value given in Table 2. The calcium and magnesium contents of the secretions of the remainder of the small and large intestine were not estimated.

It has been calculated that a 40-kgm. sheep would contain respectively 16 and 28 m.equiv. of extracellular magnesium and calcium by assuming that the volumes of plasma and interstitial fluid represent 5 and 15 per cent of the body-weight respectively, and that the concentrations of calcium and magnesium in interstitial fluid are equivalent to the concentrations of ultrafilterable calcium and magnesium in plasma. These values are of the same order as the calculated amounts of these elements entering the digestive tract (Table 2). Calcium and magnesium secreted into the alimentary tract will be excreted in the fæces of the animal if they are not re-absorbed. It is interesting in this respect that the estimated total secretion of magnesium is of the same order as values reported in the literature for the daily endogenous fæcal magnesium in sheep, and as the contribution of magnesium by the secretion of the small intestine has been ignored, some re-absorption presumably occurs.

Table 2. TOTAL INFLUX OF CALCIUM AND MAGNESIUM IN THE SECRETIONS OF THE DIGESTIVE TRACT

Secretion	Estimated daily volume* (litres)	Daily secretion of calcium (m.equiv.)	Daily secretion of magnesium (m.equiv.)
Parotid saliva	5	3·70	2·25
Submaxillary saliva	0·5	0·94	0·25
Residual saliva	5	6·30	6·80
Gastric juice	5	8·40	3·85
Bile	1	4·56	1·76
Pancreatic juice	0·3	1·42	0·34
Brünner's glands	0·4	1·13	0·36
Cæcum	0·2	0·73	0·51
Total	17·4	27·18	16·12

* Figures arrived at from literature; for references, see text.

It would seem reasonable to assume that proportionately similar amounts of calcium and magnesium enter the bovine digestive tract. Analysis of two samples of parotid saliva revealed calcium and magnesium concentrations within the range of those found for sheep. Radioactive techniques have also demonstrated that circulating calcium is secreted into all parts of the bovine digestive tract, particularly the small intestine.

There is evidence that absorption from the digestive tract is an important factor contributing to the maintenance of magnesium concentrations in extracellular fluids of the adult ruminant, and magnesium balance studies on dairy cattle during their transfer from winter diets to diets of spring grass suggest that a reduced dietary intake of magnesium, coupled with a lower availability, is an important factor in the development of hypomagnesæmia[9]. The present investigations demonstrate that, should absorption of magnesium from the digestive tract be impeded, the continued secretion of magnesium in digestive juices would contribute to a rapid loss of extracellular magnesium.

This work was carried out at the Rowett Institute during the tenure of a scholarship from the Ministry of Agriculture. I wish to thank Dr. A. T. Phillipson for preparing the isolated loops of duodenum, Mr. R. W. Ash and Dr. R. N. B. Kay for providing samples of gastric juice and saliva respectively. Samples of bile and pancreatic juice were also kindly made available by Mr. F. A. Harrison, Institute of Animal Physiology, Babraham, Cambridge.

Erythrocyte Glucose-6-Phosphate Dehydrogenase Deficiency in West Africa

EVIDENCE is accumulating that sex-linked inherited deficiency of erythrocyte glucose-6-phosphate dehydrogenase is common in Central Africa. Frequencies of 15–30 per cent have been recorded in males living in malarious parts of the Belgian Congo[1], Nigeria[2] and East Africa[3]. In non-malarious parts of East Africa frequencies of 3 per cent or less have been found[3], and in South African Bantu the frequency is about 2 per cent[4].

The present investigation was undertaken in order to ascertain the distribution of this trait in West Africa. Males only were examined. Blood specimens were obtained from northern Nigerians through the courtesy of Dr. H. M. Archibald and Dr. C. G. Berry, Kano. The majority of subjects were Hausa, but small numbers of Fulani and other tribes were included. The samples from southern Ghana were obtained from two schools near Accra; 64 were Akim and the rest Ga.

Table 1. FREQUENCY OF GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY IN WEST AFRICANS

Locality	No. tested	No. of enzyme deficient	Percentage of enzyme deficient
Northern Nigeria	136	28	20·6
Southern Ghana	96	23	24·0
Gambia	103	16	15·5

The Gambian sample was taken from adult Mandinka living at Keneba in the West Kiang District of the Gambian Protectorate. Blood specimens were collected into acid-citrate-dextrose and sent in thermos flasks to London for testing. Glucose-6-phosphate dehydrogenase activity in erythrocytes was assayed by the technique of Motulsky. The results are shown in Table 1. All three groups showed enzyme deficiency, the frequency being highest in the sample from southern Ghana. These findings suggest that the enzyme-deficiency gene has a widespread distribution in West Africa. Tests on subjects such as the southern Liberians, who show low frequencies of hæmoglobins *S* and *C*, would be of interest.

A New Technique of Chromatography and Ionophoresis on Ion-exchange Paper. Application to Separation of Compounds of Toxicological Interest : Separation of a Mixture of Promazine, Quinine, Sulphacetamide and Acetophenetidin

IN two previous communications, we[1,2] have shown that a mixture of phenobarbitone, acetophenetidin, salicylate and *p*-acetylaminophenol can be separated in 60–75 min. by a combined technique of chromatography and ionophoresis on Whatman ion-exchange cellulose papers. We have now been able to effect the resolution of a mixture of basic and neutral drugs, namely, promazine, quinine, sulphacetamide and acetophenetidin.

This separation was achieved by applying solutions of these drugs to a sheet of diethylaminoethylcellulose paper and carrying out chromatography in a 0·1 *M* solution of the disodium salt of ethylenediaminetetraacetic acid for 20 min. At the end of this period the wet sheet was subjected to ionophoresis at a constant current of 10 m.amp. for 30 min. Both the chromatography and the ionophoresis were carried out in the same tank as described previously[1,2].

Fig. 1 shows the results of this experiment, from which it is seen that chromatography effects a separation into three parts, namely, promazine, quinine and a mixture of sulphacetamide and acetophenetidin. The sulphacetamide and acetophenetidin are quite clearly separated by ionophoresis. Examination of the wet paper in 254 mμ light shows promazine as a blue fluorescent spot, sulphacetamide as a light-blue absorbing spot and acetophenetidin as a dark-purple absorbing spot. Quinine is not visible on the wet paper. After drying the paper, which takes 3–4 min. with a hair-dryer, the promazine shows up as a brilliant yellow fluorescent spot. Quinine can be revealed as a bright blue fluorescent area by holding the paper over the mouth of a bottle of concentrated hydrochloric acid. The other two compounds show the same absorption colour as on wet paper.

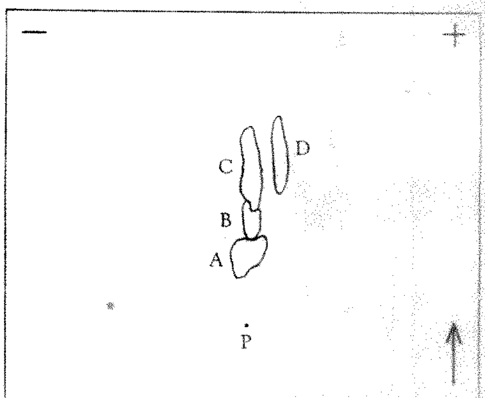

Fig. 1. Chromatography in 0·1 *M* ethylenediaminetetraacetic acid (20 min.) followed by ionophoresis in 0·1 *M* ethylenediaminetetraacetic acid (30 min., 10 m.amp.) of a mixture of promazine (*A*), quinine (*B*), acetophenetidin (*C*) and sulphacetamide (*D*). Mixture applied at point marked *P*. Arrow indicates direction of ascending solvent flow during chromatography

Detection of Small Quantities of 3,4-Benzpyrene directly from Chromatographic Paper

W. Davies and J. R. Wilmshurst recently published a report[1] on the detection of 3,4-benzpyrene, under the most favourable conditions, in a concentration of 10^{-9} gm./ml., using fluorescent spectrography (Hilger medium spectrograph).

We detected 3,4-benzpyrene directly from chromatographic paper in a quantity of 10^{-9} gm. on the chromatographic spot 60–90 mm.[2] in size. This was done by means of fluorescent spectrography (Hilger medium spectrograph, quartz optics). Actually we applied this procedure for detecting carcinogenic substances from mixtures of organic compounds as follows: an extract of coal soot, previously chromatographed on an alumina and silica column, was transferred to chromatographic acetylated paper[3] (Whatman No. 1). The spots developed on the chromatogram and which showed fluorescence were set directly facing the spectrograph slit and were illuminated with Wood's light (Quarzlampen, Hanau S., 300 *PL* 12; 220 V.; 2·5 amp., with Wood's glass filter). From one of the spectrographed spots we obtained the characteristic band spectrum of 3,4-benzpyrene.

This method, a combination of paper chromatography and fluorescent spectrography, facilitates greatly the detection of minute quantities of 3,4-benzpyrene and other fluorescent substances with a characteristic band spectrum, as in this way it is possible to avoid elution and subjecting the solution to spectrographic analysis.

PHYSIOLOGY

Effect of Feeding Two Levels of Dietary Calcium on the Growth of Broiler Chickens

The dietary requirements of calcium for chickens 0–18 weeks of age has been stated by the U.S. National Research Council[1] to be 1·0 per cent of the diet. In the United Kingdom commercial broiler rations contain at least 1·0 per cent but may contain up to 1·4 per cent. Davis[2] has presented evidence taken mainly from laboratory animal experiments indicating that the utilization of dietary protein, fat minerals, and vitamins may be reduced appreciably when the dietary calcium-level exceeds 1·0 per cent. When there is a limited intake of these nutrients, the inclusion of a high level of calcium in the diet may result in a clinical deficiency of them.

During the course of a large-scale experiment conducted by us it was possible to compare the effect of a diet containing approximately 0·8 per cent calcium with that of a diet containing approximately 1·3 per cent calcium on the rate and efficiency of gain of broiler chickens from one day to ten weeks of age. The results of this experiment provide further evidence that the efficiency of utilization of nutrients may be affected by the level of dietary calcium.

The experiment was conducted during March–May 1960 in a commercial-type broiler house designed to accommodate thirty pens, each housing one hundred and fifteen chickens from day old to ten weeks of age. Fifteen pens were allocated at random to a commercial broiler ration containing 1·35 per cent calcium, and the other fifteen pens of chickens were fed the same commercial ration with 0·83 per cent calcium. The latter ration was prepared by excluding calcium carbonate which normally was included to bring the level of calcium up to 1·0 per cent and above. The average levels of protein, calcium and phosphorus determined from five samples of each of the two rations are given in Table 1.

The average gain in live-weight, the average food consumption, and the average food conversion efficiency observed for the first six weeks and for the total ten weeks of the experiment are presented in Table 2. The birds fed the 0·83 per cent calcium diet grew 3·4 per cent faster up to six weeks and also up to ten weeks of age than the birds fed the 1·35 per cent calcium diet. These increases in gain were highly significant ($P<0·001$). Over the first six weeks there was no significant difference in food consumption, but over the total ten-week period the birds on the 0·83 per cent calcium diet consumed 2·7 per cent less food than the birds fed the 1·3 per cent calcium diet. This result was highly significant ($P<0·001$).

Table 1. Levels of Crude Protein, Calcium and Phosphorus in Rations

Ration	Crude protein (per cent)	Calcium (per cent)	Phosphorus (per cent)
0·8 per cent calcium	24·38 ± 0·49*	0·83 ± 0·08	0·52 ± 0·02
1·3 per cent calcium	23·63 ± 0·55	1·35 ± 0·11	0·53 ± 0·01

* *S.D.*

Table 2. Average Live-weight Gain, Food Consumption and Food Conversion Efficiency to Six Weeks and Ten Weeks of Age

Ration	Average gain (lb.)	Average food consumed (lb.)	Average food consumed/lb. live-weight gain (lb.)
	0–6 weeks		
0·8 per cent calcium	1·784*	3·606	2·022*
1·3 per cent calcium	1·725	3·601	2·087
S.E. of difference	± 0·014	± 0·047	± 0·017
	0–10 weeks		
0·8 per cent calcium	3·702*	9·334*	2·522*
1·3 per cent calcium	3.580	9·593	2·680
S.E. of difference	± 0·026	± 0·070	± 0·012

* $P < 0·001$

Over the six-week and ten-week stages, respectively, the birds fed the 0·83 per cent calcium diet converted their food 3·1 and 5·9 per cent more efficiently than the birds fed the 1·3 per cent calcium diet. Again these results were highly significant ($P<0·001$).

The birds were slaughtered at ten weeks of age, and the resulting carcases were graded according to normal commercial standards. The resulting data are presented in Table 3. There was no significant difference in the percentage of grade *A* or grade *B* carcases from the two experimental groups. However, the average carcase weight of birds fed the 0·83 per cent calcium diet was 3·9 per cent higher than that of the birds fed the 1·35 per cent calcium diet. This highly significant difference ($P<0·001$) resulted wholly from the increased weight of grade *A* carcases, since the weight of grade *B* carcases was not significantly affected.

Table 3. Carcase Quality Data

	0·8 per cent calcium diet	1·3 per cent calcium diet	*S.E.* of difference
Percentage of 'Grade *A*' carcases	78·0	82·4	± 2·29
Percentage of 'Grade *B*' carcases	22·0	17·6	± 2·29
Average weight of all carcases (lb.)	3·23*	3·11	± 0·02
Average weight of 'Grade *A*' carcases (lb.)	3·18*	3·06	± 0·02
Average weight of 'Grade *B*' carcases (lb.)	3·33	3·38	± 0·07

* $P < 0·001$.

It should be noted that although the 0·83 per cent calcium diet averaged 0·75 per cent more protein than the 1·35 per cent calcium diet, it is unlikely that this extra protein would have produced the effects which we have attributed to the difference in level of calcium.

Replacement of Adrenaline and Noradrenaline in the Adrenal Gland of the Rat, following Depletion and Redepletion with Reserpine

In a previous communication[1], we showed that reserpine causes a similar percentage loss of adrenaline and noradrenaline from the adrenal glands of the rat. Recovery of the catechol amines was slow, the amine content returning to normal within 21 days. The adrenaline content gradually returned to the control value, whereas the noradrenaline content first increased rapidly to a level well above normal at 7 days before falling to the control value.

To determine whether or not the recently replaced amines are bound in the medullary cells in a different manner from the amines that are not released during depletion, it was decided to redeplete the glands at 7 and 21 days. Redepletion at 7 days would detect any difference in the sensitivity to reserpine of the recently replaced amines and redepletion at 21 days would reveal whether or not the glands had, at that time, returned to normal with respect to their sensitivity to further reserpine treatment.

In this series of experiments groups of 5 male albino rats weighing 150–190 gm. were used. The treatment they received and the schedule of killing are shown in Table 1. Four 7-day and two 21-day redepletion experiments were performed. In all 88 groups of 5 rats were used. Each test group had its own control group also of 5 rats. In every instance except the 10-day point in the 7-day redepletion experiments, the control groups consisted of glands from rats given the reserpine solvent only. The control group for the 10-day point was obtained from the glands of rats given reserpine on days 0, 1 and 2 and killed on day 10 (Table 1). This represents the amine content that the redepleted group would have attained if it had not been further treated with reserpine. Subsequent to this 10-day point the controls were the normal solvent-injected rats, because it was found that the relative amounts of adrenaline and noradrenaline following redepletion were very similar to the amounts following the initial depletion. The glands were extracted with *N*/10 hydrochloric acid and assayed biologically as described previously[1].

As can be seen from Fig. 1, redepletion at 7 days caused a preferential loss of noradrenaline, the newly replaced amine thus appearing more susceptible to the action of reserpine than that remaining after the initial depletion. The subsequent recovery of the noradrenaline content was similar to the initial recovery, with a peak of noradrenaline occurring 7 days after the beginning of redepletion. The noradrenaline content was still slightly raised above the control-level at 21 days. The replacement of adrenaline was similar to that which occurred in the initial depletion experiments.

Table 1

Group	Day						
	Reserpine (1 mgm./kgm. subcutaneously) administered						Killed
Depletion	0	1	2				3
	0	1	2				7
	0	1	2				14
	0	1	2				21
7-day redepletion	0	1	2	7	8	9	10
	0	1	2	7	8	9	14
	0	1	2	7	8	9	21
	0	1	2	7	8	9	28
21-day redepletion	0	1	2	21	22	23	24
	0	1	2	21	22	23	28
	0	1	2	21	22	23	35
	0	1	2	21	22	23	42

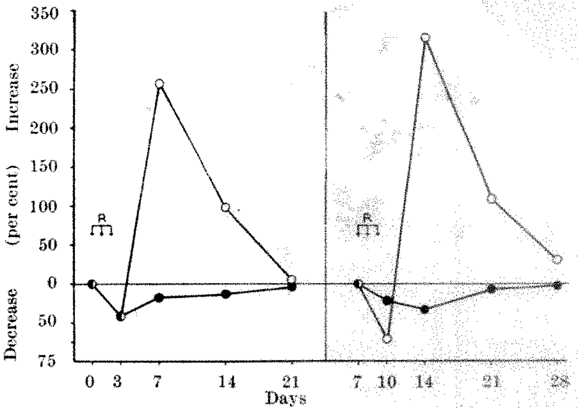

Fig. 1. Effect of redepletion with reserpine, at 7 days, on the adrenaline (●) and noradrenaline (○) content of rat adrenal glands. Left, depletion; right, redepletion

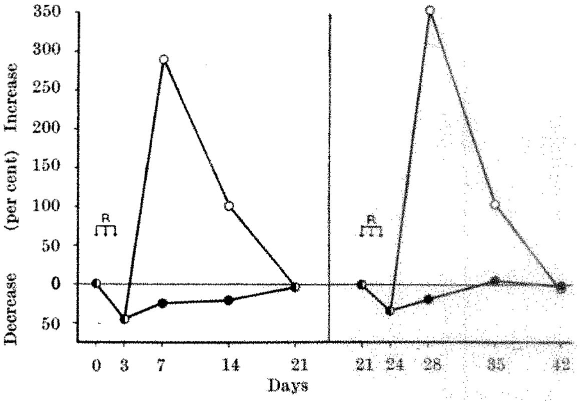

Fig. 2. Effect of redepletion with reserpine, at 21 days, on the adrenaline (●) and the noradrenaline (○) content of rat adrenal glands. Left, depletion; right, redepletion

Redepletion at 21 days (Fig. 2) caused losses of both adrenaline and noradrenaline similar to those which had occurred in the initial depletion experiments. The recovery of both amines was similar to that obtained initially with a peak of noradrenaline occurring at 28 days, that is, at 7 days following the beginning of redepletion.

Thus it appears that at 21 days the rat adrenal gland has recovered its normal catechol amine content following a 50 per cent loss produced by reserpine. However, the preferential loss of noradrenaline occurring when redepletion occurred at 7 days resulted in the noradrenaline content of the glands being depleted to the same absolute amount as that following the initial depletion. Thus it seems possible that, under the experimental conditions described here, it is the newly synthesized noradrenaline that is released before there is time for it to be converted to adrenaline.

We wish to thank Ciba Laboratories, Ltd., for generous gifts of reserpine.

Choline Acetylase in the Human Placenta at Different Stages of Development

It has long been known that there is acetylcholine in the human placenta[1] and Comline's[2] experiments established that choline acetylase, the enzyme which synthesizes acetylcholine, is in the placenta as well. The rate of acetylcholine synthesis, which he observed in extracts of acetone powders, made from mature placentæ, was between 0·6 and 0·75 mgm./gm. acetone-dried tissue/hr. Later in this laboratory, when a coupled enzyme system was used to provide an independent supply of the substrate acetyl-co-enzyme *A*, rates of 5–6 mgm./gm./hr. were obtained[3].

More recently we have re-measured the choline acetylase activity in mature and in some early placentæ (at 15, 24, 25 and 34 weeks of development) and have found that the choline acetylase activity of the early placentæ is higher than of those which reach term. But the activity even in the fully developed placentæ may be much greater than that reported earlier. Expressed (in terms of the chloride) as the amount of acetylcholine produced per gm. acetone powder, per hr., rates as high as 34 mgm. have been observed. Neither the fœtal blood nor the other fœtal membranes (amnion, umbilical cord) have any significant activity and the placental tissue washed free of blood is found to synthesize acetylcholine at the same or little higher rate than samples that contain blood. In this respect the enzyme differs from placental cholinesterase, since it appears from Ord and Thompson[4] that cholinesterase of the placental tissue and of the blood which it contains is about equal.

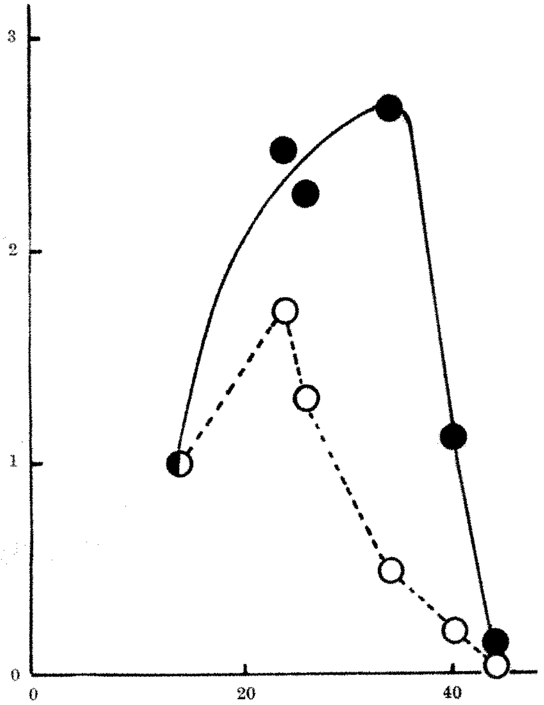

Fig. 1. Choline acetylase activity of the human placenta at different stages of development. The activity is determined by measuring the amount of acetylcholine produced by incubating an extract of a known quantity of tissue (equivalent to 1 mgm. or more) for 1 hr. at 38·5° C. in a system containing coenzyme *A*, acetylphosphate, phosphotransacetylase, choline, *l*-cysteine, potassium chloride, magnesium chloride, eserine sulphate and sodium phosphate buffer (*p*H 6·9). The ordinate is the amount of acetylcholine expressed as gm. acetylcholine-chloride and the abscissa is the developmental age of the placenta in weeks. ○, activity per 100 gm. of tissue; ●, activity per total weight of organ

By comparison with the mature placentæ those in which development had been interrupted at an early stage had extraordinarily high concentrations of choline acetylase. The highest activity was exhibited by a placenta thought to be 24 weeks old. Acetone powders made from this specimen had an average activity of 130 mgm. acetylcholine-chloride/gm./hr., equivalent to 17·1 mgm./gm. fresh tissue and a total activity for the whole organ of about 2·0 gm./hr. The specific activity of the extracts, or the amount of acetylcholine formed per mgm. of protein was 7·6 μM. So far as we are aware, this is the highest activity yet reported for any vertebrate tissue.

Fig. 1 shows how both concentration and total activity vary during development of the placenta. Although, as already mentioned, the concentration was highest at 24 weeks, the total amount was higher in the 34-week placenta. This suggests that the tissue containing the enzyme continues to grow for the first 24–34 weeks; but that some time before 34 weeks its growth is overtaken by the growth of other tissue elements with the consequence that its concentration falls. At the end of pregnancy, however, there is a decrease both in concentration and total amount of choline acetylase. This might be due either to involution and degeneration of the tissue containing the enzyme, or its denaturation. We have some evidence to suggest that this might occur by oxidation of its sulphydryl groups.

The results are of interest in that they strengthen the view that acetylcholine is of importance in placental function during pregnancy. Present indications are that the enzyme is located in the chorionic villi, in the cell layers separating maternal from fœtal blood. We are tempted to suggest therefore that its function is in the active transport of materials across this barrier.

We are grateful to Dr. J. Dickie at the County Maternity Hospital, Cambridge, for enabling us to obtain the placentæ and providing the clinical history of each.

Effect of Dimethyl Sulphoxide on the Cryo-tolerance of Mitochondria

The integrated structural and functional complexes of many biological entities have been conserved by freezing and storage at low temperatures. The cryo-tolerance of enzymes, viruses, bacteria, cells or tissues has been increased by the inclusion of 'protective substances' in the suspending medium[1,2]. We have reported recently the role of glycerol in protecting oxidative phosphorylation by suspensions of mitochondria during freezing or freezing and storage at low temperatures[3]. Dr. Audrey Smith, of the National Institute for Medical Research, London, suggested to us that dimethyl sulphoxide could replace glycerol. Our preliminary work has shown dimethyl sulphoxide to be equal to glycerol as a protective substance and to be superior in certain instances.

Suspensions of mitochondria were prepared from the livers of Sprague-Dawley rats. Two procedures were used: (1) mitochondria were prepared in isotonic sucrose containing dimethyl sulphoxide; (2) the total isolation of mitochondria was carried out in isotonic sucrose and dimethyl sulphoxide was added to the final suspension. Both preparations contained $3{\cdot}5 \times 10^{-5}$ M versene. All preparative steps were at 0–2°. Oxidative phosphorylation, using α-ketoglutarate as substrate, was measured by a modification[4] of the method of Lardy and Wellman[5]. Aliquots of suspensions of mitochondria, 0·8 ml., were placed in tubes and frozen slowly by immersion into −76° baths, 'dry ice' and acetone, with continuous swirling to distribute the mitochondria evenly on the sides of the tubes. Frozen suspensions were thawed by placing the tubes at 30° until melting was initiated; the samples were then kept in an ice-bath until used.

Because of the intimate contact between mitochondrial elements and the substance to be tested, the several concentrations of dimethyl sulphoxide were tested first by procedure 1. The concentrations of dimethyl sulphoxide of those preparations showing the best overall retention of oxidative phosphorylation after freezing or freezing and storage at low temperatures were tested further by procedure 2. The results of these investigations are shown in Table 1. Differences of 3 μmoles in the esterification of inorganic phosphate or 2 μatoms in the uptake of oxygen were statistically significant[3].

In procedure 1, oxidative phosphorylation was not affected in suspensions of mitochondria prepared in isotonic sucrose containing 5 or 10 per cent dimethyl sulphoxide. Phosphorylation was significantly lower in suspensions prepared in 20 per cent dimethyl sulphoxide; oxidation was not altered. Concentrations of 30 per cent were toxic. A significant decrease in oxidative phosphorylation was observed in suspensions containing 5 per cent dimethyl sulphoxide and frozen slowly at −76°; the decrease in phosphorylation was greater than that of the control frozen similarly. Freezing did not alter further oxidative phosphorylation by suspensions containing 10 and 20 per cent dimethyl sulphoxide. Phosphorylation was significantly less in all groups after storage at −65° for 18 days, averaging 11·7 per cent in relation to the values of frozen suspensions; oxidation was unchanged in groups exposed to 10 or 20 per cent dimethyl sulphoxide and significantly lower in the 5 per cent group.

In procedure 2, the values for oxidative phosphorylation by non-frozen, frozen or frozen and stored suspensions of mitochondria isolated in isotonic sucrose prior to the addition of dimethyl sulphoxide, in amount to give a 10 per cent solution, were not significantly different from that of the non-frozen control. Oxidative phosphorylation by non-frozen suspensions of mitochondria containing 20 per cent dimethyl sulphoxide was not different from the non-frozen control. The oxidative and phosphorylative capacities of the suspensions above following freezing or freezing and storage were not different from those suspensions containing 20 per cent dimethyl sulphoxide and prepared by the first procedure.

Neither 5 nor 10 per cent dimethyl sulphoxide nor glycerol affected adversely oxidative phosphorylation by suspensions of mitochondria (all references to glycerol are based on data in ref. 3). The losses in phosphorylation by suspensions of mitochondria prepared with 20 per cent dimethyl sulphoxide (procedure 1), were approximately one-half those observed when 20 per cent glycerol was used, being 16 and 32 per cent respectively; oxidation was affected similarly. No losses were found in oxidative phosphorylation by suspensions containing 20 per cent dimethyl sulphoxide. Suspensions prepared by procedure 2, and containing 20 per cent glycerol, on the other hand, lost approximately 25 per cent of their ability to carry out oxidative phosphorylation. Mitochondria exposed to 30 per cent glycerol (procedure 1), were inactivated; suspensions exposed to 30 per cent dimethyl sulphoxide retained their capacity for oxidative phosphorylation, but at a greatly reduced level. These results indicate that dimethyl sulphoxide is less toxic to mitochondria than glycerol.

Both 10 per cent dimethyl sulphoxide and glycerol protected fully oxidative phosphorylation by suspensions of mitochondria frozen slowly at −76°. In the case of the former, both procedures were equally effective; the latter, on the other hand, was effective fully only with procedure 1. At a diminished concentration (5 per cent), procedure 1, greater protection was observed with dimethyl sulphoxide. Thus, with comparable concentrations and techniques of application, dimethyl sulphoxide was equal or superior to

Table 1. EFFECTS OF SEVERAL CONCENTRATIONS OF DIMETHYL SULPHOXIDE ON OXIDATIVE PHOSPHORYLATION BY SUSPENSIONS OF MITOCHONDRIA FROZEN SLOWLY AT −76° OR FROZEN SLOWLY AT −76° AND STORED AT −65° FOR 18 DAYS

* Mitochondria prepared in isotonic sucrose containing dimethyl sulphoxide.
† Dimethyl sulphoxide added to isolated mitochondria suspended in isotonic sucrose.

glycerol for protecting the oxidative and phosphorylative capacities of suspensions of mitochondria following freezing.

No losses in oxidative phosphorylation were found when 10 per cent glycerol (procedure 1), or 10 per cent dimethyl sulphoxide (procedure 2) were used to protect mitochondria during storage at −65° for 15 and 18 days respectively, the only comparison possible at present. However, procedure 2 is allied more closely than procedure 1 to the methods of preserving biological materials, that is, putting cells and tissues in solutions containing the protective substance prior to freezing and storage. Therefore, it is likely that dimethyl sulphoxide, by protecting mitochondrial elements with greater efficiency than glycerol, will be found to protect cells more effectively than glycerol from freezing and storage at low temperatures.

This investigation was supported, in part, by the U.S. Atomic Energy Commission, Contract No. *AT* (11–1)–596. One of us (D. G.) holds a Senior Research Fellowship (*SF*–89) from the National Institutes of Health, United States Public Health Service; the other (M. M.) is a predoctoral trainee, Pathology training grant, 2*G*–170, Division of General Medical Sciences, National Institutes of Health, United States Public Health Service.

Preservation of Mouse Bone Marrow at −79° C. with Dimethyl Sulphoxide

DIMETHYL sulphoxide was used by Lovelock and Bishop[1] to protect bovine erythrocytes against the damaging effects of freezing to, and thawing from, low temperatures. The bovine erythrocyte is impermeable to glycerol, which does not protect it from the damage caused by freezing. Dimethyl sulphoxide has recently been shown to protect mouse bone marrow from the damaging effects of freezing to −79° C. (ref. 2). After thawing, the protected cells retained between 50 and 60 per cent of their ability to synthesize lipids and proteins. Fluorescence microscopy with acridine orange revealed the presence of many intact erythroid and myeloid cells. It has now been demonstrated that mouse bone marrow stored for one month at −79° C. in the presence of dimethyl sulphoxide will prevent the death of lethally irradiated mice.

Bone marrow cells were obtained from the femora of 12-week old female mice of an inbred *CBA* strain. The cells were suspended in Parker '199' tissue culture fluid containing 33 per cent rat serum and 15 per cent (v/v) dimethyl sulphoxide. Ampoules containing 50×10^6 nucleated cells in 1 ml. were cooled slowly to −79° C. in the apparatus described by Polge and Lovelock[3]. Marrow cells were also frozen in the absence of dimethyl sulphoxide. After one month at −79° C., ampoules were thawed rapidly at +37° C. and the bone marrow cells injected intravenously into lethally irradiated mice.

Table 1. SURVIVAL OF LETHALLY IRRADIATED MICE INJECTED WITH ISOLOGOUS MARROW PRESERVED AT −79° C. FOR ONE MONTH WITH DIMETHYL SULPHOXIDE

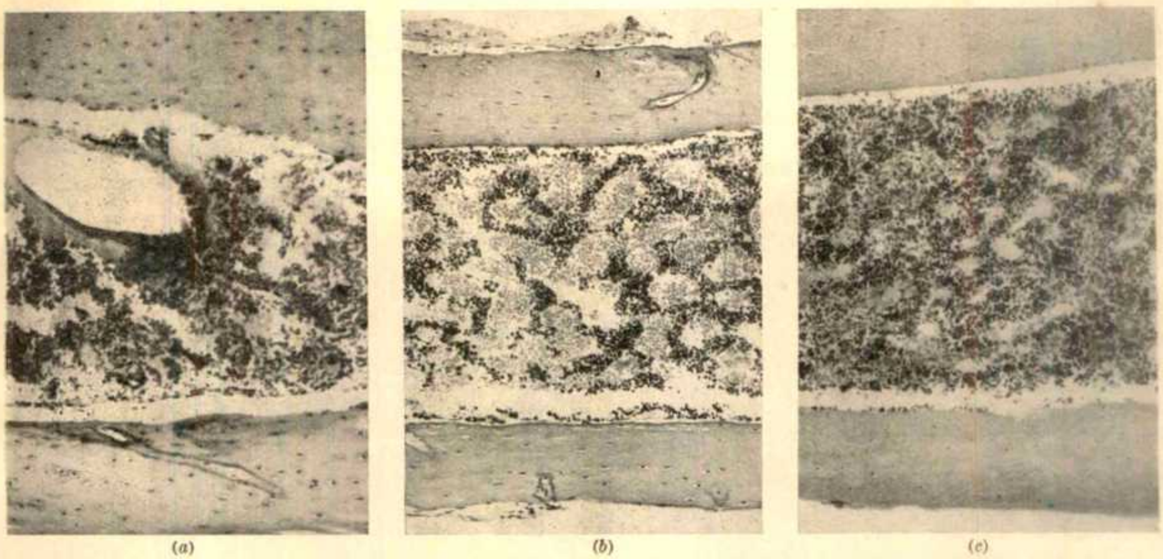
Treatment (No. of nucleated cells)	No. of mice	No. living at 30 days	Survival (per cent)
Controls, injected with Parker/serum/dimethyl sulphoxide medium (0·5 ml.)	19	0	0
Fresh marrow; 5×10^6 in 0·5 ml. of Parker/serum/sulphoxide	18	15	83
Marrow frozen without dimethyl sulphoxide; 5×10^6 in 0·5 ml. of Parker/serum	26	2	7·7
Marrow frozen in the presence of 15 per cent dimethyl sulphoxide; 5×10^6 in 0·5 ml. of Parker/serum/sulphoxide	27	19	70

Female *CBA* mice of the same strain and age as the donor animals were irradiated with 1,000 r. of X-rays (LD_{99} at 30 days). The X-ray apparatus used was a Newton Victor *G* × 10 operated with the following factors: 120 kV.; 5·5 m.amp.: 1 mm. aluminium filter; dose-rate of 48 r. per min. Immediately after irradiation, the mice were allocated at random to four groups. One group received 5×10^6 fresh marrow cells; a second group received 5×10^6 cells which had been preserved at −79° C. for one month with dimethyl sulphoxide; the third group was injected with the same number of cells frozen for one month without dimethyl sulphoxide, and the last group was injected with Parker-serum-sulphoxide medium only. The number of mice alive 30 days post-radiation in the four treatment groups is shown in Table 1. These results indicate that marrow preserved by dimethyl sulphoxide at −79° C. is only slightly inferior to fresh marrow in preventing radiation death.

A second experiment was designed to study the hæmatological response of lethally irradiated mice to fresh marrow and preserved marrow. Mice were killed at intervals following the injection of different numbers of fresh cells and a standard dose of frozen cells preserved in dimethyl sulphoxide. Re-population of the marrow cavity of the femur was evident on the eighth day after irradiation in the group of mice which received the marrow frozen in the presence of sulphoxide (see Fig. 1). By the twelfth day the cellularity of the marrow was almost normal, and cells of all types, including megakaryocytes, were present. Mice which had been injected with the same number (5×10^6) of fresh marrow cells showed evidence of re-population of the femur between the sixth and seventh day. The femora of mice which had received marrow frozen in the absence of dimethyl sulphoxide and of those which had been injected with cell-free medium showed no signs of re-population and most of these animals were dead by the tenth day.

Leucocyte counts on the peripheral blood from these animals and of others which had been injected with smaller doses of fresh bone marrow are shown in Fig. 2. The leucocyte response of mice which had received frozen marrow preserved with dimethyl sulphoxide was slightly better than the response obtained with 1×10^6 fresh cells. This implies that more than 20 per cent of the myeloid stem cells in the frozen marrow sample were viable.

Blood leucocyte-levels were normal (greater than 9,000 per c.mm.) within 14 days in those mice treated with 5×10^6 fresh cells and within 17–18 days in mice treated with the same number of cells frozen in the presence of sulphoxide. In both cases, however, the



(a) (b) (c)

Fig. 1. Femora of X-irradiated mice (hæmatoxylin and eosin). (a) Untreated control 8 days after X-irradiation. (× 85); (b) treated with bone marrow stored at − 79° C.; 8 days after X-irradiation (× 67); (c) treated with bone marrow stored at − 79° C.; 12 days after X-irradiation (× 75)

differential counts were abnormal. Nearly 75 per cent of the leucocytes were polymorphs and only 25 per cent were lymphocytes and monocytes. This is almost a quantitative reversal of the normal differential blood picture.

Work is in progress to compare the hæmatological response of lethally irradiated mice with marrow preserved with glycerol and dimethyl sulphoxide.

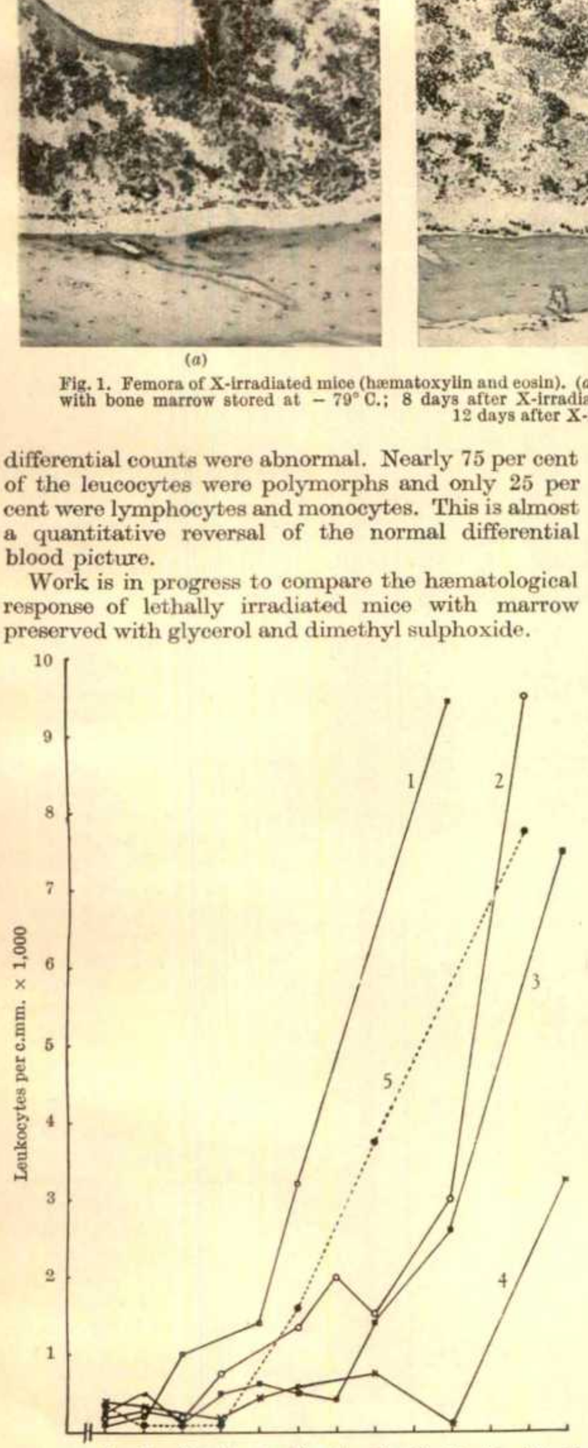


Fig. 2. Effect of fresh marrow and marrow preserved at − 79° C. with dimethyl sulphoxide on the recovery of blood leucocytes in lethally irradiated mice. (1) 5 × 10^6 cells; (2) 1 × 10^6 cells; (3) 0·5 × 10^6 cells; (4) 0·1 × 10^6 cells; (5) 5 × 10^6 frozen cells

I wish to thank Dr. A. U. Smith for useful suggestions.

Note added in proof. Since this work was completed, comparisons with marrow preserved with dimethyl sulphoxide and with 15 per cent glycerol have indicated the superiority of dimethyl sulphoxide as a low-temperature preservative agent. The number of animals which survived lethal X-irradiation when treated with either marrow preserved with glycerol or sulphoxide was about the same. The onset of reticulocytosis and the start of the leucocyte response, however, occurred about two days later in mice injected with 5 × 10^6 cells which had been kept for one month at −79° C. in the presence of 15 per cent glycerol.

Role of the Mucous Membrane in the Peristaltic Reflex in the Isolated Ileum of the Guinea Pig

Bülbring, Lin and Schofield[1] have presented evidence which suggested that receptors of the sensory neurones subserving the peristaltic reflex in the isolated small intestine of the guinea pig, rabbit and cat are present in the mucous membrane. Ginzel[2], on the other hand, showed that necrosis of the mucous membrane brought about by 30 per cent silver nitrate or 20 per cent tannic acid did not abolish the peristaltic reflex. He concluded that mucosal nerve fibres were not essential for this reflex.

When the peristaltic reflex is investigated by the technique of Trendelenburg[3], the fluid which distends the lumen and is then ejected by the peristaltic movement is not renewed during the experiment; thus any material which may be shed by the mucous membrane will accumulate in this fluid. If the preparation is left in the organ bath for some hours and the peristaltic reflex elicited at intervals, it may be noted that the fluid ejected from the lumen becomes increasingly turbid, and at the same time the intestinal wall appears more and more transparent. This suggested to us that a part of the mucous membrane is lost while the ileum is in the organ bath.

This possibility was tested in a series of experiments in which pieces of ileum were left in the organ bath for varying periods, during which the peristaltic reflex was elicited every 30 min. At the end of the experimental period the gut was fixed for histological examination.

Changes in the villi occurred as early as 30 min. after setting up the preparation and consisted of a swelling of the stroma of the villi, particularly at their tips (Fig. 1, *B*); at this stage most of the epithelial cells were still in place although they showed degenerative changes. Half an hour later (Fig. 1, *C*), the swollen distal ends of the villi had been shed into the lumen, where chains of epithelial cells were found. In the course of the next few hours more and more of the mucous membrane was lost until, after 18 hr., very little live mucosal tissue was left (Fig. 1, *D*–*F*). No obvious changes were observed in the muscle fibres.

The segments of the ileum from which the sections shown in Fig. 1, *B*–*E* were obtained, that is up to 8 hr. after setting up the preparation, still exhibited a normal peristaltic reflex. In the ileum which, after 18 hr. in the organ bath, had the histological appearance of Fig. 1, *F*, distension of the lumen elicited a reflex as late as 16 hr. after setting up the preparation. From these experiments it may be concluded that, if stretch receptors subserving the peristaltic reflex are present in the mucous membrane, they are situated in its basal layers.

HISTOCHEMISTRY

Histochemical Demonstration of Aldehydes by *p*-Phenylenediamine

A HIGHLY specific and sensitive reaction has already been proposed[1] for the microscopic detection of aldehydes in the tissues. Improvements have now been made which meet the needs of practical histochemistry.

The oxidation velocity of *p*-phenylenediamine with hydrogen peroxide is greatly increased by aldehydes[2]. Only nitriles, aldehyde ammonia and aldehyde bisulphite compounds behave similarly to aldehydes[3]. The black precipitate formed on the tissues as a consequence of this peroxidase activity of aldehydes in neutral solution was found suitable for microscopic observation after stabilization with gold chloride.

The following reagents are used: (1) 1 per cent *p*-phenylenediamine stock solution (to reduce storage oxidation, previously boiled water must be used and the solution kept in a tightly stoppered dark flask); (2) 1·5 per cent hydrogen peroxide; (3) 1 per cent gold chloride neutral solution.

The procedure used was as follows. Fix and section by any standard technique. Take sections down to distilled water in the usual manner and treat them for release of aldehydic groups (periodic acid was used in the present experiments). Wash thoroughly with distilled water. Before use, mix equal volumes of reagents (1) and (2) and immerse sections for 15 min. (operate in dark dishes, because light accelerates oxidation of *p*-phenylenediamine). Wash thoroughly with several changes of distilled water. Immerse in reagent (3) for 5 min. Wash, dehydrate and mount in the usual way

(Canada balsam). Structures containing aldehyde are stained bluish-violet.

The results obtained with *p*-phenylenediamine using sections treated in this way are comparable with those obtained with Schiff's reagent, though greater sensitivity and selectivity is obtained.

As a control on the selectivity of the method, the following reagents for blocking aldehydic groups were used before treatment with *p*-phenylenediamine: (1) 0·2 per cent 4-nitrophenylhydrazine solution in 50 per cent v/v ethanol containing 1 per cent sodium acetate, incubation for 2 hr. at 60° C.; (2) saturated hydroxylamine hydrochloride, ethanolic solution, 2 hr. at 60° C.; (3) 1 per cent aniline solution in 75 per cent v/v ethanol, 2 hr. at 60° C. All these reagents completely prevented the peroxidase oxidation of *p*-phenylenediamine.

PATHOLOGY

Growth of Tumours in Rats fed with 4-Dimethylaminoazobenzene injected with Homogenized Tumour mixed with Freund Adjuvant

THE enhancing (or *XYZ*) effect on the growth of tumour homografts in animals pre-treated with non-living donor tissue first described by Flexner and Jobling[1] led to many fruitful immunogenetic investigations in oncology. In order to explain the phenomenon, several working hypotheses have been evolved: the 'blockage' hypothesis was advocated by Medawar and co-workers[2] and Snell[3], 'immunoselection' by Hauschka and co-workers[4] and the hypothesis of some 'physiological' alteration in the tumour cells was argued by Kaliss[5]. According to experiments of Casey and co-workers[6], it is possible to enhance the tumour growth in the strain from which the tumour originated. It is difficult to explain these results on the hypotheses mentioned above.

I have tried to enhance the growth of indigenous tumours. Albino rats of mixed breed were subjected to a carcinogenic diet supplied with 4-dimethylaminoazobenzene. The daily dose of 3·5 mgm. of the drug per rat given during a period of 203 days induced liver carcinoma after a latent period of nearly 120 days after stopping the drug. The incidence of hepatoma was 68 per cent.

In the experiment to be described, 120 rats fed 4-dimethylaminoazobenzene for 203 days were divided at random into five groups and injected with normal liver tissue or liver carcinoma of the same origin, both mixed with Freund's adjuvant. The antigen mixture was heated on a water-bath at 60° C. for 45 min. No palpable liver tumour was present in animals at the time of injection, so it was assumed that the animals were in a pre-cancerous stage. The intracutaneous injections, 8 × 0·2 ml. of antigen mixture, were given along both flanks of the rats simultaneously on the fourth day after stopping the carcinogenic diet. The three intraperitoneal injections (1 ml. each of antigen mixture) were given at intervals of 1 week, the first being given on the same day as intracutaneous injections. On the twenty-second day after stopping the carcinogenic diet, the animals were killed, and diagnosis was by gross inspection and histological examinations of the liver.

Table 1. INCIDENCE OF CARCINOMA HEPATITIS IN PRE-CANCEROUS RATS TREATED WITH TUMOUR TISSUE AND NORMAL LIVER TISSUE MIXED WITH ADJUVANT

	Treatment				
	Intraperitoneal		Intracutaneous		
Animals	Tumour tissue	Liver tissue	Tumour tissue	Liver tissue	None
Pre-cancerous	12/24	0/24	0/24	0/24	0/24
Normal	0/20		0/18		

The results presented in Table 1 show that intraperitoneal application of the antigen mixture containing cancer tissue was in this instance only suitable for inducing growth promotion of the cancer. It is worth mentioning that inflammatory reaction in the abdominal cavity which occurs after intraperitoneal injection of adjuvant alone or mixed with some tissue was negligible in tumour-bearing rats in comparison with other animals injected intraperitoneally.

As already stressed[7], the enhancement of tumour growth and tumour graft may show a specific difference between cancerous and normal tissues. The effect of enhanced tumour growth produced by the stimulating effect of antibodies might be explained simply by assuming that antibodies are complementary bodies, which act on normal tissue by destroying it and on cancerous tissue on the contrary by enhancing its growth. Cachexia and enhanced tumour growth in cancer-bearing animals could thus be ascribed to a manifestation of the same process in tissues of different physiological and functional state. Further experiments are in progress to investigate the problem.

Interaction of Enzymes with Normal and Tumour Cells

WHEAT germ lipase (Worthington) has been shown[1] to reduce the adhesion of washed mouse ascites cells to glass. This was considered to be due to the adsorption of the enzyme on to the cell surface. The same lipase preparation has also been found[2] to inhibit the growth of hamster kidney tumour cells in tissue culture at certain concentrations (0·01–0·1 per cent), without inhibiting growth *in vitro* of hamster normal kidney epithelial cells from which the tumour was derived.

An investigation has been made into the cytological effects of lipase on these normal and tumour cells growing in tissue culture, using 'Anoptral' contrast microscopy. At an enzyme concentration of 0·1 per cent, the tumour cells showed extensive vacuolation

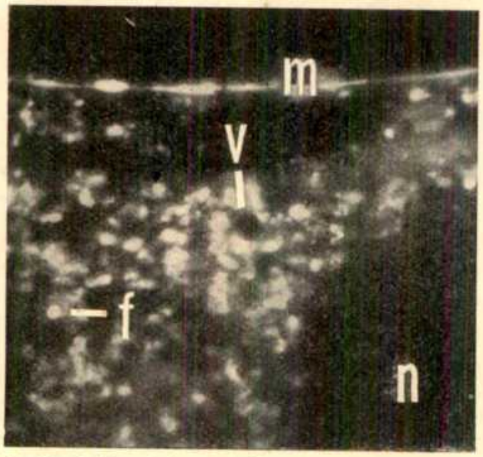

Fig. 1. Marginal part of a normal hamster kidney epithelial cell in a monolayer culture, 5 hr. after adding fluorescein-labelled lipase (0·1 per cent). Ultra-violet illumination (× 1,600). *f*, Fluorescent vacuole; *m*, cell membrane; *n*, nucleus; *v*, non-fluorescent vacuole

of the cytoplasm by the third day after addition. Such vacuolation was not found in treated normal cells.

The site of action of lipase has also been followed, by labelling it directly with the fluorescent dyes fluorescein and lissamine rhodamine *RB* 200 (ref. 3). The enzyme was assayed against triacetin before and after labelling, to check whether the conjugation procedure had destroyed its activity. It was found that the fluorescent conjugate showed half the aliesterase activity of the untreated enzyme. Schiller *et al.*[4] provide evidence that directly labelled protein conjugates are reasonably stable for at least 24 hr. under *in vivo* conditions.

Cultures were incubated in growth medium (0·25 per cent lactalbumin hydrolysate, 10 per cent calf serum, 0·001 per cent sodium bicarbonate) containing 0·1 per cent lipase conjugate. They were mounted in this medium without fixation and observed under a Reichert fluorescence microscope. In the normal cultures, many large and small droplets were taken in within the first few hours, and an intense staining of the cell membrane in some cells was observed 5 hr. after addition. Membrane staining was not observed before this period had elapsed, and was not seen later than 8 hr. after addition. Non-viable cells did not show staining of the cell membrane. As a control, lissamine rhodamine *RB* 200 was applied to growing normal cultures at the same concentration as in the conjugate-treated cultures. The dye was taken in as droplets, but did not stain the membrane.

Tumour cultures also took up many large and small droplets, but there was no obvious staining of the cell membrane, even in cells washed prior to treatment.

Lipase conjugate has also been applied to Landschütz ascites tumour cells at the same concentration, under both *in vivo* and *in vitro* conditions. About 5 per cent of the ascites cells took up pinocytosis droplets *in vivo* during the first day after intraperitoneal injection of the conjugate, but there was no staining of the membrane. Washed ascites cells after 2-hr. treatment with lipase conjugate *in vitro* did, however, show surface staining, confirming that the enzyme is adsorbed on to the surface of washed ascites cells.

Observations using fluorescent-labelled lipase indicate that the conjugate is readily taken up by pinocytosis within a few hours by normal hamster kidney and hamster kidney tumour cells *in vitro*, and by mouse ascites cells *in vivo*. The transient staining of the normal cell membrane, which has not been observed in the tumour cells, suggests that there is some accumulation of the enzyme preparation at the surface. Such an accumulation has not been detected with other fluorescent-labelled enzyme conjugates. The difference in vital staining between the normal and the homologous tumour cells provides further evidence for the altered properties of the tumour cell surface.

We wish to express our gratitude to Dr. R. D. Andrews and his staff of Glaxo Laboratories for preparing the cultures.

HÆMATOLOGY

Acetylcholinesterase and the Life-span of the Erythrocyte

The function of the relatively large amount of the enzyme acetylcholinesterase which is present in erythrocytes is unknown. The enzyme was thought to be essential for the maintenance of normal permeability of the erythrocyte[1], but experiments on cells deficient in acetylcholinesterase[2] have failed to demonstrate this function. Interest in red-cell acetylcholinesterase has been stimulated by the recent finding that in some patients with paroxysmal nocturnal hæmoglobinuria (P.N.H.) the enzyme is deficient[3]. The enzyme activity in patients with P.N.H. varies from 6–134 per cent of average normal activity[4], and there is a correlation between the degree of enzyme deficiency and some other features of P.N.H.[4]. It is thus possible that the shortened erythrocyte life-span in P.N.H. may be related to the enzyme deficiency, and that normal amounts of acetylcholinesterase are necessary for normal survival of erythrocytes.

To determine whether normal levels of acetylcholinesterase are necessary for normal erythrocyte life-span, the enzyme was inhibited *in vivo* in five hæmatologically normal subjects by the administration of octamethylpyrophosphoramide (OMPA) 5 mgm. daily, and erythrocyte survival measured with chromium-51. The administration of OMPA results in irreversible inhibition of erythrocyte acetylcholinesterase[5]. Erythrocyte acetylcholinesterase was measured according to the method of Michel[6]. Erythrocytes were labelled as described by Mollison and Veall[7] and the results expressed as the time taken for circulating radioactivity to reach 50 per cent ($T\frac{1}{2}$ ^{51}Cr). Mean cell-life was calculated after correcting for elution ($T\frac{1}{2}$ elution 64 days).

In three subjects, erythrocytes were labelled (on day 0) and OMPA administered from day 6 to day 13–18, during which time the enzyme activity was reduced to less than 50 per cent of the initial level. In spite of deficient acetylcholinesterase during the period of investigation (50 days), erythrocyte life-span was within normal limits in all subjects (Table 1). In two further subjects OMPA was administered for a period of 21 days before labelling the erythrocytes. The life-span of the erythrocytes was within normal limits in both subjects (Table 1).

Table 1

Case	Duration of administration of OMPA (days)	Erythrocyte acetylcholinesterase (Δ *p*H/hr.) Before OMPA	After OMPA	$T\frac{1}{2}$ ^{51}Cr (days)	Mean cell life (days)
1	7	0·66	0·32	28	110
2	7	0·79	0·36	33	111
3	12	0·98	0·32	32	113
4	21	0·72	0·25	36	120
5	21	0·68	0·35	29	114

Thus in five subjects where erythrocyte acetylcholinesterase was inhibited to levels comparable to those found in patients with P.N.H., shortening of erythrocyte life-span could not be demonstrated. These results suggest that normal amounts of the enzyme are not essential for the maintenance of red-cell life-span, and that the low levels of enzyme in P.N.H. do not directly contribute to the diminished erythrocyte life-span in the disease.

We wish to thank the Director, South African Institute for Medical Research, for facilities to carry out this work.

Fructose as a Component of the Fœtal Blood in Several Mammalian Species

In the examination of fœtal bloods from several mammalian species, Goodwin[1] suggested that fructose is a characteristic component of the fœtal blood of the Ungulata and Cetacea. We wish to support this generalization by reporting the presence of fructose in the fœtal blood and fœtal fluids of several further species within the order Ungulata, and the essential absence in a member of the Edentata.

The specimens from the dromedary were made available through Dr. W. R. M. Morton, of the Queen's University, Belfast, the sloth material obtained while one of us (A. St. G. H.) was in Brazil, through the kindness of Prof. Nelson Chaves, of the University of Recife. The remainder of the specimens were obtained by Mr. Tong and his staff at Whipsnade Zoological Park. Samples were obtained from the placenta at a variable interval of time after extrusion. The material was placed in bottles containing 100 mgm. powdered sodium fluoride and potassium oxalate in the ratio 1 : 3 and refrigerated pending transfer to the laboratory. After deproteinization, the filtrates were estimated for glucose and fructose by the glucose oxidase and resorcinol methods respectively. The concentrations obtained (Table 1) must be considered as minimal values, since there is evidence of a preferential utilization of glucose in the placenta after it is shed.

It is interesting perhaps to note that in the spectrum of mammalian species which have been examined by us and by others[2-4], in which fructose is present in substantial concentrations, all belong to a group of animals having either the epitheliochorial or syndesmochorial type of placenta. The latter type, typified by the sheep, is known from direct experimentation to produce fructose[5].

Transferrin-groups of Fœtal Calf-Serum

Intensive work on the occurrence of blood-group factors in embryos of cattle[1] led to the result that the pattern of blood-group factors, as special individual molecule structures, are genetically dependent and, consequently, are already fixed in the mother cells of the erythropoietic system. The substances of the blood groups undergo a maturing process before birth during embryonic and fœtal growth. With the help of strong immunosera, the blood-group factors already can be identified in the early embryonic stage in the immuno-hæmolytic and in the inhibition test. The

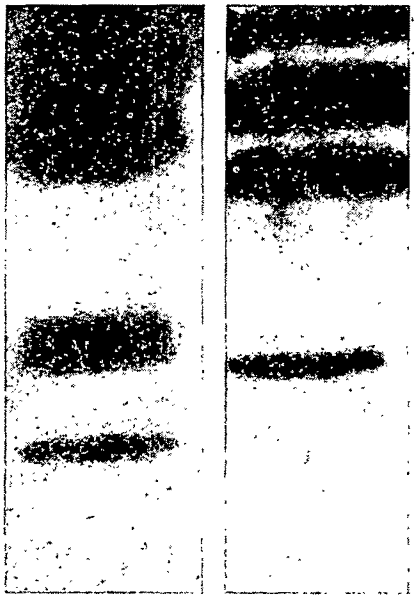

Fig. 1. Left, starch-gel electrophoresis pattern of fœtal calf serum (transferrin bands); right, starch-gel electrophoresis of fœtal calf serum after 90 per cent enrichment of fetuin (fetuin bands)

youngest cattle embryo, the blood-group factors of which we have already identified, had a head to tail length of 17 mm. This corresponds to an age of 28–35 days.

The study of fœtal sera was performed with the help of starch-gel electrophoresis[2]. As buffer solution, we used a mixture of *tris*(hydroxymethyl)aminomethane, disodium salt of ethylenedinitrolotetraacetic acid and boric acid. The migration time of the proteins was 3·5 hr. in an electric field of 7–8 V./cm. Here they showed a clear difference in the albumin/globulin ratio between fœtal serum and serum of adult cattle. The serum of embryos and fœtuses showed a minor content of beta-globulins and a relatively higher content of alpha-globulins. Between the region of the alpha-globulin complex and the post-albumin region in the serum of adult animals, in fœtal sera an additional separation appeared in wide bands (Fig. 1).

By isolating fetuin, which as mucoprotein is a regular part of calf serum, using the precipitation method of Deutsch[3] with a 90 per cent enrichment and a joining starch-gel electrophoresis, we came to the conclusion that the observed additional bands must be attributed to the fetuin fraction.

By the separation of the beta-globulins in the fœtal sera, all transferrin-groups until now observed in the serum of adult cattle of highland breeds (Fleckvieh, Brown Swiss) could be shown. Until now, neither with the adult cattle nor with cattle fœtuses has the serum-transferrin group *E*/*E* been discovered.

The smallest embryo from which we could successfully get enough serum for starch-gel electrophoresis had a head-to-tail length of 42 mm., corresponding to an age of 7 weeks.

RADIOBIOLOGY

Changes in X-ray Sensitivity of HeLa Cells during the Division Cycle

MEASUREMENT by Puck and Marcus of the reproductive survival of randomly dividing cultures of HeLa *S*3 cells after X-irradiation revealed an exponential response to dose following a shoulder[1]. However, the possibility was not excluded that these populations are in fact heterogeneous, the cells undergoing small, or large but brief, fluctuations in sensitivity during the division cycle. We have examined this possibility by irradiating synchronously growing populations at various times after mitosis.

Synchrony was achieved by selectively harvesting mitotic cells from cultures of HeLa *S*3–9*IV* (ref. 2) growing as monolayers in medium *N*16*HHF* (ref. 3). Dividing cells, being less firmly attached to the plastic culture vessels, were removed by repeated rinsing with growth medium. About 1 per cent of the cells were so gathered, and 80–90 per cent of them were in metaphase to late telophase. Their plating efficiency was 84–90 per cent; 90–100 per cent of those which attached to new plastic culture dishes completed division within 3 hr. after collection. The next division cycle did not commence for an additional 17–21 hr. Fig. 1 shows typical growth-curves for synchronous and random cultures, as determined by repeated microscopic observations of specified fields[4]. The rise in mitotic frequency in the synchronous culture at about the time of division is also shown in Fig. 1. Details of this technique will be reported more fully elsewhere.

Fig. 2 shows typical survival curves obtained for cells irradiated at 37° with 220 keV. X-rays (constant potential; 15 m.amp.; 1 mm. aluminium + 0·5 mm. copper added filtration; about 30 rads per min.; half-value layer 1·9 mm. copper) at selected times after collection. The zero-hour curve represents cells in mitosis, and if the time-course of the synthesis of deoxy-

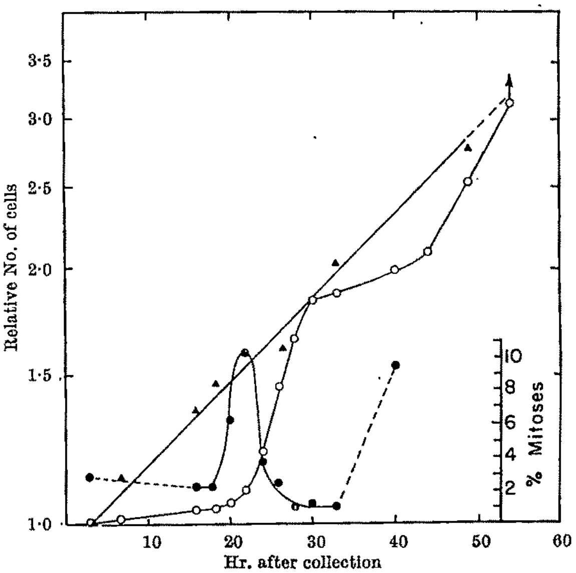

Fig. 1. Synchronous and random division of HeLa *S*3-9*IV* cells. Relative cell numbers, as determined by repeated microscopic observation of specified fields, and mitotic activity, as determined from stained preparations, are plotted as functions of time after harvesting mitotic cells. The cell counts at 3 hr. were 103 for the synchronous culture, and 94 for the random culture. The arrow at 54 hr. indicates that the value plotted was a minimum one. ▲, Random population; ○, synchronized population; ●, mitotic frequency

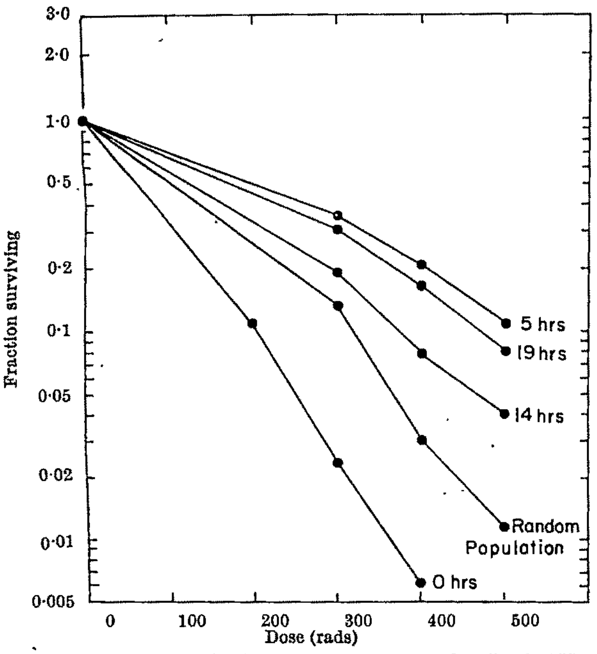

Fig. 2. Survival of colony-forming capacity of HeLa *S*3-9*I V* cells after irradiation with 220 keV. X-rays at the times in the division cycle indicated. Random population was irradiated immediately after trypsinization, while cells were still in suspension; 3 hr. later such cells showed a lower sensitivity

ribonucleic acid (DNA) as determined by Painter and Drew[5] for HeLa *S*3 cells applies to our system, then 5 hr. after cell collection lies in the pre-synthetic (G_1) phase, 14 hr. in the synthetic (S) phase, and 19 hr. in the pre-mitotic (G_2) phase.

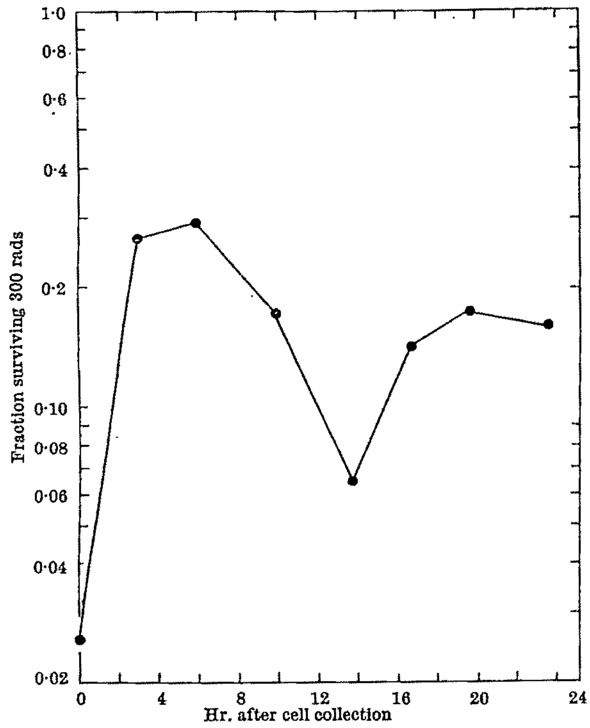

Fig. 3. Fractional survival of HeLa *S*3-9*I V* cells after exposure to 220 keV. X-rays at various times during the division cycle. Data obtained from single doses of 300 rads are plotted on semi-logarithmic co-ordinates, as this representation corresponds to changes in mean lethal dose, if the extrapolation number is constant

It is clear that mitotic cells are more sensitive (mean lethal dose, $D_0 = 59$–82 rads) than are random populations ($D_0 = 100$–120 rads). Such heightened sensitivity is probably correlated with the condensed state of mitotic chromosomes[6]; increased chromosome damage has previously been observed in cells during mitosis[7]. We are unable, with this technique, to determine changes during the various phases of mitosis.

Fluctuations in sensitivity also occur during interphase. As shown in the data of Figs. 2 and 3 (the latter showing cell survival following administration of 300 rads at different times in the division cycle), and of several other experiments, cells are relatively resistant 3–7 hr. after collecting, become progressively more sensitive during the period 7–14 hr., and then more resistant again from 14–18 hr. The data do not permit detection of small changes in extrapolation number during the cycle, but no gross changes are apparent. Accordingly, most or all the fluctuation shown in Figs. 2 and 3 is attributable to changes in D_0. Making this assumption, in four experiments D_0 decreased 16–60 per cent between 3–7 and 14 hr.

The causes of these intermitotic fluctuations in sensitivity are not apparent. The occurrence of a peak in sensitivity at about 14 hr. after mitosis suggests that no simple model will account for the fluctuations, which may result from alterations in damage, or in repair processes, or both. Further indications of the complexity of the system have been found in other experiments (Terasima, T., and Tolmach, L. J., unpublished work) which show that X-ray-induced divisional lag fluctuates in parallel with sensitivity from zero to 14 hr. after mitosis, but not over the remainder of the cycle.

This investigation was supported in part by a grant (*C*–4483) from the U.S. Public Health Service.

Trace-labelling of Insulin with Iodine

A RECENT technique for the immunological assay of human plasma insulin requires a radioactive bovine insulin of very high specific activity[1].

Crystalline bovine insulin is labelled with iodine-131 using the only method reported to produce a suitable activity, to the order of 75–300 mc. iodine-131/mgm. insulin[2]. We encountered some difficulties with this method and have made certain modifications. The following procedure has proved more reliable, consistently yielding a specific activity of 300–600 mc. iodine-131/mgm. insulin. Also there is less radiation hazard in that chloroform extraction of up to 80 mc. of iodine-131, part of the original method, is avoided, and so the number of transfers of solutions of high radioactivity into different containers is reduced.

20 μl. of iodine monochloride and 10–20 mc. of thiosulphate-free, carrier-free iodine-131 in minimal $N/50$ sodium hydroxide are added virtually simultaneously to a fresh solution of 20 μgm. of crystalline bovine insulin in borate buffer, *p*H 7·8, in a perfectly clean glass tube[3]. The tube, sealed by a secure glass stopper, is shaken vigorously for 4 min., and a third of the insulin is immediately dialysed. Several changes of distilled water, 2 l. at a time, rid the protein solution of unbound iodine-131.

Some insulin is inevitably damaged by irradiation. The amount damaged is roughly proportional to the specific activity. The damaged fraction is separated from the undamaged fraction on a cellulose column[2]. Damaged insulin labelled with iodine-131 is biologically and immunologically inactive and runs just behind albumin on chromato-electrophoresis on Whatman 3 *MM* paper strips, while the undamaged 'free' insulin is adsorbed at the origin (Fig. 1). After purification almost all the damaged fraction is removed (Fig. 2). The undamaged insulin is now available for investigation requiring truly tracer quantities of radioactive hormone.

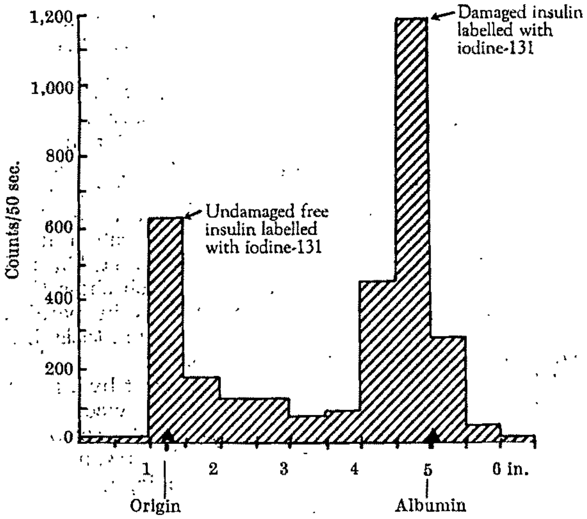

Fig. 1. Damaged insulin labelled with iodine-131 predominates on scanning the radioactivity of a paper strip after chromato-electrophoresis of the first fraction collected from a cellulose column, during purification of crystalline bovine insulin labelled with iodine-131 (specific activity 550 mc. iodine-131/mgm. insulin). Human plasma was present in this mixture

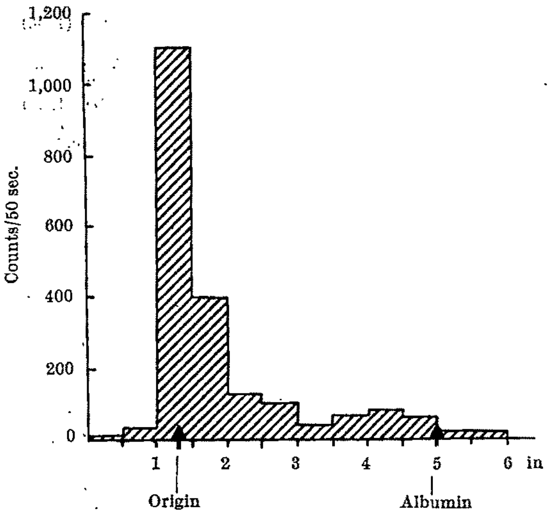

Fig. 2. Radio-chromato-electrophoretograms of a later eluate from the cellulose column, showing purified, 'free' insulin labelled with iodine-131 adsorbed at the origin

It has been suggested that damaged insulin binds indiscriminately to serum proteins and hence migrates away from the origin. We have found, however, that a solution containing damaged insulin, free of serum and albumin, shows identical migration of damaged insulin, as in Fig. 1. We have also separated the two fractions on cellulose acetate strips pre-soaked in non-radioactive insulin, confirming that damaged insulin has an electrophoretic mobility of its own.

This work was supported by the Medical Research Council and the British Insulin Manufacturers.

Radiation Effect on Yeasts of the Genus *Candida* Berkhout

So far investigations of radiation damage on yeasts were solely done on ascosporogenous yeasts of the genus *Saccharomyces* (Meyen) Reess, mostly on the species *cerevisiae* Hansen. Major radiation damage to this genus is known[1-4]. We irradiated an anascosporogenous yeast *Candida tropicalis* (Cast.) Berkh. with X-rays (1·54 Å.) and ultra-violet light. This genus is characterized by the ability to form pseudomycelium, that is, filaments similar to the hyphæ of moulds, but consisting of elongated cells which have originated by budding. Formation of pseudomycelium takes place when growth goes on and cell division (budding) is inhibited. By irradiation of *C. tropicalis* we found all the types of radiation damage discussed in refs. 1–4 and a new radiation effect, the formation of pseudomycelium. The equations of the regression-lines for this effect are: X-rays, $y = 3{\cdot}18 + 2{\cdot}78x$; $PPD_{50} = 3{\cdot}6$–$4{\cdot}47$–$5{\cdot}13$ kr. Ultra-violet light: $y = -3{\cdot}66 + 4{\cdot}7x$; $PPD_{50} = 64{\cdot}5$–$69{\cdot}7$–$74{\cdot}1$ sec.

PPD_{50} is the dose necessary to induce in 50 per cent of the irradiated cells the formation of pseudomycelium. It seems interesting to note that simultaneously with the formation of pseudomycelium, the cells lose their Gram-positivity to become Gram-negative instead. Gram-positivity is a function of ribonucleoproteins; by destroying or extracting them, the cells become Gram-negative. So, as a result of irradiation by ultra-violet light or X-rays (1·54 Å.), the metabolism of ribonucleic acid (RNA) is disturbed. In the case of X-rays, the formation of pseudomycelium results much earlier than the induction of lethal mutations, $PPD_{50} = 4{\cdot}47$ kr., whereas $LD_{50} = 10$ kr. So the first attack of X-rays on yeasts of the genus *Candida* is inhibition of cell division, expressing itself in formation of pseudomycelium coupled with damaging of the metabolism of RNA.

Coloration of the irradiated cells with Unna-Pappenheim-stain (after Brachet) confirms the extensive damaging of the metabolism of RNA.

A possible explanation that the first attack is to be found in the inhibition of budding, combined with the damaging of the synthesis of RNA, could be found in the fact that in both cases sulphydryl enzymes are involved.

W. J. Nickerson and G. Falcone[5] described evidence supporting the conclusion that the process of cellular division in yeasts is the result of a chain of events, beginning with transfer of hydrogen by protein-disulphide-reductase to —S—S— linkages in a polysaccharide-protein complex of the yeast cell-wall. Thus rupture of covalent bonds in this major component of the cell wall becomes possible. Following this hypothesis[5], the free radicals produced by irradiation would oxidize the SH-groups and so make budding impossible since pseudomycelium is formed. That this is the case is supported by the fact that by feeding certain sulphydryl-compounds to *Candida* for irradiation (*M*/300 thiourea in glucose-peptone-solution for 18 hr. under continuous stirring at 27°) all the radiation damage is greatly reduced.

This work forms part of a research work contract from the International Atomic Energy Commission, Vienna.

BIOLOGY

A Rare Earless Monitor Lizard from Borneo

Lanthonotus borneensis Steindachner—the Borneo earless monitor lizard (which forms, with two American lizards, the family Helodermatidae) is known from less than ten specimens, all from Sarawak (three in Kuching, one in Singapore, the rest in American and British museums), none of which has been collected in recent times or with satisfactory field data. Thus, although the importance of this reptile's purely taxonomic characters in lizard-snake evolution has been examined in detail[1], no supporting information on behaviour has been available.

For some years this Museum has been associated with the Chicago Natural History Museum in a reptile-amphibian collecting project[2], under the general guidance of its curator, Dr. R. Inger. Particular attention has been devoted to a search for *Lanthonotus* throughout West Borneo. Not until January 1961 was any positive report obtained. Then, a live specimen measuring 13 in. (about average size to date) was obtained only a mile from our own archæological base camp at the Great Caves of Niah, centre of intensive reptile collecting since 1954.

After an initial period in which the lizard refused any sort of food and spent most of the time in a state resembling a coma (superficially 'dead') it then responded to the raw eggs of the green turtle, *Chelonia mydas*, the distribution of which in Sarawak happens to be controlled by this Museum[3]. It sucked raw turtle yolk every night for two months. Then circumstances made us bring it back to Niah, where fresh turtle eggs are not available. Chicken eggs were accepted as substitutes ; but the animal died on April 11, 1961.

In most of its behaviour it resembled a nocturnal snake. Though taken from a hole in the ground, the front legs are so weak that it is difficult to conceive of its burrowing with these. The strong snout and head were used to enlarge any ground weakness, however. A very good swimmer, it could relax on the bottom of a tank for up to half an hour. This capacity to relax was also a striking characteristic on land ; when resting it could literally collapse along the whole length of the body. Then, with very low, slow respiration it was difficult to decide whether it was alive. Evidently, in a natural state, it is able to remain dormant for long periods underground without food and very little air. This, plus nocturnalism and a capacity to carry about earth adhering to the nodular skin, make it most difficult to notice.

When handled, however, it would quickly flatten the body into semi-rigidity. It soon showed evidence of enjoying handling and became 'tame', in a way already known for the related 'Gila monster' *Heloderma suspectum*[4]. It showed no inclination to bite either the handler or anything else (including food). It seems unlikely, therefore, that it is poisonous as has often been suggested[5].

Detailed day and night observations and film records have been made[6]. Further search is continuing at Niah ; the results so far are negative.

Growth Substances separated from the Root of Water Hyacinth by Paper Chromatography

EVIDENCE for the presence of growth substances in the root extract of water hyacinth (*Eichhornia speciosa* Kunth), presumably related to the rapid multiplication of the weed, has been reported previously from this laboratory[1]. A comparison of the effects of the extract with those of indole acetic acid or gibberellic acid indicated a different substance or substances present in the extract.

Paper chromatographic separation has now been attempted to reveal the nature of the active factors. 30 gm. of fresh root were extracted with chilled absolute alcohol at 0° C. for 18 hr. The extract was filtered and alcohol distilled off under reduced pressure. The aqueous residue was acidified with sulphuric acid to *p*H 3 and extracted with peroxide-free ether for 1½ hr. The ether-soluble factors were then partitioned into acidic and neutral fractions following Kefford[2]. The ether-insoluble substances were neutralized with barium hydroxide, filtered and evaporated to dryness. The dry mass was then dissolved in 0·5 ml. of distilled water and treated overnight with 0·5 ml. of absolute alcohol for chromatography. Acid and neutral ether fractions were evaporated separately and the dry mass dissolved in

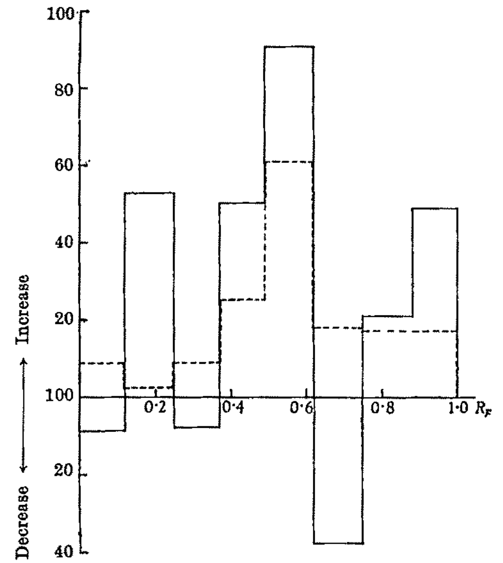

Fig. 1. Root growth (——) and shoot growth (- - - -) of rice seedlings treated with the ether-insoluble water fraction. Solvent: *iso*propanol/ammonia/water

1 ml. of dry peroxide-free ether or absolute alcohol. Three fractions were then chromatographed in Whatman paper No. 1 for 6–8 hr. with *iso*propanol/ammonia/water (16 : 3 : 1). After running the solvent for 20 cm., the air-dried filter paper was cut into 8 pieces and eluted overnight with distilled water in the cold. Root and shoot growth of the intact sprouted rice seed var. Chinsurah Boro in the eluates was used for the bioassay of growth substances. Chemical identification was sought from the R_F of chromatograms with different solvents: *iso*propanol/ammonia/water (16 : 3 : 1); benzene/acetic acid/water (4 : 1 : 2); alcohol/water (7 : 3) and *n*-butanol/acetic acid/water (4 : 1 : 1).

In the neutral ether fraction, no growth-promoting substance was detected either by bioassay or spot colour reaction. The acid-ether fraction did not show significant growth promotion in bioassay, but the colour reactions of the chromatograms run with *iso*propanol/ammonia/water were noticed at R_F 0·73–0·75, 0·76 and 0·91–0·99. The growth substance at R_F 0·73–0·75 was indole-3-acetic acid as confirmed by synthetic indole-3-acetic acid run with the extract in different solvents. The colour reaction at R_F 0·76 was obtained by potassium permanganate, but not with Salkowski or Ehrlich reagent, and was also inactive in the rice-seedling bioassay. The growth factor at R_F 0·91–0·99 appeared to be an indole compound as it gave a spot colour reaction with Salkowski and Ehrlich reagents. The ether-insoluble or aqueous fraction showed marked promotion of growth at three zones: R_F 0·12–0·25, 0·37–0·62 and 0·75–1·0 (Fig. 1). Inhibition of root growth was also observed at R_F 0·62–0·75. Positive Salkowski and Ehrlich reactions were given by the fractions with R_F 0·71–0·75 and 0·97–0·99, suggesting the presence of indole compounds. It is interesting to note that the substance present in the fraction with R_F 0·49–0·60 has marked growth-promoting activities both in the root and shoot of the test material. It gives a colour reaction with potassium permanganate like gibberellic acid but at widely different R_F. On the basis of these results it is concluded that the root extract of water hyacinth contains growth substances in addition to indole compounds or gibberellins.

Further work on the chemical nature and propertie of the substances is in progress in this laboratory.

Life-span of the Fronds of the Giant Kelp, *Macrocystis pyrifera*

THE large brown attached alga, *Macrocysti pyrifera*, member of a widespread genus, is c considerable importance as the direct and indirec source of food for a large number of near-shor animals; it is also gathered by man, to be used a fertilizer, food additives, and it is processed fo certain of its chemical constituents. The frond develop continuously from growing points located o the perennial hold-fast at the base of the plant Little information exists about the life-span of th fronds, although this is a factor of considerabl importance in management of the resource and i computing the productivity of the kelp grove Authors have estimated the life-span as severa months[1,2]. Further information is now available a a by-product of work on rate of growth in severa kelp-beds spread over a geographical range of abou 150 km.

Individual fronds were tagged with numbered smal white plastic squares, by divers using self-containe underwater breathing apparatus (SCUBA)[3]. Tw tags were attached to each frond by a rubber ban loosely encircling the stipe; thus if one marke disappeared, replacement could be effected withou loss of the identity of the frond (in practice, howeve few tags were lost). Two or more fronds per plan were always tagged. It has always been possible t relocate the plant on subsequent visits, except whe the entire organism was removed by a storm or b concentrated grazing. Elimination of the paren plant was disregarded in the statistical calculation of the loss of fronds.

Results for eleven different time periods and thre locations are presented in Table 1. For work o rate of growth, fronds were tagged when quite smal 30–100 cm. long; measurements of length wer made at intervals as they developed. Experiment 1, 2, 4 and 5 show consecutive measurements o groups of fronds tagged at the beginning of eac series. For experiments 2 and 3 many of these tim intervals are lumped in Table 1 and only a few c the visits are represented. In preparing Table 1, frond was considered as being defunct when it ha lost the distal growing tip from which all its blade originate. Measurements have shown that althoug elongation can occur after loss of this apical blad overall growth-rates quickly slow down and no mo blades are produced (as was also observed in *Macro cystis integrifolia*[1]).

The first experiment in Table 1 summarizes long-term investigation that began with a larg number of young stipes. Experiment 4 in Table was started at about the same time, at Pt. Loma about 16 km. away. Both beds showed similar rate of mortality, but the Pt. Loma site was abandone after the final observations shown in experiment 4

* A composite sample of plants along a straight transect line 125 m. long; experiments 2 and 3 were conducted on 2 groups of plants along this same line, separated by about 100 m.

† 3 incomplete fronds were found remaining.

‡ These 3 fronds, although complete, seemed unhealthy, fragile, and brittle, and were heavily grazed and encrusted.

because of the encroachment of a horde of sea-urchins, *Strongylocentrotus franciscanus*, which destroyed all the plants at their bases. At La Jolla, in experiment 1, only 3 incomplete fronds remained after 162 days, and these bore evidences of heavy grazing and deterioration. Their lengths were 28, 32 and 35 m.; the stipes were so fragile and chewed that they broke in several places during recovery and measurement, although extreme care was used in handling. Had the fronds been complete, their lengths would probably have been increased by perhaps as much as 5–10 m. Growing conditions during the period of this experiment were favourable with respect to temperature and water clarity, throughout the water column, but a series of storms presumably took a considerable toll of both the Pt. Loma and the La Jolla fronds.

Experiments 2 and 3 describe late spring and summer observations on other groups of fronds when the ocean was comparatively calm. After 72 days, only 1 of the original 9 fronds in experiment 2 had broken, indicating a much slower rate of mortality than had been observed in the winter and spring in experiments 1 and 4. Subsequent to the final observation of this group, the fronds grew up into the warm water above the thermocline and rates of growth quickly decreased practically to nil. All the fronds took on an unhealthy appearance, involving loss of pigment, and became brittle. The mortality-rate increased markedly. A younger set of 14 fronds nearby, below the thermocline, constituting experiment 3, exhibited a very low rate of mortality and normal growth-rates during the period when the older fronds of experiment 2 were suffering heavy losses.

Experiments 5*a*–*d*, which were run consecutively in a very small bed in a cold upwelling area at Punta Banda, Baja California, illustrate a continuous attrition process, as was likewise demonstrated by experiments 1 and 4. The loss per unit of time was somewhat variable in this bed. The half-life expectation of the fronds ranged from 12 to 38 days (Table 1). These values compare with a winter half-life of 23 days at La Jolla (experiment 1) and of 47 to 48 days at Pt. Loma (experiment 4). The chief damaging factor in the Punta Banda bed was apparently an excessively thick and continuing encrustation of the bryozoan *Membranipora serrilanella*, which restricted growth, deformed the tissues, and induced brittleness and breakage by water movements.

It is apparent from the examples just cited that considerations of the life-span of kelp fronds can be quite complex. It is important to define accurately the terms used. In some circumstances the average age of a group may be considerably less than the maximum age. The age of our experimental fronds at the time of tagging may be safely estimated from our growth data as 1–2 months, hence the observations indicate that the maximum age of a frond in 20 m. of water under favourable growing conditions is about 6 months, confirming the values of Scagel[1] and Brandt[2]. The average age, however, may often be only 2–3 months.

If unfavourable conditions, such as the temperature destruction of the fronds in experiment 2, develop suddenly, the maximum age of a population of fronds may almost coincide with the average age, and may be substantially less than 6 months.

Support of this work by the California Department of Fish and Game and the State Water Pollution Control Board is gratefully acknowledged.

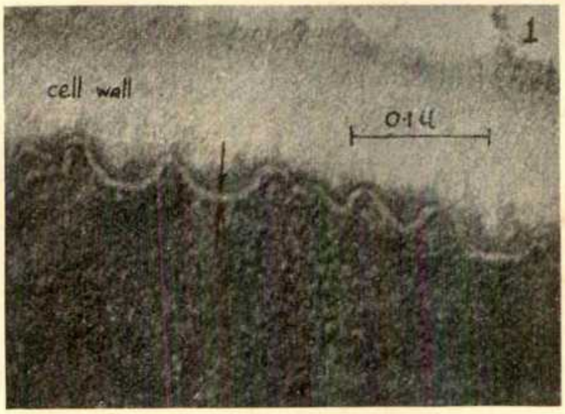
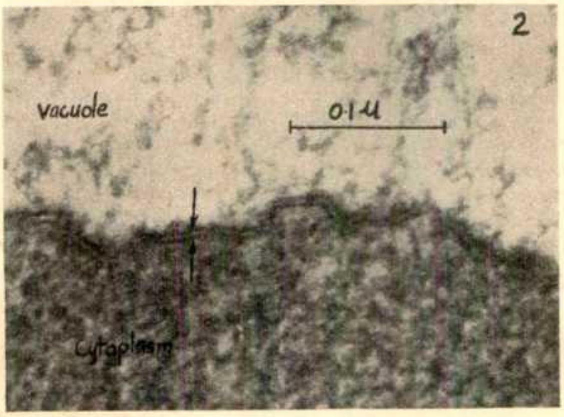
Method for revealing the Membrane Systems in Micro-organisms

THE use of potassium permanganate as a biological fixative for revealing the membrane systems of cells is well known to electron microscopists[1]. This fixative has been successful in preserving the fine morphology of bacteria and yeast; but, up to date, workers have failed to show the true nature of the membranes in these organisms[2,3]. This communication describes a method for stabilizing and increasing the electron density of membranes in micro-organisms by post-fixing them with a uranium salt.

The organisms are fixed in suspension with a 2 per cent solution of potassium permanganate buffered with veronal acetate. This is followed by washing them in several changes with a 2 per cent solution of uranyl nitrate and allowing them to remain in the





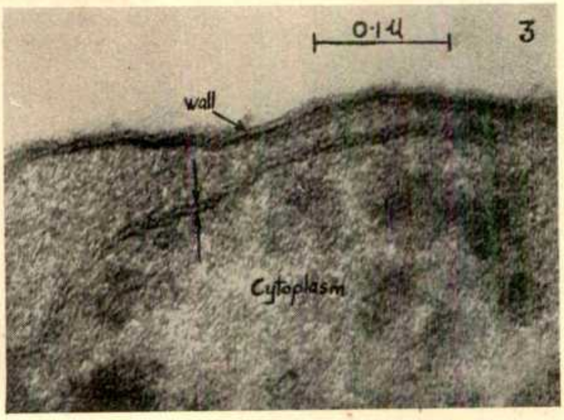


Fig. 1. Yeast cell wall and the cytoplasmic unit membrane
Fig. 2. Yeast vacuolar membrane
Fig. 3. Wall of *Rhizobium* and the limiting cytoplasmic membrane

final change for 1 hr. Washing, dehydration, embedding and sectioning are then carried out in the conventional manner.

Robertson[4,5] regards the unit membrane as two protein layers each about 20 Å. thick separated by a lipid layer approximately 35 Å. thick. The use of post-fixation has enabled me to resolve these layers in the nuclear membrane, cytoplasmic membrane, mitochondrial membranes and vacuolar membrane of yeast and has also enabled me to show a limiting cytoplasmic unit membrane in the bacterium *Rhizobium trifolii*.

In the three electron micrographs (Figs. 1–3) the components of the unit membranes are resolved. The two electron-dense lines represent the protein layers and the clear space dividing them the lipid layer.

I prefer to call the uranyl nitrate treatment a post-fixation since, fixing with permanganate followed by the staining of sections with uranium on the grid in the usual fashion fails to show the membranes satisfactorily. It appears that post-fixation retains something in addition to that retained by the permanganate alone.

Function of the Caudal Appendage of *Priapulus caudatus*

THE caudal appendage of *Priapulus* consists of central hollow stalk from which numerous finger-like tubes project. The lumen of the appendage communicates with the voluminous cœlomic cavity by an opening surrounded by circular muscles[1]. Severa authors ascribe a respiratory function to the appendage[2,3], but other theories have also been proposed[4] The following observations may throw light on th function of the appendage.

Ten specimens of *Priapulus caudatus* were store overnight in 100 ml. sea-water. The next day th animals were motionless and probably asphyxiated but when new sea-water was added the animal started lively movements. At intervals the cauda appendage and its processes contracted vigorously (Fig. 1), injecting cœlomic fluid into the body cavity Shortly afterwards the appendage relaxed an cœlomic fluid streamed back into it. The streamin of cœlomic corpuscles could be observed through th transparent walls of the appendage. In othe experiments specimens of *Priapulus* were asphyxiate by bubbling nitrogen through the water. Also i these cases rhythmical contractions and relaxation of the caudal appendage followed the addition o aerated sea-water.

From the observations, it seems probable that th caudal appendage has a respiratory function. It

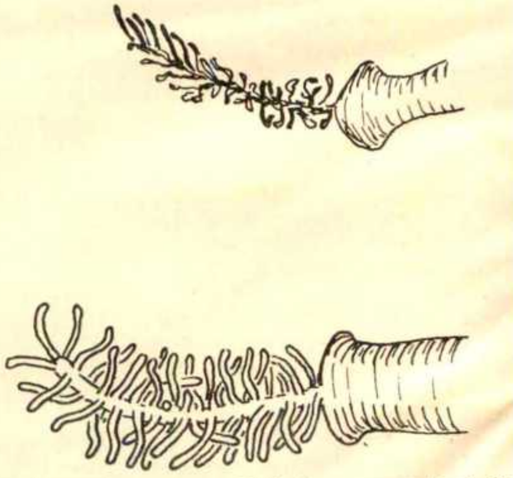

Fig. 1. *Priapulus caudatus*. Respiratory movements of the caudal appendage, contracted stage (above), relaxed stage (below)

thin walls allow a rapid uptake of oxygen, and the rhythmic muscular contractions bring oxygenated cœlomic fluid into the body cavity. The presence of a respiratory pigment in the cœlomocytes[5,6] makes the cœlomic fluid well suited for transport of oxygen. That the pigment is a hæmerythrin, as stated previously[5,6], was confirmed by a spectrophotometric examination of a hæmolysate with distilled water. The appearance of an absorption maximum at 4900 Å. agrees well with observations on *Sipunculus*[7,8].

In spite of its content of a respiratory pigment the oxygen capacity of the cœlomic fluid is rather small. By measurements with a van Slyke apparatus the value of 0·014 ml. oxygen per ml. fluid was obtained. For sea-water the value 0·006–0·007 was found. The oxygen dissociation properties of cœlomic fluid was studied by a crude colorimetric method. Half saturation was obtained at an oxygen tension of 60 mm. mercury, which indicates a slowly sloping dissociation curve. However, the measurements were made at 19° C., which is above the temperature of the natural environment of *Priapulus caudatus*.

It is an unsolved problem how respiratory movements of the caudal appendage can be triggered by an increase of oxygen tension in the surrounding sea-water. Probably, the movements are initiated from the nervous system, because the muscles of the appendage are innervated from the abdominal nerve trunk[1].

We are grateful to Dr. Knut Schmidt-Nielsen of Duke University, Durham, North Carolina, who made the van Slyke analyses.

ANATOMY

Properties of Stressed Bone

PROF. DREYER's communication[1] raises a matter of considerable interest and importance. Engineers know that all materials react similarly on broad principles. That is, they obey Hooke's law, within wide ranges, of course, and conform to other physical changes under stress such as Poisson's ratio.

There is no reason to doubt that bone material differs in principle from other created material. As such it should be, and probably is, elastic up to a yield point. Experiments on living bone may be difficult, but if Young's modulus for bone tissue, or the range of elastic limit, could be determined it would be most helpful. Moreover, its subsequent behaviour beyond that point up to fracture should be established, and would then provide an answer to the problem under investigation by Prof. Dreyer.

Moreover, the amount of compression and extension under stress, as well as the degree of bending under torque, or eccentric loading, are clearly forms of bone characteristics that ought to be known. Naturally the reactions on colour referred to by Prof. Dreyer are a measure of the reaction set up to applied stresses, and are familiar to every engineer. 'Perspex' and celluloid, in the form of full-size models, indicate changes in colour under stress, and show the pattern and distribution of stresses set up under applied loads. They can also be used to reveal the effects and redistribution of stress under fatigue due to repetitive loading. A breakdown then occurs of normal strength leading to failure at a much lower stress. This, of course, is of considerable importance with a lowering of the elastic limit by age.

THE problem that needs elucidation is to determine the nature and origin of the osteoblastic and osteoclastic stimuli which, when associated with a normal metabolism, will influence the deposition or removal of bone.

These stimuli may originate as a result of function or non-function of a bone. It is therefore tempting to suggest that stress produces some change in the inorganic or organic portion of the bone. The stress is then converted to a stimulus which affects the neighbouring osteogenic tissue.

The crystalline structure of bone had led us to believe that these stimuli may be electrical. The piezoelectric properties of bone have been investigated, but so far my results have not been encouraging. Thus when I found the alteration in staining properties and birefringence of bone as a result of stress I felt that these changes may well be related to the origin of locally produced osteoblastic and osteoclastic stimuli in bone.

I am not sure that the phenomenon that I have described is quite comparable with the changes seen in colour in stressed 'Perspex', celluloid, transparent 'Balelite' and 'Araldite' (Ciba).

When these materials are stressed with mild forces the changes in colour occur almost immediately and conversely disappear as soon as the force is released. My *in vitro* experiments show that the birefringent portion of the bone does not, even after 24 hr., revert to its unstressed state when the stress is removed; yet *in vivo* this must be a reversible process. Of course, the picture with massive forces and the influence of temperature is an entirely different matter.

Influence of Large Doses of Œstrogens on the Structure of the Bones of Some Reptiles

IT was first shown by Kyes and Potter[1] that, during reproductive activity, the marrow cavities of the bones of female pigeons become filled with endosteal bone. It is thought that this medullary bone is formed under the synergistic action of the androgens and œstrogens[2] which are produced in the female bird during the breeding season. Similarly, injections of œstrogens induce the formation of medullary bone in male birds. Medullary bone differs from cortical bone histologically[3,4], and it appears to act as a labile calcium store which can be mobilized rapidly during the formation of the eggshell.

Although medullary bone has been found in all species of birds which have been investigated it has only been possible to demonstrate it in one species of mammal, the mouse[5], although six other species have been investigated. Medullary bone never occurs naturally in mice and there is in fact evidence to suggest that even when it is induced experimentally it differs from that which occurs normally in birds[6].

The question arises therefore whether the early reptiles possessed medullary bone, and the ability to form it has been lost in mammals with the loss of the calcified eggshell; or whether the ability to store calcium in this way has been evolved only in the birds.

Some answer to this question is provided in the recent work of Edgren[7], who found that there was a fall in the density of the bones of female turtles during the reproductive season. This indicates that calcium is withdrawn from the long bones of the limbs to provide calcium for the eggshell. If calcium were stored before the formation of the eggshell, this would have been detected as an increase in the density of the bones, but this was not found. This would appear to indicate that there is no formation of medullary bone which could act as a special store of calcium, but that the cortical bone is resorbed during the formation of the eggshell.

The work reported here concerns two observations which are pertinent to the scheme implied by Edgren's work. A male eastern painted turtle, *Chrysemys picta picta*, was caught, in Georgia, United States, during August and given an initial injection of 1 mgm. of œstrone (10,000 International Units) in 1 ml. of peanut oil. The animal was then given daily intramuscular injections, into alternate hind limbs, of 5,000 I.U. of this hormone for 12 days and it was then killed. At death it weighed 200 gm., of which the shell comprised 63·5 gm. The femurs were cleaned and fixed in 5 per cent formalin. Pieces of bone were decalcified and sectioned.

A similar experiment was performed on a female gopher tortoise, *Gopher polyphemus*, which at death weighed 350 gm., of which the shell comprised 169·5 gm. Although the ovary contained ova of up to 1 cm. in diameter, there were no eggs in the oviduct. The femurs were again examined histologically.

The bones from these animals contained many trabeculæ, possibly related to their curved shape. There was no medullary bone present. Methylene blue extinction values were taken at various *p*H-levels using barbitone buffers[8]. In both cases the bone had values of about *p*H 4, whereas avian medullary bone has a value below *p*H 3 (ref. 4).

The experiments described must be regarded as preliminary ones, but they provide evidence from an entirely independent source to confirm the system suggested by the work of Edgren. Thus it appears that these Chelonia do not form medullary bone under the influence of the sex hormones and do not store calcium before egg-laying. There is therefore a definite difference in the calcium metabolism of these reptiles and the birds.

It is a pleasure to acknowledge the assistance of Hugo Greiner and Miss E. M. H. Wilson in these experiments. The work reported was performed in the Anatomy Department, Emory University, Georgia, United States, through the hospitality of Prof. G. H. Bourne and during the tenure of a Lalor Foundation research award for the summer of 1960 and a Wellcome research travel grant.

IMMUNOLOGY

Partial Inhibition of Antibody Formation by means of Anti-Ribonucleoprotein Serum

NUCLEOPROTEINS seem to be effective antigens[1], and anti-nucleoprotein sera produced in rabbits exhibit a definite cytotoxic activity on the cells of different lines grown in tissue culture[2]. On the other hand, it is generally believed that ribonucleic acid and ribonucleoprotein are instrumental in protein synthesis, and that these cell constituents provide also the patterns for *de novo* production of highly specific proteins, such as immune antibodies. It may be deduced, therefore, that the capacity of antibody-protein formation can be affected by the action of an anti-nucleoprotein serum. The present experiment was done in order to investigate the immunological events which are associated with the activity of anti-ribonucleoprotein and anti-deoxyribonucleoprotein sera.

Ribonucleoprotein-rich fraction[3], 11·0–15·0 mgm./ml. of protein, 45–70 γ/ml. of deoxyribonucleic acid (DNA), and 1,300–1,600 γ/ml. of ribonucleic acid (RNA) and deoxyribonucleoprotein-rich fraction[4] (9·2–11·6 mgm./ml. of protein, 975–1,250 γ/ml. of DNA, and 300–420 γ/ml. of RNA) were isolated from Rhode Island Red chicken organs (spleen, liver and lung). Immune sera were prepared by injecting chicken ribonucleoprotein and deoxyribonucleoprotein into rabbits. Two three-injection series were performed, with an interval of 10 days between them (3 ml. of nucleoprotein per injection subcutaneously). Ten days after the last injection the rabbits were bled and γ-globulin fraction (96·25 mgm./ml. of protein) of anti-ribonucleoprotein serum, and γ-globulin fraction (76·37 mgm./ml. of protein) of anti-deoxyribonucleoprotein serum were prepared as described by Bassett *et al.*[5]. The γ-globulin fraction (89·31 mgm./ml. of protein) of normal rabbit serum was also used in the experiments. Rabbit antisera were investigated for the presence of specific antibodies by diffusion-gel technique and complement fixation[6]. The supernatants obtained by centrifuging at 3,000 r.p.m. for 30 min. chicken nucleoprotein fractions served as antigens. The supernatant of ribonucleoprotein contained 1,915 γ/ml. of protein, 25 γ/ml. of DNA and 450 γ/ml. of RNA, and that one of deoxyribonucleoprotein 2,065 γ/ml. of protein, 900 γ/ml. of DNA and 160 γ/ml. of RNA. Chicken ribonucleic (RNA) and deoxyribonucleic (DNA) acids were also used in complement fixation. In the agar-diffusion reaction a maximum of five zones was observed with

protein and corresponding anti-
well-defined precipitin lines with
onucleoprotein and anti-deoxyribo-
serum. Normal rabbit serum did not
gar medium with chicken nucleoproteins.
anti-ribonucleoprotein serum in comple-
on were 0–1/2 with RNA and 1/64–1/128
ucleoprotein, and those of anti-deoxyribo-
otein serum were 1/8–1/32 with DNA and
28 with deoxyribonucleoprotein.

ode Island Red chickens were divided into three
oups: the first group received γ-globulin of anti-
ucleoprotein serum, the second group γ-globulin
nti-deoxyribonucleoprotein serum, and the third
up γ-globulin of normal rabbit serum (control). A
rst injection (0·3 ml. of corresponding γ-globulin)
was given to 6-day-old embryos. The mortality-rates of embryos were 60·7 per cent for the first, 66·7 per cent for the second and 57·2 per cent for the control group. The other four injections were performed on chickens at the age of 32, 35, 38 and 41 days (1 ml. of corresponding γ-globulin per injection intravenously). After a rest of one day, all three groups were injected intravenously with 1 ml. of a 10 per cent suspension of human *O* red cells. Three days later the first group of chickens received the last 1 ml. of anti-ribonucleoprotein, the second group 1 ml. of anti-deoxyribonucleoprotein and the third group 1 ml. of normal rabbit γ-globulin. Seven days after the final injection, the chickens were bled for the first time, and further bleedings were performed every 7 days. A semi-quantitative agglutination reaction was used to test the presence of agglutinins for human *O* red cells in chicken sera.

Table 1. EFFECT OF RABBIT ANTI-NUCLEOPROTEIN SERA ON HÆMAGGLUTININ PRODUCTION IN CHICKENS RECEIVING ONE INJECTION OF HUMAN *O* RED CELLS AT THE AGE OF 42 DAYS

Days after red cell injection	Chickens treated with γ-globulin from anti-deoxyribonucleoprotein serum	anti-ribonucleoprotein serum	Normal rabbit serum (control)
7	7·52 (10)	6·47 (13)	7·72 (15)
14	6·65 (9)	5·86 (13)	7·05 (15)
21	6·32 (8)	5·23 (12)	6·53 (14)
28	5·69 (8)	4·65 (10)	6·09 (10)
35	4·82 (8)	4·43 (10)	5·43 (10)

The values represent mean peak agglutinin titres ($\log_2$). In parenthesis is the number of chickens tested.

The results are presented in Table 1. The rates of appearance of hæmagglutinins in two experimental groups of chickens are similar to the control one. Peak agglutinin titres in the sera of chickens treated with anti-deoxyribonucleoprotein serum were lower than those obtained in control group, but not so low that the difference observed can be considered significant. However, partial suppression of agglutinin production occurred among the chickens injected with anti-ribonucleoprotein serum.

Although the mechanism by which anti-ribonucleoprotein serum causes a decrease in antibody-forming capacity is not clear, it may be postulated that its action is rather at the level of nucleoproteins and cellular membrane (Colter *et al.*[2]). Since the metabolic activity of antibody-forming cells is accompanied by an increased amount of ribonucleic acid[7], it may also be supposed that the anti-ribonucleoprotein serum exhibits an indirect effect on ribonucleic acid, by acting on nucleoproteins which are bound with this nucleic acid. This view seems to be supported by the observation made in the present work, namely, ribonucleic acid scarcely showed antigenic properties, while its protein component reacted rather well with anti-ribonucleoprotein serum. It must be pointed out that the promising results obtained in the present experiments are preliminary ones, and that further investigations are planned in which more specific techniques will be used, including the tissue culture of antibody-producing cells.

This work was supported by a grant from the Yugoslav Foundation for Scientific Research.

MICROBIOLOGY

Formamidase in Mycobacteria and its Use in differentiating Saprophytic Mycobacteria from other Mycobacteria

RECENTLY, biochemical methods have been proposed to differentiate various types of mycobacteria without resorting to their growth characteristics or animal pathogenicity. Thus human tubercle bacilli can be distinguished from all other types of mycobacteria by determining their nicotinic acid production (Konno's niacin test)[1]. Bovine and avian tubercle bacilli would be differentiated from other mycobacteria by determining the activity of nicotinamidase[2] and urease[3], respectively. As for the other types of mycobacteria, namely, unclassified mycobacteria and saprophytic mycobacteria, however, such a reliable method has hitherto not been reported. Bönicke[4] and Kitamura[14] attempted to sub-divide unclassified mycobacteria by the amidase activity of bacterial suspension.

In this communication, we report the occurrence in mycobacteria of an enzyme which catalyses the formation of ammonia from formamide. This enzyme activity was found, among various mycobacteria tested, only in saprophytic mycobacteria. Amidase activity towards formamide has not so far been demonstrated with various preparations, such as rabbit liver, yeast, and *Torula utilis*, and assumed to be non-existent[5]. Halpern and Grossowicz suggested its occurrence in some mycobacteria[6]; but no other report has appeared at present on this enzyme. The natural production of formamide was reported in 1955 as the final product of histidine metabolism in *Aerobacter aerogenes*[7] and *Clostridium tetanomorphum*[8].

Twenty-three strains of various mycobacteria were grown on the surface of Sauton's synthetic liquid medium for 3 weeks (one week for saprophytic mycobacteria). The pellicles were filtered off, and washed four to five times with water. The cells (about 3 gm.

wet weight) were ground in a mortar by hand with equal amount of sea-sand for 30 min. Cell-free extracts were prepared by extracting the paste with five volumes of water for 10 min. and centrifuging at 10,000*g* for 40 min.

The reaction mixture contained 0·5 ml. of the cell-free extracts (approx. 2 mgm. protein), 10 µmoles of formamide, 1·0 ml. of 0·05 *M* phosphate buffer (*p*H 7·0) in a total volume of 2·0 ml. Solutions of enzyme without substrate and substrate alone were used as controls, which were essential. The mixtures were incubated for 4 hr. at 37°. The ammonia formed was determined colorimetrically by Imai's modified procedure[9] of Russel's phenol-hypochlorite method[10].

Among 23 strains tested, the activity of this enzyme was observed only with extracts from saprophytic mycobacteria, as shown in Table 1. With other types of mycobacteria, no activity was detected. Thus, it might be possible to distinguish saprophytic mycobacteria from all other mycobacteria by determining this enzyme activity.

Table 1. FORMAMIDASE ACTIVITY OF EXTRACTS FROM VARIOUS MYCOBACTERIA

Type	Strain	Activity (NH_3 formed, µmoles*)
Human tubercle bacilli	*H37Rv*	0
	H37Rv–INH–R	0
	H37Ra	0·2
	Aoyama B	0
Bovine tubercle bacilli	Bovine D_4	0
	Bovine Miwa	0
	BCG (Japan)	0
	BCG–INH–R	0
Avian bacilli	11755	0
	4110	0
Unclassified mycobacteria	*P*–1 (Photochromogens)	0
	P–8 (Photochromogens)	0
	P–6 (Scotochromogens)	0
	100616 (non-photochromogens)	0
	Kofu (non-photochromogens)	0
	M. fortuitum	0
Saprophytic mycobacteria	*M. phlei*	5·7
	M. smegmatis	7·8
	M. 607	10·0
	Asami	9·5
	Guinea pig I	10·1
	Soil III	7·3
	M. takeo	8·6

Substrate, formamide 10 µmoles; *p*H 7·0; incubation at 37° for 4 hr.

* Values are corrected for controls: substrate only and enzyme blank.

Some properties of the enzyme were examined with the preparation from saprophytic *Mycobacterium* 607. This preparation split 79·3 per cent of substrate within 2 hr. under the above assay condition. The rate of the reaction remained constant for more than 2 hr. At a concentration of 5 µmoles formamide per ml. the rate was almost maximum. Dialysis against distilled water had no effect on the activity.

The enzyme solution showed a considerable activity, besides formamide, towards nicotinamide, pyrazinamide, benzamide, *iso*-nicotinamide, L-asparagine, and urea; only weak activity towards L-glutamine, glycinamide, and acetoamide.

The enzyme activity towards formamide was observed over a wide *p*H range (6·0–9·0), with an optimum at *p*H 7·0–8·0. The *p*H activity curve was, though similar to that of nicotinamidase activity, slightly but definitely different from that of benzamidase activity, and markedly different from that of urease activity. This fact seems to suggest that the enzyme might be different from urease, and possibly from benzamidase.

Heating the enzyme solution [illegible] 10 min. abolished about 80 per ce[illegible] activity towards nicotinamide, pyra[illegible] amide, and *iso*-nicotinamide to the sam[illegible] none of the activities towards formamid[illegible] and urea was impaired. Heating at 60° [illegible] complete loss of the aromatic amidase acti[illegible] as asparaginase without affecting the activit[illegible] formamide and urea. (By this heat-treatm[illegible] *p*H curve for formamide was not affected.[illegible] enzyme activity was destroyed by heating at [illegible] These results render it probable that the enzyme responsible for formamide is not identical with any of these known amidases.

Evidence for this hypothesis was provided by t[illegible] mixed-substrate method[11]. Further addition o[illegible] nicotinamide, benzamide, asparagine, or urea to an enzyme system already saturated with formamide increased the rate of ammonia production additively. This indicates that these added substrates are hydrolysed by different enzymes from that concerned with formamide.

Our results seem to indicate that the activity observed towards formamide is due to a new, distinct enzyme which we propose to call 'formamidase'. We are aware that kynurenine formamidase (formylase) is called sometimes by this rather misleading name[11]; but as for this enzyme we think it is more appropriate to call it either 'kynurenine formamidase' as used at present[12] or simply 'formylase' as originally proposed[13]. The name 'formamidase' should be reserved strictly for the enzyme specific for formamide.

This work was aided by a grant from the Committee on Medical Research of the American Thoracic Society, medical section of the National Tuberculosis Association.

ENTOMOLOGY

Resting Habits of *Anopheles gambiae* and *Anopheles pharoensis* in Salt Bush and in Crevices in the Ground

THE failure to eradicate *Anopheles gambiae*, the most important vector of malaria in tropical Africa, by spraying the inside of houses with insecticides, had directed attention to the importance of alternative resting places. Box shelters[1] around cattle enclosures were used to assess the numbers of *A. gambiae* biting cattle during an experiment to break malaria transmission in the Pare-Taveta area of East Africa. Catches in the boxes, in the village of Bumba, showed peaks that corresponded to the dry months June–October, and were thought to be due to the artificial shelters competing favourably against the nearby vegetation as resting places. This is supported by complementary catches in natural resting places outdoors at Bumba between September and June.

Searches, for a total of 333 man/hours, were made in grass, foliage of trees, cacti (*Opuntia* sp.) earth banks, crevices in the ground and salt bush (*Suaeda* sp.) within a radius of three hundred yards of the village, and the mosquitoes collected by sucking tubes. The results are summarized in Table 1. Salt bush and crevices in the ground were the chief sources of *A. gambiae* and were studied in detail; for *Anopheles pharoensis* grass was also an important resting place. The salt bush covered an area of approximately 1,500 sq. yd., stretching along two sides of the village near the huts and cattle enclosures and then beyond for 300 yd. Where the villagers had taken branches for firewood and for enclosure walls, parts of the bush were thin and sparse, but other parts had been left to grow thick to give cover for places used as latrines. The terrain between the village and rice swamps comprised grassland in which deeply creviced patches of bare ground appeared during the dry season, but which were usually absent during the rainy season, November–May. The catches included *A. gambiae* and *A. pharoensis* in all stages of ovarian development, but recently-fed mosquitoes predominated. Precipitin tests on both species, carried out by Mr. B. Weitz, of the Lister Institute, London, showed that specimens from salt bush and crevices in the ground had fed almost entirely on cattle.

Table 1. AVERAGE NUMBER OF *A. gambiae* AND *A. pharoensis* CAUGHT PER MAN/HR. IN DIFFERENT RESTING PLACES

Resting place	Wet season (November–May)		Dry season (June–October)	
	A. gambiae	*A. pharoensis*	*A. gambiae*	*A. pharoensis*
Thick salt bush	3·6	0·1	0·4	0
Thin salt bush	0·3	2·1	—	—
Crevices near village	0·03	0	36·6	0·5

A. gambiae was found in greatest numbers in salt bush in which the foliage was dense. The characteristic resting place was in the large salt bushes, on the main branches inside the cavity produced by the arching of the branches as they inclined to the ground. Thin salt bush, either young bushes or new growths from old bushes that had been cut down, was little used as a resting place. In the dry season, dense salt bush lost much of its luxuriant growth and became ess suitable as a resting place. Thus the shortage of natural outdoor resting places in the vicinity of the box shelters during the dry season accounted for the seasonal increase in the catches of *A. gambiae* in the boxes. The shortage of outdoor resting places in the dry season was reflected again in the high concentra-ion of *A. gambiae* in a relatively small area of reviced ground about 300 yd. from the boxes. This inding also shows that there was a seasonal change of esting place depending on the availability of dense alt bush in the wet season and crevices in the dry eason.

A. pharoensis was quite different in its resting habits and was found in greatest numbers in thin salt bush during the wet season, where it rested on the outer leaves of the veegtation. Small numbers of *A. pharoensis* were found in crevices as well as in grass during the dry season, and it was noted that they rested higher up the crevices than *A. gambiae*.

After establishing that dense salt bush was the principal resting place of *A. gambiae* in the wet season, the bush was cut down at the end of June. Subsequent catches in the box shelters showed that the peak in them was transposed to the wet months[2], thus confirming that, in the absence of nearby natural resting places outdoors, *A. gambiae* entered artificial shelters in large numbers in areas where many cattle were penned outdoors at night.

Members of the *Culex pipiens* Series in New Caledonia and the New Hebrides

IN 1952–54, during studies of South Pacific mosquitoes and the ecology of their larval habitats, *Culex* (*Culex*) *pipiens fatigans* Wiedemann was recorded from numerous localities[1]. At that time, *C. pipiens australicus* Dobrotworsky and Drummond[2] was known only from Australia. However, this sub-species has since been reported from New Caledonia[3] and the New Hebrides[4], although the latter record is queried in a recent review[5]. Furthermore, another member of Edward's *Culex pipiens* series, *C. iyengari* Mattingly and Rageau, has now been described from the Loyalties and New Caledonia[6].

Accordingly, all specimens identified as *C.p. fatigans* in the account of my investigations[1] have been re-examined. The material still proves referable to this sub-species, with three exceptions, the collection numbers quoted being those of the account referred to:

Collection 2 (in part), ex whaling try pot, Anelgauhat, Aneityum Id., New Hebrides, August 3, 1952.
Collection 49, ex pot hole in rock, Uala, Art Is., Belep Is., New Caledonia, November 28, 1952.
Collection 56 (in part), ex 44 gallon drum, Poum, northern New Caledonia, December 3, 1952.

All fourth instar larvæ of collection 2 have four pairs of subventral tufts on the siphon, which in most cases tapers most pronouncedly in its distal half, its index being 4·2–4·4. Such larvæ are regarded as undoubted *C.p. fatigans*, although their antennæ are unusually long—0·45–0·52 mm., as compared with a New Caledonian figure of 0·41–0·44 mm. (ref. 3) and 0·41–0·43 mm. in examples from Polynesia (Samoa and Aitutaki) in my own collection. Seven others have an evenly tapered, very slightly curved siphon, its index ranging from 5·8 to 6·2, and their antennæ are 0·55–0·63 mm. long. In all respects other than siphonal curvature, which is characteristic of the Australian type strain of *C.p. australicus*[2], they agree with the New Caledonian larvæ of this sub-species examined by Marks and Rageau[3].

Iyengar's[5] doubt as to the occurrence of *C.p. australicus* in the New Hebrides presumably stemmed from the low siphonal index (4–4·5) given by Rageau and Vervent[4] for their material from Espiritu Santo. The presence of the sub-species in the southern part of the Group, at least, may be due to human agency, for Anelgauhat was formerly a watering point for ships[7].

Collection 56 includes both *C.p.fatigans* and larvæ in which the siphon has a distinct sinusoidal flexure, an index of 5·0–6·1, and only three pairs of sub-ventral tufts. These features, in combination with the length of the antennæ (0·48–0·52 mm.), identify them as *C. iyengari*[5,6]. All specimens of collection 49 (originally assigned to *C.p. fatigans* with some reluctance[8]) are also referable to *C. iyengari*. This species was previously known from an outlier of New Caledonia, the Isle of Pines, as well as from the mainland and the Loyalty Group. Its range is now extended to the Belep Islands, Art lying as far to the north-west of New Caledonia (approximately 30 miles) as the Isle of Pines does to the south-east.

VIROLOGY

Negative Evidence against Passage of Whole Plant Virus Particles through Gut Wall in Aphid Vectors

IN transmission of so-called persistent aphid-borne plant viruses, an incubation period in the insect is generally observed. It is understood that this time is required for the virus circulation in the insect body. Virus taken up with the plant juice is supposed to penetrate the intestinal wall and later the wall of the salivary glands, transport of the virus from the former to the latter being brought about by the blood. This theory is supported strongly by the fact that blood from infective aphids injected into non-infective individuals has been shown to make the latter able to transmit the virus in question. This has been demonstrated for potato leaf roll virus[1–3] and (Ossiannilsson, F., unpublished), beet yellow-net virus[3], and pea enation mosaic virus[4].

Nothing is known, however, about the form in which the virus is thus moving in the body of the vector. From work found in the literature on these matters one is apt to get the impression that the virus is supposed to pass through the insect tissues in the shape of complete molecules, that is, particles like those observed by electron microscope examination of infective plant sap or purified virus preparations. The size of these particles is, however, extremely large, as we know. The molecules of normal protein are very much smaller, but nevertheless the protein has to be broken down by the digestive enzymes before absorption by the mid-gut cells can take place. Since phagocytosis of food particles by the mid-gut cells is unknown in insects[5], a penetration of the intestine wall by intact plant virus particles would be possible only if there existed special pores or ducts through this wall. Results of recent experimental work[6] indicate the presence of capillary leaks of at least 120 Å. radius in the blood-lymph barrier in *Canis*. Analogous conditions might possibly be present in some part of the alimentary canal of aphids. This point does not seem to have been investigated so far, in spite of its significance in the present connexion.

In order to find out whether any such ducts do exist, I have examined the ultrastructure of the wall of the alimentary canal of *Myzus persicae* (Sulzer). These investigations were pursued for two years (1958–60) and concerned four parts of the intestine, namely, the œsophagus, the stomach, the posterior slender part of the mid-gut, and the hind-gut. The aphids were dissected under water, and the parts to be investigated were fixed in osmic acid and embedded in 'Methacrylate'. Thin sections were made by aid of a Philips ultra-microtome and examined in the electron microscope. The results of this work yield a negative answer to the question in point. No ducts whatever through the intestinal wall have been observed, with the exception of tracheoles. It is very difficult to see how the latter could possibly take any part in transport of virus, of course. The intestinal wall is throughout very compact, and a passage of bodies with the dimensions of, for example, 32 × 300 mμ (particles of beet yellow-net virus[7]) through this wall appears to be out of the question. The base membrane of the posterior part of the mid-gut is 0·1–0·3μ in thickness, and no pores could be observed. Moreover, the fore-gut as well as the hind-gut are lined in the interior by a cuticular intima. This is certainly very thin (in the œsophagus <0·02μ) but devoid of pores visible at a magnification of ×27,000. After treating the hind-gut with 10 per cent potassium hydroxide, examination in the electron microscope revealed a reticulate structure of the intima, recalling conditions in the rectal cuticle of *Calliphora*[8], but in this region, too, no open holes or pores could be established.

In work[9] on the ultra-structure of the salivary glands of *Myzus persicae*, Wohlfarth-Bottermann and Moericke established that the basement membrane enclosing these glands, as well as the salivary ducts, has a very dense microstructure, apparently making penetration by virus particles from the hæmocœle into the salivary glands impossible. The conclusion of these authors is that the virus must be assumed to enter the glands in the shape of smaller units. The same conclusion seems to be applicable also for the transport of virus through the wall of the gut, according to the results summarized here.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, June 26

University College (in the Physiology Theatre, Gower Street, London, W.C.1), at 5 p.m.—Dr. Severo Ochoa (New York University School of Medicine): "Propionic Acid Metabolism in Animal Tissues".*

Monday, June 26—Wednesday, June 28

National Physical Laboratory; National Engineering Laboratory; and the Building Research Station (at the National Physical Laboratory, Teddington, Middlesex)—Conference on "The Control of Noise".

Wednesday, June 28

Bone and Tooth Society (at 234 Great Portland Street, London, W.1), at 4.15 p.m.—Annual General Meeting, followed by a programme of Casual Communications.

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. N. L. Flacon: "Major Earth Flexuring in the Zagros Mountains of South-West Iran"; Dr. M. H. P. Bott: "Geological Interpretation of the Magnetic Anomalies over the Askrigg Block".

Medical Research Council (at the National Institute for Medical Research, Mill Hill, London, N.W.7), at 5 p.m.—Dr. Severo Ochoa (New York University School of Medicine): "The Biosynthesis of Ribonucleic Acid".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Research Assistant in the Department of Geology, for work on hydrated silicate melts and glasses—Prof. F. W. Shotton, University of Birmingham, Edgbaston, Birmingham 15 (June 28).

Assistant in the Departments of Logic and Metaphysics and Moral Philosophy in St. Salvator's College—Joint Clerk to the University Court, College Gate, St. Andrews (June 30).

Assistant Lecturer in Psychology—The Registrar, The University, Manchester 13 (June 30).

Assistant Lecturer (with a good honours degree or equivalent together with industrial experience, and preferably an interest in research) **in Mechanical Engineering**—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11 (June 30).

Lecturer (with experience in electrical measurement or measurement and control) in Electrical Engineering—The Secretary, Queen's University, Belfast (June 30).

Lecturer (with experience in the use of digital computers, preferably in applications to crystallography or business calculations) **in the Computing Laboratory**—The Secretary of University Court, The University, Glasgow (June 30).

Organic Chemist (recent graduate, or undergraduate now taking final examinations) **in the Nutrition Department**, for work on the synthesis of substances of biological interest—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (June 30).

Research Assistants (2) (with a first- or second-class honours degree in mathematics) **in the Mathematics Department**, to work in one of the following fields: hydrodynamics, elasticity, numerical methods and computing—The Clerk to the Governors, Woolwich Polytechnic, Woolwich, London, S.E.18 (June 30).

Scientific Assistant, Abstractor (with a degree in agriculture or natural science, and able to read Russian)—The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, Berkshire (June 30).

Assistant Lecturer in the Department of Biochemistry—The Dean, St. Thomas's Hospital Medical School, London, S.E.1 (July 1).

Junior Research Fellow in Pure Mathematics—The Registrar, The University, Sheffield (July 1).

Research Assistant (Biologist or Chemist), to assist in research on the tank culture of bivalve shellfish at Poole, Dorset, under the supervision of the Professor of Zoology—The Secretary and Registrar, The University, Southampton (July 1).

Junior Lecturer in Organic Chemistry—The Registrar, Trinity College, Dublin (July 3).

Assistant (with a first- or second-class honours degree in astronomy, mathematics or physics, and preferably an interest in radio astronomy) **in Astronomy**—The Secretary of University Court, The University, Glasgow (July 7).

Junior Lecturer in Mathematics—Prof. E. C. Titchmarsh, Mathematical Institute, The University, 10 Parks Road, Oxford (July 7).

Research Fellow (preferably organic chemist with a Ph.D.) in the College of Science and Technology (Department of Chemistry), for work in connexion with the development of organic dye filters which will be used for nebular and cometary night-sky photography for astronomical purposes—The Registrar, Manchester College of Science and Technology, Manchester 1 (July 8).

Chair of Microbiology in the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, July 15).

Lecturer or Assistant Lecturer (with qualifications in mathematical analysis and/or statistics) **in Mathematics** at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (July 17).

Assistant in Research (with an honours degree in the natural sciences with chemistry, geology or mineralogy as principal subjects) **in Soil Science**—The Secretary, School of Agriculture, The University, Cambridge (July 19).

Lecturer or Assistant Lecturer (with a recognized honours degree or equivalent qualification and experience in teaching and research) **in the Department of Chemistry**, University of Malaya, Kuala Lumpur—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Kuala Lumpur and London, July 27).

Chair of Education in Fourah Bay College, The University College of Sierra Leone—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (July 31).

Chair of Geography in Fourah Bay College, The University College of Sierra Leone—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (July 31).

Lecturer (applied mathematician with experience of numerical analysis and the use of digital computers for the solution of engineering problems) **for the Nuclear Power Group**—Dr. P. J. Grant, Department of Mechanical Engineering, Imperial College of Science and Technology, London, S.W.7 (July 31).

Lecturer in the Department of Mineralogy and Geology, University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (July 31).

Reader; a Senior Fellow; and Research Fellows in the Department of Nuclear Physics, Institute of Advanced Studies, Australian National University—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, July 31).

Reader in Bacteriology at St. Bartholomew's Hospital Medical College—The Academic Registrar, University of London, Senate House, London, W.C.1 (July 31).

Research Assistant (graduate with research experience, an interest in numerical analysis or in some field of the application of numerical computers) **in the Computing Laboratory**—The Director, University Computing Laboratory, 1 Kensington Terrace, Newcastle upon Tyne 2 (July 31).

Senior Technician in the Department of Zoology, University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (July 31).

Foundation Chair of Pure Mathematics in the School of Mathematics, University of New South Wales, Kensington, New South Wales, Australia—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2 (Australia and London, August 14).

Senior Lecturer (with an engineering degree and knowledge and experience of industrial or production engineering, or a science or arts degree with qualifications in statistical methods and operations research) **in Industrial Engineering** at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, August 31).

Assistant, Grade B (honours graduate, preferably with teaching or research experience), **in Mathematics**; and an **Assistant**, Grade B (honours graduate, preferably with teaching or research experience), **in Geology**—The Principal, Kingston Technical College, Fassett Road, Kingston-upon-Thames.

Chemist or Biochemist (with a first- or second-class honours degree) **in the Radiobiochemistry Department**, to join a small team working on the metabolism of fat in the ruminant, and in particular involves a study of the biochemical forms of radioactivity in blood, milk and various organs after the administration of labelled lipids——The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting Ref. No. 61/20.

Graduate Research Assistant in the Department of Biology and Geology, to work in a team engaged on a survey of marine plankton—The Principal, Norwood Technical College, Knight's Hill, London, S.E.27, quoting Ref. FE.3/N/1553/6.

Lecturer or Assistant Lecturer (with qualifications in mathematical analysis and/or statistics) **in Mathematics** at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

Lecturer (with teaching experience and preferably qualified to undertake some teaching of biology) **in Physiology**—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11.

Principal Scientific Officer (with training in physiology and/or biochemistry, and preferably also in physics and experience in work on blood) (Ref. 61/18); and an Assistant Experimental Officer (preferably with a pass degree or equivalent and experience in biological work) (Ref. 61/19), for work on the flow and coagulation of blood—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting appropriate Ref. No.

Research Students (with, or anticipating to have, a good honours degree in chemistry, Grad.R.I.C., or Dip.Tech. in chemistry) in the Department of Pure and Applied Chemistry; research topics will be selected from the following fields: the chemistry and origin of coal tar constituents; low temperature carbonization studies; physico-chemical studies, including electro-chemistry, surface chemistry, and states of aggregation in solution—Head, Chemistry Department, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

Senior Assistant (with physics and/or mathematics to degree standard and some secretarial experience), for work which will include preparation of material for publication, correspondence in connexion with publications, a small amount of committee work and responsibility for day to day running of the office; and an Editorial Assistant (with physics and/or mathematics to degree standard, and preferably able to type), to assist in the preparation of material for publication—The Editor and Deputy Secretary, Institute of Physics and the Physical Society, 1 Lowther Gardens, London, S.W.7.

Senior Lecturers and Lecturers in Applied Psychology (Psychometrics and Experimental Psychology); Botany; Mathematics; and Physics in the Faculty of Science, University of New South Wales, Australia—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2, and The Appointments Section, University of New South Wales, Box 1, Post Office, Kensington, N.S.W., Australia, quoting Ref. SA1.

TECHNICIAN IN THE RESEARCH LABORATORY, to assist in the preparation of material for human chromosome studies—The Administrative Office, Mount Vernon Hospital, Northwood, Middlesex.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Air Ministry: Meteorological Office. Scientific Paper No. 5: An Experiment in Numerical Forecasting. By E. Knighting, G. A. Corby, F. H. Bushby and C. E. Wallington. Pp. iii+67. (M.O. 682.) 5*s*. net. Scientific Paper No. 8: Factors Associated with the Formation and Persistence of Anticyclones over Scandinavia in the Winter Half of the Year. By M. K. Miles. Pp. ii+19. 3*s*. net. (London: H.M. Stationery Office, 1961.) [104

University of Cambridge: Department of Engineering. Report for the year 1959–60. Pp. 13. (Cambridge: The University, 1961.) [104

Imperial College of Science and Technology; and the London School of Hygiene and Tropical Medicine (University of London). Postgraduate Courses in Public Health Engineering. Pp. 15. (London: Imperial College of Science and Technology; and the London School of Hygiene and Tropical Medicine, 1961.) [104

Chelsea College of Science and Technology. Sixty-fifth Annual Report, Session 1959–60. Pp. 45. (London: Chelsea College of Science and Technology, 1961.) [104

The British Journal Photographic Almanac, 1961. Edited by Arthur J. Dalladay. Pp. 596+32 plates. (102nd year of publication.) (London: Henry Greenwood and Co., Ltd.; New York: Amphoto, 33 West 60th Street, 1961.) 10*s*. net. [104

Empire Cotton Growing Corporation. Annual Report for 1960. Pp. ii+20. (London: Empire Cotton Growing Corporation, 1961.) [104

University of London. University College Annual Report, 1959–60. Pp. 103. (London: University College, 1961.) [104

Government of Northern Ireland: Ministry of Agriculture. Leaflet No. 9: Commercial Apple Culture. Pp. 24. (Belfast: Ministry of Agriculture, 1961.) [104

General Register Office. The Registrar General's Quarterly Return for England and Wales, No. 448, quarter ended 31st December, 1960: Births, Deaths and Marriages; Infectious Diseases; Weather; Population Estimates. Pp. 28. (London: H.M. Stationery Office, 1961.) 2*s*. 6*d*. net. [104

Association of Consulting Actuaries. Retirement and Death Benefits for Employees and their Dependants. Pp. 8. (London: Association of Consulting Actuaries, Grosvenor Gardens House, 1961.) [104

Privy Council. Medical Research Council Memorandum No. 39: Introductory Manual on the Control of Health Hazards from Radioactive Materials. (Committee on Protection Against Ionizing Radiations.) Pp. vi+21. (London: H.M. Stationery Office, 1961.) 1*s*. 9*d*. net. [144

Imperial College of Science and Technology (University of London). Shorter Postgraduate Courses, Session 1960–61, Summer Term. Pp. 10. (London: Imperial College of Science and Technology, 1961.) [144

The Zoological Society of London. Annual Report, 1960. Pp. 54+8 plates. (London: Zoological Society of London, 1961.) [144

Low Temperature Research Station, Cambridge. Annual Report, 1959. Pp. 39+1 plate. (Cambridge: Low Temperature Research Station, 1961. Obtainable from H.M. Stationery Office.) 2*s*. 6*d*. [144

City of Liverpool. Guide to the rebuilt Brown Library and the New Links with the Picton and Hornby Libraries. Pp. 32. (Liverpool: Brown, Picton and Hornby Libraries, 1961.) [144

Department of Scientific and Industrial Research: National Physical Laboratory. Note on Applied Science, No. 21: Measurement of Load by Elastic Devices. By B. Swindells and Dr. J. C. Evans. Pp. iv+20+8 plates. (London: H.M. Stationery Office, 1960.) 3*s*. net. [144

Other Countries

East Africa High Commission. Annual Report of the East African Meteorological Department for the year 1st July, 1959, to 30th June, 1960. Pp. ii+34. (Nairobi: East African Meteorological Department, 1960.) Sh. 3/50. [44

National Academy of Sciences—National Research Council. Science in Antarctica: a Report by the Committee on Polar Research. Part 1: The Life Sciences in Antarctica. Pp. xi+162. Part 2: The Physical Sciences in Antarctica. Pp. xi+131. (Washington, D.C.: National Academy of Sciences—National Research Council, 1961.) 1.50 dollars each part. [54

The Australian Scientist, Vol. 1, No. 1 (February, 1961). A monthly journal on Research, Development and Application. Pp. 70. Subscription rates (1 year): Australia, Fiji, New Guinea, New Zealand £A. £4 4*s*. 0*d*.; Commonwealth countries (excluding the above) £ Sterling £3 12*s*. 6*d*.; Non-Commonwealth Countries £ Sterling £4 5*s*. 0*d*. (Leichhardt, Sydney: Tasman Productions, 9–23 Upward Street, 1961.) [54

Tokyo Astronomical Observatory. Tokyo Astronomical Bulletin, Second Series. No. 135 (February 5, 1961): Fluctuation in the UT2 System and the Further Correction for the Seasonal Changes. By Shigetaka Iijima and Seiichi Okazaki. Pp. 1707–1718. No. 135 (February 5, 1961): Frequency of Cesium Resonator in Terms of Ephemeris Time, and some Related Problems. By Shigetaka Iijima and Seiichi Okazaki. Pp. 1719–1730. No. 137 (February 5, 1961): Meridian Observation of Right Ascension of Moon's Limb made with Repsold Transit Instrument, Report No. 5 (January–December 1959). By Kônosuke Tuzi and Kiyoshi Nagane. Pp. 1731–1741. No. 138 (February 20, 1961): An Interpretation of Frequency Change in WWVH Signals as received at Tokyo. By Shigetaka Iijima and Iwao Oguma. Pp. 1743–1755. No. 139 (February 20, 1961): Ephemeris Time determined from the Meridian Observation of the Moon. By Masahisa Torao and Yasumori Adachi. Pp. 1757–1758. (Tokyo: Tokyo Astronomical Observatory, 1961.) [6

Laboratoire d'Astronomie de Lille. Astronomical News Letter, No. 102. Pp. i+50. (Lille: Laboratoire d'Astronomie de Lille, 1961.) [74

The Nuclear Research Foundation within the University of Sydney and the School of Physics. Pp. 36. (Sydney: The University, 1961.) [74

The Results of the Japanese Oceanographic Project for the International Geophysical Year 1957/58. Pp. iv+198. (Tokyo: National Committee for the International Geophysical Year, Science Council of Japan, 1960.) [74

Food and Agriculture Organization of the United Nations. FAO Agricultural Studies, No. 49: The Grass Cover of Africa. By J. M. Rattray. Pp. v+168+map. (Rome: Food and Agriculture Organization of the United Nations; London: H.M. Stationery Office, 1961.) 12*s*. 6*d*.; 2.50 dollars. [74

Bulletin of the American Museum of Natural History. Vol. 121, Article 3: The Frogs of Eastern New South Wales. By John A. Moore. Pp. 149–386+plates 27–46. (New York: American Museum of Natural History, 1961.) 6 dollars. [104

A Collection of Papers of the Rational Theory, Book 8. By F. Harrison Stamper. Pp. 14. (Los Angeles, Calif.: F. Harrison Stamper, 1990 Barnett Road, 1961.) [104

United States Department of the Interior: Fish and Wildlife Service. Circular No. 96: Index of Fishery Technological Publications of the Fish and Wildlife Service and the Former Bureau of Fisheries, 1918–55. Compiled by M. E. Stansby and Rosemary Schairer. Pp. ii+237. (Washington, D.C.: Government Printing Office, 1961.) [104

L'Homme et l'Espace, No. 1 (Avril, 1961). Pp. 56. Abonnement annuel (12 numéros) Suisse: Fr. 45; France: N.F. 54. Autres pays: S.fr. 54. Prix du numéro: Suisse Fr. 5; France: N.F. 6.50. Autres pays: S.fr. 8. (Lausanne: Actualité Scientifique et Technique S.A., 4 Place de la Riponne, 1961.) [104

University of California Publications in Meteorology. Vol. 1, No. 1: Studies of the Structure of the Atmosphere over the Eastern Pacific Ocean in Summer. 1: The Inversion over the Eastern North Pacific Ocean. By Morris Neiburger, David S. Johnson and Chen-Wu Chien. Pp. 1–94. (Berkeley and Los Angeles: University of California Press; London: Cambridge University Press, 1961.) 2.50 dollars. [104

Société de Physique et d'Histoire Naturelle de Genève. Archives des Sciences, Vol. 13 (fascicule special): 9e Colloque Ampère, Pise, 12–16 Septembre, 1960. Pp. 711. (Genève: Labrairie Payot, S.A., 1960.) [104

Council for Scientific and Industrial Research, Pretoria. C.S.I.R. Research Report No. 174: Low-Cost Housing for South Africa: an Investigation into the Housing Problems and Policies with particular reference to Bantu Housing. By R. Merle Frean. (Thesis submitted for the Diploma in Town Planning at the University of London.) Pp. viii+37. (National Building Research Institute, Bulletin No. 20.) (Pretoria: Council for Scientific and Industrial Research, 1960.) [104

Battelle Memorial Institute, Columbus. Research at Battelle Memorial Institute: The First Thirty Years. Pp. 48. (Columbus, Ohio: Battelle Memorial Institute, 1961.) [104

United States Department of the Interior: Geological Survey. Bulletin 1078: Geology and Coal Resources of the Buffalo-Lake De Smet Area, Johnson and Sheridan Counties, Wyoming. By William J. Mapel. Pp. vi+148+23 plates. Bulletin 111–B: Field Description and Sampling of Coal Beds. By James M. Schopf. Pp. iv+25–70+plates 6–27. Water-Supply Paper 1535–B: Geological Control of Mineral Composition of Stream Waters of the Eastern Slope of the Southern Coast Ranges, California. By G. H. Davis. Pp. iii+B1–30. 20 cents. Professional Paper 330–A: Paleozoic Species of *Bairdia* and Related Genera. By I. G. Sohn. Pp. iii+105+6 plates. 1 dollar. (Washington, D.C.: Government Printing Office, 1959, 1960 and 1961.) [104

National Science Foundation, Washington. Current Projects on Economic and Social Implications of Scientific Research and Development, 1960. Pp. v+124. (Washington, D.C.: Government Printing Office, 1961.) 40 cents. [144

Comptes Rendus des travaux du Laboratoire Carlsberg. Vol. 32, No. 5: A Comparison of Two Proteinases from *Bacillus subtilis*. By M. Ottesen and A. Spector. Pp. 63–75. 2 kr. Vol. 32, No. 6: On the Occurrence of Yeasts in the Mountainous Soils of Jotunheimen, Norway. By C. Roberts. Pp. 75–88+2 plates. 3 kr. 15 øre. Vol. 32, No. 7: A Reinvestigation of the Effects of LiBr on Proteins. By Charles C. Bigelow and Irving I. Greschwind. Pp. 89–106. 2 kr. 55 øre. Vol. 32, No. 8: Osmometry on Insulin and Ribonuclease in Dissociating Media. By D. W. Kupke. Pp. 107–124. 2 kr. 55 øre. Vol. 32, No. 9: Osmometry and General Characterization of α-Lactalbumin. By D. B. Wetlaufer. Pp. 125–138. 2 kr. 15 øre. (Copenhague: Danish Science Press, Ltd., 1960 and 1961.) [174
